In the study of the etiology of cardiovascular dysfunctions in general and of heart disease in particular, attention has been focused mainly on infectious and degenerative processes and on congenital malformations. Since cardiovascular disease is the most important cause of death, and since in life the body comes in closest contact with environment through nourishment, the interrelation between the cardiovascular system and nutrition is a problem of primary importance. It is our purpose in this communication to describe nutritional factors that are responsible for abnormal function of the cardiovascular system. McCarrison¹ sums up the nutritional origin of disease as follows: "faulty food, faulty nutrition, faulty function, faulty structure, faulty health, disease." In certain nutritional states such a sequence of changes results in disease of the heart and of the blood vessels. Our present knowledge of these matters is meager, but the available clinical observations and experimental data suggest the probable significance of the field as yet unexplored.

Both deficiencies and excesses of food can lead to disturbance of the circulation. In some instances a deficiency of a substance may become pathogenic, so far as the cardiovascular system is concerned, only when combined with an excess of another food substance. Thus the clinical manifestations of certain vitamin deficiencies are conditioned not only by the total caloric intake and the total amount of energy expended but also by the proportional intake of carbohydrate, protein and fat. Evidence is available which suggests that disturbance of the intermediary metabo-

lism, such as occurs in diabetes, can also enhance the manifestations due to unbalanced diet. Rigid separation of the morbid effects of nutritional excesses and deficiencies is therefore not always possible, as the coexistence of the two factors may be responsible for disease.

Among the nutritional excesses, increased intake of calories, as manifested by obesity, frequently exerts harmful effects on the heart and particularly on the circulation. Pronounced corpulence should be looked on, therefore, as a debilitating condition of great significance. There is no substantial experimental or clinical evidence, on the other hand, indicating that a diet disproportionately rich in vegetable or animal protein causes cardiac or vascular disease.² It has been amply demonstrated that feeding of cholesterol to certain species of animals can induce atherosclerosis or, rather, "cholesterinsteatosis," and through it heart disease.³ The significance of the cholesterol content of the diet in the causation of human arteriosclerosis, on the other hand, is not established.⁴ In diabetes a high fat diet is apparently particularly apt to cause arteriosclerosis.⁵ Excesses of water and of mineral constituents play no appreciable rôle in circulatory disturbances except through indiscriminate use in postoperative states and in patients with heart disease.

At present there is no conclusive evidence that hypervitaminosis plays a rôle in the causation of functional or structural changes in the human cardiovascular system. The arteriosclerosis induced in animals with large doses of vitamin D has nothing in common with human arteriosclerosis. The rare instances of cardiac damage attributed to vitamin D⁶ cannot be accepted as due to hypervitaminosis. It is of interest that in a case in which there was evidence of hypervitaminosis D no cardiovascular lesions were noted.⁷

NUTRITIONAL DEFICIENCIES

*Caloric Intake (Undernutrition and Inanition).—*Fasting or severe restriction of diet results in a bradycardia of from 30 to 40 per minute, a decrease of the arterial pressure and a lowering of the metabolic rate.⁸ The degree of lowered metabolism in chronic undernutrition may be out of proportion to the loss of body weight.⁹ Since the blood flow is related to the level of the oxygen consumption, undernutrition is presumably associated also with decreased blood flow and cardiac work. These circulatory changes, if maintained for a short period, may exert a beneficial effect in congestive circulatory failure caused by organic heart disease.¹⁰ Prolonged undernutrition, on the other hand

causes unfavorable cardiac changes. Thus general wasting of the skeletal muscles is associated with similar changes in the myocardium,¹¹ and also with intracellular deposition of fat (fatty degeneration) and with decrease of interstitial fat. The extensive data available in the literature indicate that in adult animals and man chronic malnutrition results in considerable loss, from 20 to 50 per cent, in cardiac weight, while in malnourished young animals or children the loss is slight. In general the degree of loss in heart weight is somewhat less than that in total body weight.¹¹ The heart of animals and men dying as a result of chronic starvation may show reduction in the size of the myocardial fibers with changes in the cross striation and a deposition of iron-free pigment granules (brown induration). So far as is known there are no experimental or clinical studies on the response of such hearts to various types of strains. One of us has had the opportunity, however, to observe that malnourished dogs and cats brought to the laboratory are apt to respond with unexpected cardiac standstill to operative procedures and drugs, both of which are well tolerated by animals that have previously received a balanced diet.

Malnourished patients, as observed during famines, are considered poor surgical risks. The association of famines with epidemics of infectious diseases suggests lowered resistance of these patients, especially to infections. Evidence is lacking, however, to indicate that chronic undernutrition is responsible for vascular disease, including arteriosclerosis. Prolonged famines and chronic wasting diseases are not known to be associated with increased incidence of cardiovascular disease.

Proteins—The role of proteins in the maintenance of the osmotic pressure of the circulating blood is well established. Chronic protein deficiency leads to edema, which may be generalized ("nutritional edema") and which exerts a harmful effect on the circulation, particularly when it involves the lungs. In the presence of low serum proteins there is loss of fluids into the tissues and a tendency to circulatory collapse. In patients with organic heart disease, a low protein content of the blood associated with high venous and hence high capillary pressure can accentuate or precipitate pleural and peritoneal transudation and can increase the tendency to cardiac asthma and pulmonary edema.¹² In conditions associated with continuous protein loss, such as occurs in pleural or peritoneal exudates or transudates requiring repeated taps, particular effort should be made to reestablish the normal protein content of the blood by means of adequate protein in the diet.

Carbohydrates—Reduction of the blood sugar below a certain level can result in syncope, circulatory collapse and convulsions associated with a striking fall in the arterial pressure.¹³ Such states occur as a result of hyperinsulinism, caused either by overdosage or by abnormal production, as is the case in certain hyperplasias and tumors of the islands of Langerhans and other glands of internal secretion. A similar type of circulatory collapse can occur also in diabetic patients with a normal or even elevated blood sugar if it has been lowered

too abruptly from an unusually high level. In hypoglycemic shock administration of dextrose promptly reestablishes normal circulation.

Water and Salts—While the human body possesses adequate mechanisms for the maintenance of a homeostatic state against increased intake of water and salt, its protective mechanisms against loss of water or salt are poor. Hence dehydration and salt depletion occur relatively frequently, and they represent grave danger to the organism mainly through circulatory collapse and shock. Whether, in addition, water restriction can reduce the cardiac weight, and thereby produce circulatory failure, is not definitely established, although there are reports indicating that animals dying from thirst can lose from 30 to 40 per cent or more of their cardiac weight.¹⁴ The high infant mortality from diarrheal states and the decimating effects of cholera and other dehydrating infectious diseases on certain sections of the human race demonstrate the practical significance of circulatory collapse and shock of dehydration origin.¹⁴ It has been estimated that normally between 7,500 and 10,000 cc of fluid is secreted into the intestinal canal within twenty-four hours. Whereas in health the greater part of this fluid is reabsorbed, in certain pathologic conditions, particularly those associated with vomiting and diarrhea, most of it, together with its organic and inorganic constituents, may be lost. Unless corrected or counteracted by adequate supply, such a fluid and salt loss rapidly leads to a reduction of blood volume with hemoconcentration and with accumulation of toxic waste products, and, finally, to fatal collapse and shock. In diseases associated with fever, fistulous opening, as in biliary and pleural fistulas, heat exhaustion, adrenal insufficiency, or vomiting with pyloric stenosis, the adequate replacement and supply of water and salts are most effective measures in the prevention of peripheral failure of the circulation. Collapse and shock of dehydration and of "hypochloremia" may also result from the indiscriminate use of gastric or duodenal drainage with suction ("Wangensteen tube"), such as is in vogue at present in certain surgical and medical conditions, which often are already associated with a tendency to collapse and shock. We have observed instances of abdominal distention and post-operative conditions in which constant gastric suction produced the typical syndrome of dehydration and "hypochloremic" shock. The relative role of low blood chlorides in the circulatory collapse associated with vomiting and alkalosis is not clearly understood as yet. The treatment of patients with collapse caused by water and salt deficiency has been described elsewhere.¹⁵

Iron and Certain Other Nutritional "Extrinsic" Factors—Deficiency of iron and of certain protein derivatives essential for normal blood formation produces, through hypochromic or macrocytic anemia, changes in the circulation. These changes are characterized mainly by an increase in the velocity of blood flow and in the cardiac output, by a fall in the arterial pressure¹⁶ and frequently by an increase in pulse pressure. In one group of patients enlargement of the heart occurs, and at necropsy cardiac dilatation and hypertrophy may be found. While by x-ray examination the cardiac

shadow is increased in but 8 or 9 per cent of the cases presenting a hemoglobin content of from 56 to 65 per cent, it is increased in all cases in which a hemoglobin level of from 12 to 15 per cent is reached.¹⁷ The initial enlargement is to the left, and later to the right. In pernicious anemia fatty degeneration of the myocardium, accentuated around the venous ends of the capillaries, can result in the "tiger lily" appearance of the cut section. Since the introduction of liver therapy, however, such changes have become rare. The cause of cardiac enlargement in some instances of anemia remains obscure, since it cannot always be related, in our experience, either to increased work of the heart or to the degree of anemia. In only one group of anemic patients with cardiac enlargement does the size of the heart return to normal with the return of the hemoglobin to a normal level. In the remainder this enlargement is possibly caused or influenced by simultaneous deficiency of factors other than hemoglobin.

In anemia systolic murmurs over the apex and base of the heart are frequent as a result of dilatation of the heart. Rarely, in severe anemias, transient diastolic murmurs occur. With improvement they disappear long before the subsidence of systolic murmurs. Patients with severe anemia often suffer from palpitation, brought on mainly by emotions and exertion. There may also be a tendency to syncope. Rarely anemia may precipitate congestive failure, as well as angina pectoris, even without coronary disease. Finally, angina has been observed in cases of pernicious anemia during treatment, presumably the result of a sudden increase of cardiac work without simultaneous increase of cardiac strength.

Vitamins—In spite of recent advances in the chemistry and physiology of the vitamins, the role of these substances in human disease is relatively little understood. There are several reasons for the slower progress in the clinical than in the experimental field. The most significant one is that man seldom chooses his diet so that it is deficient in only one factor. The possible modifying influences of simultaneous deficiencies on the human body prevent analysis of the effects of a single deficiency under controlled conditions. Among the vitamins, deficiencies of the B complex and of vitamins C and D have been claimed to cause disturbances in the cardiovascular system.

Vitamin B Complex—Deficiency of these vitamins is related, at present, mainly to two diseases: vitamin B₁ to beriberi and B₂ to pellagra. In the United States the two diseases frequently occur in the same patient in a combined form.

Beriberi—Of all the vitamins, B₁ is the most important in relation to the heart. Beriberi has been known for centuries as a devastating disease of the rice-eating peoples of the Orient. Subsequently it was found that it occurs in as widely separated areas as South America, Africa, Labrador and the United States. In the Orient the disease has been known in its "dry" and its "wet" form. The dry form manifests itself mainly in muscle wasting and peripheral neuritis. The wet form is associated with cardiovascular disturbances and generalized edema. Although the severe dry form of beriberi usually is not associated with serious cardiovascular disturbances, moderately severe cardiovascular dysfunction may be present, and, contrariwise, moderately

severe neurologic manifestations may occur in cases of severe wet beriberi. Strenuous exertion is a dangerous aggravating factor in beriberi, and severe neuritis, by making work impossible, may protect against serious or fatal circulatory failure. From the point of view of the clinical course, mild and severe forms and acute, subacute and chronic types have been differentiated. In the acute "pernicious" type, death of cardiac origin can come with unexpected rapidity. The cardiovascular disturbances in beriberi of the Orient have been described and summarized by Shimazono¹⁸ and Wenckebach.¹⁹ The main cardiovascular manifestations are dilated heart, embryocardia, tachycardia, arterial sounds ("pistol shots"), warm skin, edema, dyspnea and circulatory collapse.

Psychic, gastro-intestinal, metabolic, hemic and bony disturbances are often present in beriberi patients, and it is not definitely known just what role deficiency of one or another substance may play in the production of these symptoms. In patients with beriberi the clinical picture is the result primarily of deficiency of vitamin B₁, but deficiency of other substances is contributory, and this should be considered in treatment.

Beriberi in the United States—The first step in the discovery of beriberi as a disease of regular occurrence in the United States was the recognition that certain types of neuritis are related to nutritional disturbances and particularly to lack of vitamin B₁.²⁰ These contributions have, in turn, raised the obvious problem that if certain types of polyneuritis are caused by deficiency of vitamin B, some of the patients should present manifestations related to the cardiovascular system, such as are observed in beriberi patients of the Orient. Our investigation then revealed that patients with nutritional and particularly with vitamin B deficiency show not only disturbances in the nervous system but also in the cardiovascular system similar to those described in the Orient.²¹ This finding lent support to the nutritional origin of alcoholic polyneuritis and of the polyneuritis of diabetes and of pregnancy.

Sporadic instances of "beriberi heart" in the United States, both in adults and in infants, have been reported before.²² A systematic study, however, revealed that beriberi with cardiovascular as well as with neurologic manifestations is of regular occurrence in the United States. One hundred and twenty such cases presenting cardiovascular manifestations were observed in the Boston City Hospital.^{21b} Thirty-five cases of this group, on which special investigations were conducted, occurred out of 5,506 medical admissions. The condition occurs, at least in a certain section of the population, more frequently than congenital heart disease or subacute bacterial endocarditis. Beriberi, however, is a far more

common disease than is indicated by the frequency of the cardiovascular manifestations, as in the majority of instances it manifests itself in neurologic disturbances only. Most of the patients observed regularly drank large amounts of alcohol. In a smaller group drug addiction, pregnancy, diabetes, gastro-intestinal disease, psychic peculiarities (food fads) and poverty played a role. The patients were usually well nourished, with caloric intake adequate or more than adequate, but with an estimated vitamin B (B_1) intake less than that indicated by Cowgill as liable to produce polyneuritis. Many of the patients also had symptoms of pellagra and a few had scurvy.

The most common cardiovascular symptoms of beriberi, in our experience, are dyspnea on exertion associated with palpitation, tachycardia and embryocardia. During improvement the tachycardia may change to bradycardia. Gallop rhythm, prominent cardiac and epigastric pulsations and bounding peripheral pulses with sounds ("pistol shots") are also frequently present. The heart may be normal in size or enlarged, and systolic and rarely diastolic murmurs may be heard. In the severe cases the dyspnea is intense and can appear with unexpected severity. Cardiac asthma (paroxysmal dyspnea) has also been observed. Signs of pulmonary congestion are frequently present, and cloudiness of the lung fields is seen on roentgenologic examination. The arterial pressure is usually normal, with a tendency to increased pulse pressure. In some cases the systolic pressure is moderately elevated during the acute stage of circulatory failure, but it returns to normal when the patient's condition improves. The veins of the neck are normal or engorged, as is confirmed by the normal or elevated venous pressures. The skin is usually warm and of normal color, at times it is cyanotic. Edema is frequently present, either diffuse or dependent, and it may be of extreme degree. The patients with severe cardiovascular manifestations are prone to develop fever and thus, in turn, aggravates failure of the circulation.

Patients incapable of exertion because of severe polyneuritis, like those described in the Orient, are less liable to have advanced circulatory failure. Contrariwise, those with mild cardiovascular symptoms may be made to have pronounced symptoms by moderate exercise.^{21a}

In five of our cases a hyperactive carotid sinus reflex was responsible for syncope. Following the administration of a diet rich in vitamin B (B_1) the hyperactive state of the carotid sinus reflex subsided and subsequently the stimulation of the sinus produced no symptoms. Sudden circulatory collapse without premonitory symptoms occurred in a few patients. Electrocardiograms taken in sixty-seven cases presenting normal blood pressures and no clinical evidence of organic heart disease disclosed abnormalities in all but five cases. The most common observation was alteration in the T waves. The hemodynamics were characterized by low vital capacity of the lungs, high venous pressure and normal arterial pressure, and by a relatively or absolutely increased velocity of blood flow with decreased peripheral utilization of arterial oxygen. The osmotic pressure of the blood usually was moderately low. There was often an increase in the bisulfite binding substances in the blood.²³

Postmortem examination in the majority of instances revealed that the weight of the heart was normal and that there was a moderate dilatation of the right ventricle. In only nine out of thirty cases was there an increase in weight and a considerable degree of dilatation of the cardiac chambers, particularly the right ventricle. The dilatation of the right ventricle was not so marked or so frequent in the group observed in Boston as in the cases studied by Wenckebach in Java. In various species of animals in which nutritional polyneuritis has been induced decreased, normal and increased cardiac size and weight have been reported.²²

The histologic changes, hydropic degeneration of the myocardial fibers, swollen collagen, perivascular "edema" and separation of the myocardial bundles were identical with those described by Wenckebach. The histologic changes, however, are not regular, nor specific to or even characteristic of beriberi. The water content of the left and right ventricles was the same in cases of beriberi as in normal persons or in patients with organic heart disease.^{21a} This suggests that the accumulated intercellular substances contain a normal amount of solids.

The symptomatology and the studies of the hemodynamics indicate that the type of cardiovascular disturbances of beriberi as observed in Boston does not form a rigid clinical syndrome. Right ventricular failure, left ventricular failure, peripheral arteriolar dilatation and increased blood flow, peripheral circulatory collapse and shock, singly or in combination, have been observed. Beriberi causes marked changes not only in the heart but also in the vascular system, hence the term "beriberi heart" is inadequate for the designation of the cardiovascular dysfunctions in this disease.

The diagnosis of beriberi cardiovascular disease is facilitated by the frequent simultaneous presence of certain noncirculatory manifestations of dietary deficiency, such as peripheral neuritis, psychosis, glossitis, diarrhea, dermatitis, anemia, hypoproteinemia, dysphagia, hoarseness, dry and irritating cough, aphonia and purpura. In the differential diagnosis the absence of recognized etiologic causes of organic heart disease and the history of an abnormal diet or intestinal dysfunction may be helpful. The combined presence of congestive failure of the circulation and a relatively or absolutely increased rate of the circulation is the most outstanding characteristic of the condition. The assured diagnosis may depend on the complete recovery of the patient after rest and vitamin B therapy.

The fact that beriberi is a disease of regular occurrence among adults in the United States now raises the question of the occurrence of this disease in infants and children. Lehnendorff and Mautner²⁴ have discussed the problem of whether the cardiac hypertrophy and dilatation sometimes observed in children is a manifestation of avitaminosis. Haas²⁵ reported the occurrence of beriberi in infants who suffered from celiac disease. Abt²⁶ has recently reviewed this subject.

It is of interest that the infantile type of beriberi in Japan²⁷ and the Philippines²⁸ occurs mainly among

breast fed rather than among artificially fed babies. This suggests that beriberi and avitaminosis of the mother can have an important bearing on the nutritional state not only of the new-born but also of the nursing infant. Whether some instances of "idiopathic" cardiac hypertrophy will be explained on this basis is not known at present. This problem has not been investigated in the United States.

The response of the cardiovascular system in beriberi to treatment is not uniform. Some patients show improvement on a deficient diet when simply put to bed, others may show sudden aggravation of the symptoms or even fatal collapse when kept in bed and on a deficient or even a normal diet. From the experience so far acquired, one gains the impression that some of the patients are benefited by digitalis and diuretics. The effect of diets rich in vitamins and particularly B (B_1), of extracts rich in B_1 and of crystalline B_1 is beneficial, but the rate of improvement of different aspects of the circulation, as measured by changes in the velocity of blood flow, oxygen utilization, vital capacity of the lungs, venous pressure, edema, cardiac size and electrocardiographic complexes varies considerably. Some patients improve rapidly, and the clinical course may show a dramatic change within a week with a loss of 30 or 40 pounds (13.6 or 18 Kg.) of edema fluid. In others the improvement is slower, and recovery may take from four to six weeks. In this respect, too, these patients behave like those with beriberi in the Orient and in Labrador. In general, improvement is most rapid in patients with a severe degree of congestive failure of relatively short duration. The histologic changes in the heart indicate that prolonged dietary deficiency may lead to structural changes, and under such conditions recovery may be slow.

Following the intravenous administration of from 5 to 10 mg. of crystalline vitamin B_1 three or four times daily to patients kept during a control period on a deficient diet, the first change observed was the increased peripheral utilization of oxygen and slowing of the blood flow as a result of disappearance of the arteriolar dilatation. This occurred as early as twenty-four hours following the administration of the first dose of vitamin B_1 . Simultaneously there was symptomatic improvement and often marked diuresis. Following this there was a slow but steady rise in the vital capacity of the lungs and a decrease in cardiac size. The cardiovascular abnormalities last to disappear were those revealed by the electrocardiogram. This is in contrast to the situation in animals deficient in vitamin B_1 , in which the changes in the heart rate and in the electrocardiographic complexes may be abolished as early as within four to six hours after subcutaneous administration of 5 micrograms of crystalline B_1 .²⁹ In some patients a temporary elevation of the arterial pressure of several days' duration followed the first course of treatment with crystalline B_1 , but this change could not be repeated by a similar course when the patients were not deficient in vitamin B_1 . Administration of parenteral doses as large as from 30 to 100 mg. daily for from five to eight days, followed by oral administration of large amounts of B_1 extracts, failed to induce any detectable changes in the cardiovascular function of normal subjects or of nondeficient patients with organic heart disease or with various types of edema.

Comparative observations indicate that there is no rigid parallelism between the rate of improvement in the circulatory functions and in the nervous functions. The improvement was usually more striking, rapid and complete in the cardiovascular than in the neurologic disturbances. The only exception to this was the occasional remarkably rapid disappearance of psychosis after the administration of large amounts of vitamin B_1 . Because of the frequent presence of multiple deficiencies in beriberi, attention should be paid in the treatment to the correction also of the anemia with iron and liver extract, of the hypoproteinemia with a high protein diet and of the hemorrhagic tendency with cevitamic acid.

The Role of Alcohol—The following evidence indicates that alcohol per se is not the primary factor responsible for changes described. 1 Chronic alcoholism is an exceedingly common condition, in comparison with which beriberi is relatively rare. 2 Pharmacologic studies do not indicate that alcohol per se causes polyneuritis or cardiovascular disease. 3 Symptoms of dietary deficiency may appear long after the consumption of alcohol, particularly if prolonged gastrointestinal disturbances follow the alcoholic debauch. 4 It is known that patients with alcoholism are predisposed also to pellagra, and that they frequently have low cevitamic acid content of the blood.³⁰ It is improbable that a substance through "toxic action" should produce manifestations similar to those known to be caused by vitamins B_1 , B_2 and C. 5 Finally, polyneuritis, pellagroid lesions and cardiovascular dysfunction disappear on continuous alcohol intake provided vitamin B is administered simultaneously.³¹

On the other hand, we attribute to alcohol a secondary predisposing role in the precipitation of beriberi. Alcohol is a food substance *par excellence* in its capacity to supply the body with necessary calories but with a minimum of vitamin B. This is an ideal combination for beriberi, as high caloric and low vitamin B_1 intake, rather than general inanition, precipitates the clinical vitamin deficiency. The gastro-intestinal changes often present in chronic alcoholism³² may well interfere with the absorption or utilization of the available vitamin B_1 , while alcohol itself, a freely diffusible substance, is absorbed readily. There is also a possibility that a high intake of alcohol plays an additional predisposing rôle, similar to that of a diet rich in carbohydrate, as is common among the rice eaters. It is known that if B_1 avitaminotic animals are kept on a diet that is rich in fatty acids instead of carbohydrates, the manifestations of B_1 deficiency may be prevented.³³

The origin of the "beer heart" cannot be explained on the basis of increased intake of alcoholic fluid. This condition was described before the use of the sphygmomanometer and it has "disappeared" since the recognition of the clinical significance of arterial hypertension, hence it is probable that these instances of cardiac hypertrophy represent unrecognized cases of hypertensive heart disease. Such a careful investigator

as Hirsch³⁴ observed as early as 1899 that patients with "beer hearts" suffer from nephritis, and he suggested that beer drinking causes nephritis and this, in turn, cardiac hypertrophy

Pellagra—Patients suffering from pellagra may exhibit cardiovascular symptoms, but, in the light of present knowledge, this is attributed to the frequent association of the vitamin B₁ component in the deficiency.^{21b} There is no experimental evidence that lack of vitamin B₂ is responsible for cardiovascular disease. When pellagra occurs in its pure form the heart at postmortem examination is small or normal, owing to the frequent presence of dehydration and emaciation. Histologic changes, if present, are those of brown induration.

Vitamin C—The relation of deficiency of vitamin C to capillary fragility is established, but its role in cardiac disorders is not well understood. Experimental scurvy in animals has been observed to cause hemorrhages into and fatty degeneration of the cardiac muscle.³⁵ Rinehart³⁶ has stated that scorbutic guinea-pigs respond to intradermal infections with beta hemolytic streptococci with degenerative and proliferative changes in the heart valves and myocardium. This work has not been uniformly confirmed. In a recent study Taylor³⁷ has stated that scurvy alone produces cardiac lesions in the guinea-pig and that added infections increase neither the incidence nor the severity of the lesions. Experimental "scorbutic carditis" if allowed to become chronic results in congestive failure. In such hearts the lesions cannot be cured with the administration of cevitamic acid. Thus vitamin C can prevent such lesions but cannot cure them once the damage is done. The pathologic changes in scorbutic carditis, as found by Taylor, are those of nonspecific valvulitis, myocarditis and occasionally pericarditis. The lesions often contain gram-positive organisms, even though no organisms were injected. In the acute lesions neutrophilic leukocytes predominate, whereas in the chronic lesions endothelial cells, lymphocytes and fibroblasts are more abundant. Giant cells and vegetations are not present.

Changes in the myocardium in human scurvy have been described, but it is questionable whether such changes can be attributed to vitamin C deficiency. Darling³⁸ has described enlargement of the right side of the heart. Hift and Brull³⁹ observed acute recurrent hemorrhagic pericarditis among the scorbutic inmates of a Russian concentration camp in Siberia. Of 325 cases of scurvy, twenty-eight showed severe pericardial effusion with congestive failure of the circulation. In six the pericardial effusion was fatal. Erdheim⁴⁰ performed postmortem examinations on thirty-one Viennese children who died as a result of scurvy in

the famine year of 1918. He noted that cardiac hypertrophy and dilatation were regular manifestations in these cases and he called the hearts observed "Barlow-herz." The myocardial hypertrophy was moderate in eight, considerable in seven and "enormous" in six. Unfortunately no clinical data or histologic examinations were reported. It is mentioned that the duration of malnutrition was long and that many of the children were marantic and suffered from diarrhea. In view of the fact that osteoporosis was also present, it is probable that these children suffered from multiple deficiency, including lack of vitamins B, C and D, and that the cardiac changes were due to lack of B₁. Hess⁴¹ mentions that x-ray examination in scurvy may reveal enlargement of the heart to the right with broadening of the base at the origin of the large vessels. The histologic studies of the heart in human scurvy do not reveal the type of myocarditis described in scorbutic animals.⁴²

The relation of vitamin C deficiency to rheumatic fever and rheumatic heart disease has been extensively investigated in recent years.⁴³ These studies indicate that in rheumatic fever, as in other chronic infections due to inadequate intake and/or to increased utilization of vitamin C, the cevitamic acid of the blood is low and the body is partially depleted of its normal storage.⁴⁴ The capillary fragility of some of these patients is often increased and can be reduced by the administration of cevitamic acid.⁴⁵ Vitamin C, on the other hand, fails to influence the clinical course or reduce the incidence of recurrent attacks of rheumatic manifestations.⁴⁶ A causative relationship between vitamin C deficiency and rheumatic fever therefore does not exist. In spite of these negative correlations between rheumatic fever and vitamin C, it seems advisable, on the basis of general principles and recent experimental work,⁴⁷ to feed rheumatic patients with a balanced diet rich in vitamins, including vitamin C.

The increased vascular fragility in vitamin C deficiency may lead to well recognized, extensive hemorrhages and tissue damage. It is of interest that recent observations indicate that the level of the cevitamic acid in the blood of chronic alcoholic patients is frequently low and may reach the level observed in subclinical scurvy.³⁰ The tendency to vascular fragility may contribute to the occurrence of epidural, subdural and intracerebral ("polyencephalitis haemorrhagica Vermicke") hemorrhages so frequently observed after relatively slight or no trauma in such patients. The same factor may play a role in the hemorrhagic birth injuries.

Vitamin D—Cardiac changes with right ventricular hypertrophy in rickets occasionally have been observed. Some authors have considered these to be secondary to defects in the thoracic cage with increased pul-

monary resistance, but cardiac changes have been noted without alteration of the thoracic cage. Meixner⁴⁷ emphasized the fact that frequently the left ventricle is dilated and slightly hypertrophied. The usual microscopic changes, as observed by Meixner, are a slight and irregularly scattered increase in the connective tissue and a separation of the muscle fibers, changes not unlike those observed in the heart in beriberi. At present one is justified in assuming that the cardiac changes observed in rickets may be attributed to the simultaneous presence of vitamin B₁ deficiency.

COMMENT

While human cardiovascular functions may be impaired only by an excess caloric content of the diet, they may be disturbed by dietary deficiencies of several types. The body can usually eliminate disproportionate excesses of food substances effectively, but its storage capacity for certain minerals and vitamins, as well as for water, is relatively limited. The susceptibility of the body and of the cardiovascular system to deficiency depends not only on intake but also on storage and rate of utilization of the substances in question.

In order to understand clinical vitamin deficiency it is essential to appreciate that, judging from the behavior of vitamins B and C, symptoms are apt to develop when there is simultaneously present with a deficiency of these substances an elevated metabolism (caloric/vitamin ratio of Cowgill)⁴⁸. This may arise because of increased muscular activity, increased caloric intake, fever, hyperthyroidism, and the like. Under such conditions specific metabolic processes influenced by or dependent on vitamin may become disturbed and harmful chemical products may accumulate. In simple chronic undernutrition, on the other hand, because of the simultaneous and proportionate reduction of both oxidative processes and available vitamin, symptoms of any specific deficiency usually do not develop, or, if present, the symptoms are mild ("subclinical avitaminosis"). When, however, an acute strain is placed on the metabolic system of such moderately avitaminotic patients as a result of infection, fever or increased activity, the symptoms and signs of deficiency may appear with great rapidity. This is well illustrated by the behavior of chronic alcoholic patients who have contracted pneumonia or typhoid. It is also of interest that we have observed patients in whom mild manifestations of avitaminosis became temporarily aggravated when a diet rich in vitamins and calories was administered.

The proportion of the various calorigenic substances in the diet also plays a rôle in the pathogenesis of certain avitaminoses. Thus high carbohydrate or alcohol diets favor but high protein or fat diets hinder, the development of beriberi. Finally, the functional and structural states of certain organs must be taken into consideration in the etiology of the avitaminoses, as well as of the other nutritional deficiencies. Disorders of the gastro-intestinal tract causing alterations in motor and secretory functions and in absorptive capacity may so interfere with the utilization of dietary factors that deficiency may develop in the body in spite of an adequate supply by mouth.⁴⁹ Indeed, certain deficient diets may themselves produce changes

in the gastro-intestinal tract which further handicap the utilization of food substances, so that a vicious cycle is established. Severe damage to other important organs of the body can also affect the utilization of nutritional factors. Thus damage to the liver impairs the metabolism of vitamin A and protein and probably also can be responsible for other deficiency syndromes in spite of a diet suitable for a normal person. The occasional finding of cardiovascular disturbances similar to those of beriberi in patients with cirrhosis of the liver or chronic pancreatitis but who apparently have had a normal diet supports the contention that intrinsic factors, such as alteration of the function of important organs, play a role in conditioning dietary deficiencies.

The symptoms of deficiencies must not be considered as arising from a simple lack of specific nutritional substances in the organs affected. Vitamin deficiency is followed by changes in the intermediary metabolism which cause, first, "biochemical lesions," later, functional and, finally, structural lesions. These changes may progress from a state of easy reversibility to one of slow or of nonreversibility. It is for this reason that, depending on the exact nature and duration of a deficiency disease, substitution therapy may or may not lead to prompt or to complete restoration of normal functions.

In vitamin B₁ deficiency the disturbances of intermediary metabolism of carbohydrates and the resulting alterations in nervous and cardiovascular functions and structures are good examples of secondary and tertiary changes precipitated by avitaminosis. The individual variations in biochemical responses and in the accumulation of abnormal substances in deficiency states may explain some of the variations in symptoms and pathologic manifestations. The exact mechanism of the nutritional deficiencies is therefore more complex than it was first thought to be. We are now entering into the third stage of our knowledge in this field. The original "toxic theory" of nutritional disorders was recently abandoned with the discovery of the "deficiency theory." We are now beginning to realize, however, that the deficiency of a substance by altering the normal pattern of intermediary metabolic processes, may lead to a secondary accumulation of "toxic" products, as, for example, lactic acid, pyruvic acid and methylglyoxal in vitamin B₁ deficiency.⁵⁰ The symptoms and changes in the body may depend on the effect of these substances on various structures. Thus the principles of "deficiency" and "toxicity" are not mutually exclusive, but interdependent.

Recognition of the fact that nutritional imbalance frequently affects the heart, the vessels, the blood and the nervous regulatory mechanisms of the circulation, singly or in various combinations, is necessary to a proper understanding of cardiovascular physiology and disease. Only by a broad and complete consideration of all the factors involved can a correlation of symptoms with bodily changes be made and preservation or restoration of health be effected.

SUMMARY

Of the vitamins, B₁ deficiency is the most important cause of cardiovascular disturbances. Beriberi with cardiovascular dysfunction is a disease of regular occurrence in the United States. Cardiac disturbances observed in human scurvy, with the exception of

hemorrhagic pericarditis, and in rickets are usually due to coexisting vitamin B₁ deficiency

Intrinsic factors, such as the metabolic state of the organism and the functional state of various organs, particularly of the digestive organs, may be as important as the intake of extrinsic factors in conditioning clinical nutritional deficiencies

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS

HOWARD A. CARTER Secretary

ALOE CSW 12 METER SHORT WAVE DIATHERM ACCEPTABLE

Manufacturer A S Aloe Company, St Louis

The Aloe CSW 12 Meter Short Wave Diatherm unit is intended for medical and surgical use. It is equipped for use with both pad and cuff electrodes. This semiportable unit comes in a natural wood finish with chrome ventilator grille and handles. The subcabinet has ample storage space for electrodes and equipment with two drawers and a large door beneath these.

Aloe CSW 12 Meter Short Wave Diatherm

This machine utilizes two tubes in a half-wave self-rectifying, balanced, push pull, tuned plate tuned grid, oscillatory circuit. The output circuit is inductively coupled to the plate circuit and the power output is controlled by a variable air condenser in series with one patient terminal.

The total power input is approximately 300 watts under idling conditions. Under a load test the input is about 900 watts. The output is about 400 watts. This was measured by

Schematic diagram of circuit

adjusting the supply voltage to 110 volts and using an artificial resistance load comprising two 200 watt lamps in parallel, capacitatively coupled to the patient electrodes. The coupling to the load and the output control were adjusted to give the

Averages of Six Observations

	Deep Muscle	Subcutaneous	Skin	Rectal
Initial	96.5	91.5	87.1	99.1
Final	107.0	104.1	94.9	99.4

highest output. As no acceptable means of measuring the output has as yet been proposed, this value is stated as an approximation.

The firm submitted evidence to substantiate the claims for the heating ability of the unit when applied to the thigh of a living subject. Six tests were performed on three healthy male medical students by a competent investigator. Temperature readings were taken by means of thermocouples calibrated against a thermometer standardized by the Bureau of Standards.

These readings were taken before and after twenty minute treatment periods at maximum tolerance of the subject. The skin surface temperature, as well as that of the muscle and subcutaneous tissues, was measured by hypodermic thermocouples. Investigations were made with cuffs measuring 23 1/2 by 2 1/4 inches. The average thigh circumference was 21 1/2 inches. Several thicknesses of toweling were placed between the skin and the cuffs. The latter were separated 9 inches from edge to edge. The room temperature was from 71 to 74 F and the humidity ranged from 41 to 43 per cent. The averages of the six observations are given in the accompanying table.

The unit was tried out in a clinic acceptable to the Council. In operation under actual clinical conditions, the unit rendered satisfactory service. The transformer temperature rise and the temperatures inside the cabinet taken at various levels were within the limits of safety prescribed by the Council. Burns may occur with this type of machine but are less apt to occur than with conventional diathermy and may be avoided by use of ordinary precaution.

In view of the favorable report based on the use of the cuff technique, the Council on Physical Therapy voted to include the Aloe CSW 12 Meter Short Wave Diatherm in its list of accepted devices.

COLLINS OXYFLO OPEN TOP OXYGEN TENT ACCEPTABLE

Manufacturer Warren E Collins, Inc, Boston

The Collins Oxyflo Open Top Oxygen Tent (previously known as the Burgess-Collins Oxygen Tent) is designed for use in the hospital or the home. The specifications include a tent frame, cooling chamber with six pound ice capacity, two gum rubber tent fabrics fitted with three nonflammable windows, a well balanced stand adjustable horizontally and vertically, allowing the tent to be tilted, heavy cast iron base equipped with casters, art metal finish with nickel trimmings, and it is complete with oxygen regulator and oxygen analyzer. The tent and stand weigh 45 pounds and can be dismantled for convenience in storing or for transportation to the home.

The open top tent has a neck opening approximately 5 feet from the ground at its highest point and 26 inches from the floor at its lowest accommodating anything from a baby's crib to an adult sitting up in bed. According to the firm, the open top principle makes possible an oxygen tent with several advantages. It is portable, its operating cost is modest, it is equally effective with infants or adults, and it is noiseless since no electrical connections are required to operate it. The firm claims that a 50 per cent concentration of oxygen with only a 3 or 4 liter flow may be obtained with the top of the tent open. The Council found a slightly higher flow necessary.

The unit was investigated in a clinic acceptable to the Council. The observations were started with the patient lying in a prone position. The temperature of the room was 78 F and the temperature of the inside of the tent was 75 F with a 38 per cent relative humidity. The concentration of oxygen was taken during normal breathing periods and after two minute runs of rapid (60 per minute) respirations in both prone and sitting positions. In all these observations the concentration of oxygen dropped below 50 per cent only once, and then only to 49 per cent. It went as high as 72 per cent. The flow of oxygen was regulated at 5 or 10 liters per minute. By increasing the flow, the concentration could be held well over 50 per cent during periods of rapid breathing. During these tests the temperature in the tent ranged from 68 to 74 F. The humidity rose from 42 per cent to 54 per cent. The data obtained in these observations essentially substantiated the claims of the manufacturer. The tent handled easily and operated well during the test, the patient was comfortable with no complaints of tightness at the neck and apparently there was no leakage at that point. The only disadvantage is that the person lying flat with rapid respiration can reduce the oxygen saturation, but if the rate of flow of the oxygen is increased a good concentration may be regained.

In view of the favorable report on the efficiency of the unit in actual clinical practice, the Council voted to include the Collins Oxyflo Open Top Oxygen Tent in its list of accepted devices.

THE DUKE-FINGARD METHOD IN RESPIRATORY DISEASES

The New York *World Telegram* for August 24 published, on its front page, a feature article syndicated by Science Service concerning the so-called Duke-Fingard method for the treatment of asthma, tuberculosis and other respiratory diseases. Behind this item is the rather slimy trail of an attempt to force on the medical profession a secret method of treatment, unsupported by anything resembling acceptable clinical evidence.

Readers of *Time* will perhaps remember an article published Jan. 18, 1937, which called attention to the career of David Fingard. Briefly, Mr. Fingard appears to be a chemist from Canada who came in contact years ago with the development by one J. Rudolph Duke (perhaps J. J. or just plain Rudolph) of a method of treating asthma by the inhalation of air modified by a mixture of antiseptics and oils. The method was apparently promoted with little success in California and in China. Eventually Mr. Fingard appeared in London en route, as he said, to the Soviet Republic. Finding sympathetic listeners in Great Britain, he remained there until he left for the United States in December, the government having refused him an extension of his stay. Previously he had endeavored to obtain an official trial of his method by the British government. However, Sir Kingsley Wood, Minister of Health, failed to authorize such an experiment. Attempts were made in Parliament to force an investigation, but in each instance these attempts failed. Mr. Fingard obtained in London a staunch supporter in the dowager Duchess of Suffolk and Berkshire, a daughter of the late Chicago department store executive and owner, Levi Leiter. In the development of his promotion in Great Britain another prominent factor has been Lieutenant-General Sir Harold Ben Fawcus, KCB, CMG, DSO, DCL, MP and DPH, who is director general of the British Red Cross. Quite recently Messrs. Fawcus, Fingard and

Greene arrived in the United States. They seem to have been freely introduced and in general recommended by Dr. Clarence Lieb. Because of his connection with the British Red Cross, Lieutenant-General Fawcus and Mr. Fingard were tendered a banquet by members of the American Red Cross and other official agencies. They offer as evidence of their standing photostatic copies of letters from the Red Cross with the list of guests. At present, according to Mr. Greene, Mr. Fingard is in Canada endeavoring to straighten out with officials in that country certain matters of an extralegal financial character which have caused him considerable embarrassment in some of his travels in the British empire.

Mr. Greene presents also a photostatic copy of a list of distinguished citizens of Winnipeg who have recently tendered an official luncheon to Mr. Fingard.

Now what is the remarkable discovery which has attracted such a list of notables, political, aristocratic and financial, in its support? From what can be ascertained, the method involves the use of a cabinet containing twelve trays of a liquid which is an oily brown mixture in "carefully worked out" proportions of creosote, phenol, iodine, garlic, aromatic essences and essential oils and glycerin. Air is dried by passing through a short tube into a box containing calcium chloride, which is said to "filter off dust and microbes." It is then sucked into the apparatus by a small electric fan and, after being heated to between 70 and 80 F., is driven over the twelve trays of medicaments and out into the room. The patient breathes this mixture of air and whatever it can pick up, beginning with three hours a day and going on to sixteen hours a day. It is alleged that by this method of treatment asthma is brought under control, recovery occurs in hopeless cases of tuberculosis, and patients with sinus trouble are freed of their disturbances.

In the process of British promotion an investigation was made on some patients, and the bibliography which follows is the only scientific evidence thus far available as to the merits of the treatment.

Fawcus, H. B., Greene, A. C., and Houston, J. W. A Short Account of the Duke-Fingard Treatment for Diseases of the Respiratory Passages, *Practitioner* 37:740 (Nov.) 1936.

Fraser-Harris, D. F. The Duke-Fingard Method of Medication as Applied to the Respiratory Tract, *Medical Press and Circular* 93:381 (Oct. 28) 1936.

Thornton, J. Raymond, Fraser-Harris, D. F., and Vaughan, V. St. George. The Duke-Fingard Inhalation. Some Results Obtained in Chronic Respiratory Disease, *Medical Press and Circular* 94:151 (Feb. 17) 1937.

Salen, Ernst B. Duke-Fingard Treatment of Diseases of Respiratory Tract, *Svenska Lakartidningen* 34:681 (May 7) 1937.

The method has been studied in Great Britain in 1935, 1936 and part of 1937, certainly time enough

if it possessed any real merit, to have received recognition by the British medical profession

The case reports which appear in the bibliography cited are far from convincing. The evidence in relationship to cases of asthma, tuberculosis, bronchiectasis and sinus disease is no better than that which has been published from time to time for a dozen other methods of treatment not half as fantastic. Mr Fingard refuses to reveal a quantitative formula or anything even resembling a complete qualitative formula for the compound of drugs he uses. The details regarding the process have apparently been submitted to a board of trustees and are now locked away in a safe in Great Britain. In support of their method, Mr Greene submits a number of letters from representatives of the Red Cross in various countries indicating that the Red Cross connection of Lieutenant General Fawcus is being used freely to introduce this method in various parts of the world. Inquiry at the headquarters of the American Red Cross in Washington indicates that a luncheon was tendered to Lieut Gen Sir Harold Fawcus, The Hon Sir Arthur Stanley, GBE, Mr Fingard and General Sir Hubert Gough, GCMG, KCB, KCVO, who are trustees for the Fingard treatment. The American Red Cross has said, however, that it will do nothing whatever to exploit the Duke-Fingard asthma treatment.

Here then is a method of treatment secret in character, fantastic in its administration, unsupported by any scientific evidence, promoted by a chemist and financiers whose records are far from clear, supported by letters of politicians, military officers and aristocrats. The American medical profession has established the Council on Pharmacy and Chemistry as an official body available for testing and evaluating new remedies and new methods of treatment when the investigators and the promoters are willing to state the nature of the treatment and to submit it to controlled, scientific experimentation. Obviously the British promoters of the Duke-Fingard treatment have no intention of submitting to such an investigation. Until they do so they can hardly anticipate a hearing before the critical bar of American medical opinion. Mr Greene, when he visited the headquarters of the American Medical Association in an endeavor to induce belief in the Fingard method, was kind enough to leave an outline of the proposed method of promotion which is headed with the following naive statement:

'Dear Greene: Would you be good enough to get this published in one of the American medical journals? H B Fawcus.'

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION has no intention of lending its columns to such an exploitation. Whether or not some of our commercially minded medical publications will yield to the blandishments of this pseudo-scientific embassy, as Science Service yielded, remains to be seen.

HYPOGLYCEMIC THERAPY IN TRYPANOSOMIASIS

More than fifty years ago, Pasteur and his co-workers thought that acquired immunity to specific infections might be due to the destruction of food factors in the body necessary for bacterial growth. This so-called specific exhaustion theory, however, was not substantiated. The chief objection to it was the failure to conceive of a specific antiserum capable of carrying a specific chemical deficiency to another animal.

The recent work of Schern and Artagaveitia-Allende¹ of Montevideo brings this theory from the purely historical to a stage of possible practical importance. Schern observed some thirty years ago that trypanosomes in citrated blood samples from recently infected rats retained a high degree of motility for several hours at room temperature. The motility of these parasites, however, was much more poorly retained when they were isolated from the animals in the later stages of experimental infection. The parasites thus obtained lost all motility within ten to fifteen minutes at room temperature. Further it was found that these apparently moribund trypanosomes could be revived by the addition of a small amount of normal rat serum and would remain actively motile for several hours at room temperature. The addition of certain aqueous tissue extracts, especially liver, produced the same results. From the biochemical analysis Schern and his co-workers concluded that the rejuvenation was due solely to the sugar content. Hence it became theoretically possible that the loss of motility in late stages of trypanosome infections might be due to the sugar depletion of the experimental animal. Further confirmation was obtained by subsequent studies of the sugar content of the tissues in long standing trypanosome-infected animals. Observations by the Jancsos² lent support to this view.

In an endeavor to find methods of practical therapeutic application, Schern and his co-workers found that rats could be rendered almost glycogen free by prolonged starvation. This procedure, however, did not make the rats immune to experimental trypanosomiasis, and partially starved rats usually died more quickly than the normally fed controls. Finally, these investigators tested the effect of hypoglycemia following intoxication with "synthalin"—an organic preparation once offered for the treatment of diabetes. This toxic agent causes glycosuria and polyuria with a rapid decrease in blood sugar and hepatic glycogen in rats. When it was injected in divided doses on the fifth, sixth and seventh days of experimental trypanosomiasis in rats, the parasites disappeared from the blood stream and the life of all rats was prolonged with the apparently permanent cure of about 75 per cent. When it was given prophylactically, the animals were rendered

1 Schern, Kurt and Artagaveitia-Allende, Ricardo. *Ztschr f Immunitätsforsch* 89: 21 (Sept) 1936.
2 von Jancso, N. and von Jancso, H. *Ztschr f Immunitätsforsch* 85: 81 (May) 1935.

relatively insusceptible to the experimental infection. While this hypoglycemic therapy appears to be a confirmation of the old Pasteur exhaustion theory, the effectiveness of "synthalin" may be due to other factors. Thus Schern and his co-workers found that the preparation used contains a co-enzyme, which increases the efficiency of the starch-splitting enzymes in human saliva. When added to a culture of yeast, it at first increases the rate of gas production but is followed by a complete inhibition of fermentation presumably from its effect on the sugar-splitting enzymes. A similar effect on trypanosomes is therefore a possibility.

Interesting as these observations are, their practical significance awaits further investigation and the careful analysis of the factor or factors which cause these differences in trypanosome behavior in infected rats. Certainly none of the results so far reported can as yet be interpreted in whole or in part as necessarily related to human parasitic or bacteriologic infections.

THEORIES ON THE CAUSES OF SUICIDE

Suicide and its causes are matters of general interest primarily because suicide represents a voluntary attempt to substitute an unknown state for a known one—a step frequently causing hesitation in other less radical human decisions. The general attitude toward suicide is much affected by the emotions, religion and customs of a people. Hence it has been frequently noted that the numbers of suicides, the apparent precipitating causes and the methods by which self destruction is accomplished or attempted have varied widely in different parts of the world at different periods.

Review of some of the recent studies of the subject reveals a disparity in both approach and conclusions. Thus comparison of suicides among civilized and primitive races has been reported by Zilboorg.¹ He points out that the popular reaction to the act is confused and one hears with apparently equal frequency either that it takes great courage to commit suicide or that only a coward would kill himself. That the rate of suicide increases with the development of civilization or that it is a result of some psychopathologic process and intimately connected with some form of mental disease are misconceptions, he believes. He quotes Steinmetz, who says "It seems probable from the data I have been able to collect that there is a greater propensity to suicide among savage than among civilized peoples."

According to Vorwahl,² the rate of suicide varies also in the different races. He states that before the war the suicide rate in Germany was five times that in Italy and ten times that of Spain. Gross statistics of this nature, however, are difficult to compare, since so many elements are involved, including the method and source of

compilation and the political, economic, religious or social factors, any one of which might be of more influence on the apparent suicide rate than the mere difference in race.

Pacheco³ in writing on suicide in India states that the most usual method of suicide among males there is by poisoning. Burning, poisoning, jumping from heights and drowning are common among female suicides. He further states that the causes that lead to suicide among males are financial difficulties and want of employment, and, among females, ill treatment at the hands of husbands or mothers-in-law, or loss of children. Available records indicated that more suicides occur in the hot season than in any other.

It has been believed that studies of attempted suicide might throw light on the whole problem. In the interpretation of such studies, however, it must be remembered that there is one fundamental difference between attempted suicides and actual suicides, and that is the difference between failure and success. The possibility that this diversity even may be actually so planned emphasizes the noncomparability. Hopkins⁴ carried out an investigation on 656 attempted suicides admitted to the Smithdown Road Hospital of Liverpool. His figures indicate that unsuccessful attempts occur much more commonly than successful ones. It was noted that the relative incidence in the two sexes was six males to five females but that up to the age of 25 female attempts were twice as frequent as male.

Even more recently another investigation from this angle has been reported by Moore.⁵ From Jan 1, 1915, to Jan 1, 1936, the Boston City Hospital admitted 1,147 patients who had attempted suicide. Twenty-one were dead on arrival. The outcome was known in 464 of the males and 566 of the females (there were 100 more women than men in the series). Fifty-five women, 9 per cent of the females, were successful, seventy-two men, 13 per cent of the males, succeeded. It was also noteworthy that 61 per cent of the women as against 33 per cent of the men were between the ages of 16 and 30. Records of motivation, Moore points out, are of questionable validity. Nevertheless the admitted cause in seventy-one female and twenty-seven male attempts as "domestic trouble" may possibly be significant. Seven main methods were used by each sex group, with poison by mouth and inhalation of gas leading for both. In the former, iodine by mouth was the most popular and least effective choice.

The relation of suicide to mental disease has been the subject of frequent study. Jameison⁶ recently reviewed the clinical records of 100 patients who committed suicide. The study included a diagnostic enumeration, a correlation of the intensity of desire for suicide with the

type of psychosis, and an analysis of the apparent motives behind the act itself. He concluded that probably many persons who commit suicide today are suffering from personality disorders. The potential suicidal patient may, however, be normal in an intellectual sense. On the controversial issue of family background, his material indicated that predisposition to return to psychologic levels of immaturity exists in certain persons.

Zilboorg,⁷ in another discussion of the subject, suggests that a mere review of the various "difficulties" which patients happen to endure cannot serve as a criterion of the causation of suicide. Such facts as a sense of inadequacy, complex family relationships and neurotic or psychotic complications are in themselves of little clinical value in the evaluation and understanding of suicide. He believes that an intimate study of the details of suicide frequently reveals the ceremonial quality of a number of self-inflicted deaths and offers psychologic links with the suicides among many primitive peoples. With most of Zilboorg's methods and conclusions, Wile⁸ takes definite issue. Wile believes that Zilboorg's psychoanalytic concepts are not to be accepted as *prima facie* evidence, especially when they lack the validity of exact statement.

It is obvious that no unity of thought yet surrounds the causes of suicide, in spite of centuries of study and speculation. It would seem to be relatively safe to believe that the causes leading to suicide are affected by different circumstances at different times. One can also accept suicide as a definitely asocial and minority phenomenon.

Current Comment

VITAMIN C AND PYORRHEA ALVEOLARIS

Pyorrhea may be one of two types: a local inflammatory disease, beginning at the gingival margin, or a diffuse atrophic disease of systemic origin. According to Boyle and his co-workers,¹ systemic pyorrhea alveolaris may be readily produced in guinea-pigs by vitamin C deficiency. Within six months after guinea-pigs have been placed on a vitamin C free diet, loosening and wandering of the teeth are demonstrable. X-ray studies of sagittal sections of the heads reveal marked rarefactions of the alveolar bone with widening of the periodontal membrane. The microscopic details are identical with those found in human periodontal disease of the atrophic type. Similar changes take place at a slower rate in guinea-pigs maintained for many months on a relatively low ascorbic acid intake. They have not yet studied the effectiveness of vitamin C therapy as a cure of experimental pyorrhea, nor has the alleged therapeutic value of tooth pastes plus massage thus far been confirmed.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

State Provides Drugs for Venereal Diseases—As a part of its campaign against syphilis, the state department of health will distribute without charge drugs for the treatment of venereal diseases. Heretofore this service has been available only for the treatment of indigent persons, newspapers reported.

ARKANSAS

Changes in Health Department—Dr. Arthur M. Washburn has been placed in charge of the division of communicable disease control of the state department of health, Little Rock, and Dr. Doyle W. Fulmer, Benton, of the division of malarial control, it is reported. Both physicians recently returned from Harvard University Medical School, Boston, where they took a year's graduate work on leave of absence from the state department. Dr. Washburn graduated from Rush Medical College, Chicago, in 1917 and formerly served as health officer of the city of Blytheville and Mississippi County. Dr. Fulmer graduated at the University of Arkansas School of Medicine in 1932.

CALIFORNIA

Society News—At a meeting of the Hollywood Academy of Medicine, August 19, Dr. John S. Chase spoke on "Aviation Medicine." Douglas Shearer, chief sound engineer, Metro-Goldwyn Mayer Studios, discussed the related psychophysical aspects of flying. Dr. Clarence O. Sappington, Chicago, addressed the industrial accident section of the Los Angeles County Medical Association at a joint meeting with the Casualty Insurance Adjusters' Association, August 12, on "Practical Problems in Industrial Health and Disease."

Changes in the Faculty at University of California—Announcement is made of the following promotions on the faculty at the University of California Medical School, San Francisco, among others, effective July 1:

Dr. Ottwell W. Jones, Jr. to be associate professor of surgery.
Drs. Paul Campiche, Thomas F. Mullen, Mary F. Montgomery and Robertson Ward, assistant clinical professors of surgery.
Dr. Leon Goldman, assistant professor of surgery.
Dr. Dorothy A. Wood, associate clinical professor of anesthesiology.
Dr. Clark M. Johnson, associate clinical professor of urology.
Dr. Francis J. Rochex, assistant clinical professor of medicine.
Dr. Isabella H. Perry, assistant professor of pathology.
Dr. Warren D. Horner, associate clinical professor of ophthalmology.

The title of Dr. Albert J. Houston has been changed from clinical professor to clinical professor emeritus of otorhinolaryngology, and that of Dr. Herbert C. Moffitt from clinical professor to clinical professor emeritus of medicine.

CONNECTICUT

Annual Clinical Congress of State Society—The annual clinical congress of the Connecticut State Medical Society will be held at New Haven, September 21-23. The following speakers will appear on the program among others:

Dr. Francis C. Grant, Philadelphia. Treatment of Cranial Trauma.
Dr. Joseph Earle Moore, Baltimore. Treatment of Early Syphilis.
Dr. Robert H. Aldrich, Boston. Treatment of Burns with a Compound of Aniline Dyes.
Dr. Frederick C. Irving, Boston. The Place of Cesarean Section.
Dr. Isidor S. Ravdin, Philadelphia. Surgical Diseases of the Extrahepatic Bile Ducts.
Dr. William B. Castle, Boston. Treatment of Various Types of Anemias.
Dr. Emil Novak, Baltimore. Treatment of the Menopause.
Dr. Maurice Lenz, New York. Clinical Experience with the Use of Radium and X-Rays in the Treatment of Cancer.
Dr. Oskar Dietheim, New York. Treatment of Psychoneurotic Disorders.
Dr. Arthur Steindler, Iowa City. Fracture Deformity of the Upper Extremities—Wrist and Forearm.
Dr. Claude S. Beck, Cleveland. The Treatment of Coronary Sclerosis and Angina Pectoris by Grafting a New Blood Supply to the Heart.
Dr. Warfield T. Longcope, Baltimore. Some Problems in Relation to Bright's Disease.

There will be symposiums, clinics and panel discussions. Wednesday the section on anesthesia will meet with the American Society of Anesthetists with the following speakers: Dr. Henry S. Ruth, Philadelphia. Problems in Resuscitation. Louis S. Goodman, New Haven. The Chemical Moderation of Nerve Stimuli. Paul M. Wood, New York. Modern Anesthesia for Upper Abdominal Surgery. Meyer Saklad, Provi-

dence R I, "A Method for the Collection and Analysis of Anesthetic and Surgical Statistics" The Connecticut Medical Examiners' Association will meet during the congress and Dr Robert P Knapp, Manchester will address the Connecticut Public Health Association on 'Progress of Industrial Medicine'

FLORIDA

District Meetings—The first annual meeting of the North-east Committee District (C) of the Florida Medical Association will be held at St Augustine, September 23, at the Munson Hotel. Dr Charles C Grace, president, St Johns County Medical Society, will give the address of welcome. Other speakers will include Drs Samuel R Norris, Jacksonville, on "Some Complications of Labor", Thomas M Palmer, Jacksonville, "Congenital Osseous Syphilis," and Hugh West, DeLand, "Anomalies of Intestinal Rotation and Report of a Case." The first annual meeting of the Southeast Committee District (F) was held at Miami, September 3, in the Columbus Hotel, with the Dade County Medical Society acting as host. Among the speakers were Drs Lloyd J Netto, West Palm Beach, "Ectopic Pregnancy", Kenneth Phillips, Miami, "Resume of Fever Therapy," and Shaler A Richardson, Jacksonville, "The Treatment of Retinal Detachment."

ILLINOIS

Personal—Dr Amos W Ball, Rushville, was guest of honor at a dinner given by the Rushville Rotary Club, August 10, to celebrate his completion of fifty years in the practice of medicine. He was presented with a Rotary pin. Speakers included Drs Everett P Coleman, Canton, counselor of the fourth district of the state medical society, Don W Deal, Springfield, Perry H Stoops, Ipava, Henry O Munson and Frederick D Culbertson. Dr Ball graduated in 1886 from Missouri Medical College, St Louis.

Advisory Board to Division for Handicapped Children—Fifteen persons have been named by the governor to a newly created advisory board of the division for handicapped children, state department of public welfare. Dr Paul H Harmon is director of the division and members of the committee include Drs Henry B Thomas, Edward L Compere, Philip Lewin, Julius H Hess, Edwin W Ryerson, Robert A Black, Philip H Kreuscher, all of Chicago, Frank J Jirka, state health director, Gerald M Cline, Bloomington, Fred S Etherton, Carbondale, Roland L Green, Peoria, Harold M Camp, Monmouth, Charles S Skaggs, East St Louis, Miss Mable Dunlap, Moline, and Mark Penney, state board of vocational rehabilitation, Springfield.

INDIANA

Personal—The completion of fifty years in the practice of medicine was observed by Drs Robert E Trout, Oaktown, Simon P Schroeder, Nashville, Ill, and Isaac H Doolittle, South Bend, at a joint celebration at Dr Trout's home in Oaktown, July 4-5. Dr Edith M B Schuman, Bloomington, has been appointed assistant physician at Indiana University, succeeding Dr Margaret A T Owen, who will enter private practice.

New Cancer Clinic—The Indianapolis City Hospital, Indianapolis, has received a gift of \$100,000 to establish and endow a cancer clinic. Edwin L Patrick, president and secretary of the C B Cones & Son Manufacturing Company, is the donor. The clinic will be named Patrick Hall in memory of his wife, the late Mrs Kathryn Cones Patrick, and her father and mother, newspapers announced. Complete equipment for the treatment of cancer, including x-ray machines and radium, will be provided and accommodations for twenty-two patients will be available. Dr Charles W Myers is superintendent of the hospital.

IOWA

Norman Baker Fined—One Day in Jail—Norman G Baker, operator of the Baker Hospital and identified with alleged cancer cures was fined \$1,000 and sentenced to one day in the Muscatine County Jail, Muscatine, by Judge D V Jackson in district court, August 14 following his plea of guilty to an indictment charging him with practicing medicine without a license, according to the Davenport Democrat. The plea was entered through Baker's attorney, J F Devitt and the indictment was returned by a Muscatine County grand jury Sept 30, 1935. The one day jail term will be served concurrently with a similar sentence imposed by the state supreme court when Baker was found guilty of contempt for violating, through the fiction of a lease of the Baker Hospital to Dr Johnson L Statler and others, an order enjoining him from practicing medicine in Iowa (THE JOURNAL July 31, p 375).

KANSAS

Election of Medical Board—Dr Oliver S Rich, Wichita, was recently elected president of the Kansas State Board of Registration and Examination and Dr John F Hassig, Kansas City, was chosen secretary. The latter succeeds Dr Charles H Ewing, Larned, who served in the position from January 1931 to July 1937, he is no longer a member of the board. All matters pertaining to medical registration should be addressed to Dr Hassig, 804 Huron Building, Kansas City. Other members of the board are Drs Henry E Haskins, Kingman, James E Henshall, Osborne, Mirl C Ruble, Parsons, and Frederick S Hawes, Russell.

KENTUCKY

Society News—Dr Edward C Rosenow, Rochester, Minn., addressed the Southwestern Kentucky Medical Society at its quarterly meeting in Arlington, August 10, on infantile paralysis. Drs James Vernon Pace, Paducah, and George W Payne, Bardwell, spoke on "Appendicitis in Childhood" and "Chronic Nephritis" respectively. Dr Irvin Abell, Louisville, President-Elect of the American Medical Association, was the guest of honor at the quarterly meeting of the Muldraugh Hill Medical Society, Elizabethtown, August 12. Dr Francis M Massie, Lexington, addressed the Bourbon County Medical Society, Paris, August 19, on empyema. Dr John Y Harper, Jenkins, addressed the Letcher County Medical Society at a recent meeting in Jenkins on "Fractures of the Femur and Their Treatment."

MAINE

Personal—Dr Herbert R Kobes, Augusta, has been placed in charge of a maternal and child health program to be carried out by the state department of health with social security funds.

Society News—At the annual meeting of the Maine Medical-Legal Society at Belgrade Lakes, June 22, the following officers were elected: Drs John G Towne, Waterville, president, Oscar F Larson, Machias, vice president, George L Pratt, Farmington, secretary, and William Holt, Portland, treasurer.

MARYLAND

Semiannual Meeting of Medical and Surgical Faculty—The semiannual meeting of the Medical and Surgical Faculty of the State of Maryland will be held at the Washington County Hospital, Hagerstown, September 27. According to the preliminary program, Dr Samuel F Marshall, Boston, will discuss "Surgical Indications for and Surgical Treatment of Peptic Ulcer," and Dr Frank H Lahey, Boston, "Diagnosis and Management of Thyroid Disease." Dinner will be at the Alexander Hotel in the evening.

New Syphilis Clinic—The Baltimore city health department opened a new clinic for the diagnosis and treatment of congenital syphilis at 1516 Madison Avenue recently. The new service has been established for babies born of infected mothers in families that are unable to afford the services of a private physician. The clinic will be under the joint supervision of the bureaus of venereal diseases and child hygiene so that the children will receive the benefits of pediatric advice as well as of diagnostic and treatment service for syphilis.

MICHIGAN

New Health Districts—Alger and Schoolcraft counties have organized a joint district health department and selected Dr Ervin J Brenner, East Jordan, as health officer. He will have headquarters at Manistique. Ontonagon and Baraga counties have planned a similar organization, with Dr Clifford C. Corkill, Fennville as director. Headquarters will be at L'Anse.

Changes in the Faculty—At a recent meeting of the board of regents of the University of Michigan, Ann Arbor, the following promotions on the staff of the medical school were announced:

Henry C Eckstein, Ph D to be associate professor.
Dr Ralph G Smith, associate professor of pharmacology.
Dr John L Law, assistant professor of pediatrics and infectious diseases.

Dr Jacob Sacks, assistant professor of pharmacology.
Testimonial to Physician—Dr Leo G Christian, Lansing, chairman of the legislative committee of the Michigan State Medical Society, was honored by the Ingham County Medical Society at its meeting in July for his work in bringing about the passage of the basic science law. A resolution was unanimously adopted expressing the society's appreciation, and a Tiffany watch was presented to him. In addition the society dedicated its July bulletin to him.

State Society Officers Visit Counties—Officers and councilors of the Michigan State Medical Society made a tour of the county medical societies of the Upper Peninsula during August and 'state society meetings' were regular features of the programs of the various units. The following schedule was announced:

Chippewa Mackinac at Sault Ste Marie August 17
Luce and Schoolcraft at Blaney August 17
Marquette Alger at Marquette August 18
Upper Peninsula Medical Society annual meeting at Houghton August 19-20
Ontonagon at Ontonagon August 23
Gogebic at Ironwood August 23
Dickinson Iron at Crystal Falls August 24
Menominee at Menominee August 25
Delta at Escanaba August 25

MINNESOTA

Dr Meyerding on Leave of Absence—Dr Edward A. Meyerding, St. Paul, secretary of the Minnesota State Medical Association since 1924 has been granted a year's leave of absence without pay, beginning September 1. Mr. R. R. Rosell, now field secretary, has been appointed executive secretary of the association. Dr. Meyerding will remain as executive secretary of the Minnesota Public Health Association. In a statement to members of the association it was explained that the pressure of work with the two organizations made it necessary for Dr. Meyerding to ask to be relieved of the medical secretaryship for a year.

"Divine Healer" Fined—A. C. Martin pleaded guilty in the district court at Shakopee to the charge of practicing medicine without a license and was sentenced to pay a fine of \$200 and costs or serve one year in the McLeod County jail. He paid the fine. For some time Martin had been making weekly trips to Brownston, where he had a hotel room for the reception of patients. He also operated in Pine City and Arlington. He is listed in the Minneapolis city directory as a 'healer' residing at 1916 Hennepin Avenue. He prescribed alum, boric acid and iodized salt dissolved in water and applied externally to the neck and throat for goiter; he also suggested and furnished 'gland tablets' to be taken internally. According to the state board of medical examiners he also applied some massage. He admitted that he had never studied medicine but stated that he had been a farmer and a traveling salesman.

MISSOURI

New Psychopathic Institute—Plans for a new \$1,000,000 city psychopathic institute in St. Louis, named in honor of the late Dr. Malcolm A. Bliss have been announced. The new building will be six stories tall and occupy the block north of City Hospital, bounded by Grattan Street, Park Avenue and Dillon and Carroll streets. It will accommodate 185 patients, with 142 beds for white patients and forty-three for Negroes. The site cost about \$109,000 and funds for the entire project came from a 1934 bond issue and a PWA grant, newspapers reported. The institute will be primarily for the study of new and borderline cases; the latter to be segregated from the actually insane. The new building will be ready about March 1939. Dr. Bliss, in whose honor it is named, was for many years associated with the city institutions. He died in 1934.

MONTANA

Society News—Dr. E. Martin Larson, Great Falls, was elected president of the Montana Health Association at its annual meeting in Great Falls. Dr. William F. Cogswell, Helena, remains as secretary.

NEW JERSEY

Society News—The Society of Surgeons of New Jersey will hold its twenty-fifth anniversary meeting in Trenton, November 20. At a meeting of the Middlesex County Medical Society, June 16, in Metuchen speakers were Drs. Harry J. White, Metuchen, on 'Early Recognition of Pulmonary Tuberculosis'; Walter Grossman, Metuchen, 'Pulmonary Cavitation—Pathologic Types'; and Paul Geary, Plainfield, 'Treatment of Tuberculous Pulmonary Cavitation'. Dr. Earl W. Fuller, Greystone Park, will address the Bergen County Medical Society, Hackensack, September 14, on 'Mental Diseases'.

Personal—Dr. Irvin E. Deibert, Haddonfield, has been reelected president of the state board of health and E. W. Smilie, VMD, Plainsboro, has been elected vice president. Dr. David A. Kraker, Newark, was the guest of honor at a dinner July 16 given by officers of the 303d Medical Regiment, U. S. Army Reserve Corps, observing his completion of fifteen years as commander of the regiment. He

received an engraved saber as a memento. At a meeting of the Hunterdon County Medical Society, Glen Gardner, July 27, certificates of fifty years of practice and engraved golden keys were presented to Drs. Francis Asbury Apgar, Oldwick, Harry M. Harman, Frenchtown, and Edward W. Closson, Lambertville.

NEW YORK

Smallpox at Niagara—Eleven cases of smallpox occurred in Niagara Falls and the town of Niagara between June 21 and August 3. *Health Aegis* reported August 16. The cases were limited to four related households. Twenty-two known immediate contacts were vaccinated and are under strict quarantine and about 200 other persons in the immediate neighborhood affected have been vaccinated. The outbreak was believed to be sufficiently under control that visitors to Niagara Falls need have no special concern, the bulletin said.

Director of Research Appointed at Saratoga—Oskar Baudisch, PhD, recently of Stockholm, Sweden, has been appointed director of research at the Simon Baruch Research Institute for Balneology and Hydrology to be established at the state spa at Saratoga Springs. Dr. Baudisch is a native of Austria and received his doctorate at the University of Zurich, Switzerland, in 1904. From that time until 1921 he was associated with various universities in Europe. In 1921 he became research associate at Yale University, New Haven. From 1923 to 1929 was on the staff of the Rockefeller Institute for Medical Research, New York, and again was research associate at Yale from 1929 to 1933. Recently he has been research associate at the University of Stockholm, Sweden. Plans for the establishment of the research institute have not been completed.

New York City

Aid for Nurses with Tuberculosis—Nurses in Manhattan and vicinity are forming an auxiliary to Stony Wold Sanatorium, Lake Kashaqua, to provide care for nurses with tuberculosis. Stony Wold is an institution for the care and treatment of women and girls exclusively. It has a small endowment and is otherwise supported by patients, auxiliaries, donations, and endowed free beds. At present there are thirteen nurses in the sanatorium, only one of whom is paying full rates for her care. Miss Lillian Amelung, 598 Madison Avenue, is executive secretary of the auxiliary.

University News—The class of 1912 of the College of Physicians and Surgeons of Columbia University held its twenty-fifth reunion recently at a dinner in New York with Dr. Frank R. Mount, Portland, Ore., president of the class as toastmaster. It was reported that eighty-three of the eighty-six members of the class are living, all but one active in medical practice. Among other statistics it was reported that nineteen of the class are members of medical school faculties, fifteen hold federal, state or municipal medical offices. Members of the class are affiliated with 126 hospitals and are authors or co-authors of thirty-seven textbooks.

Smallpox on Ocean Liner—A liner carrying seventy-seven passengers and a crew of 128 was held in quarantine for six hours when it came into port from South America with a case of smallpox on board, August 19. Every one on board had been vaccinated by the ship's physician as soon as the disease was discovered and the patient had been isolated with a special steward to care for him. Passengers who had New York addresses or who planned to stay in New York were released with the understanding that they would be kept under surveillance by the health department during the period of incubation. Out of town passengers agreed to report to their local health officers. Members of the crew were not allowed to leave shore unless they could prove residence in New York. The smallpox patient, an 80-year-old man, was removed to the Kingston Avenue Hospital for Contagious Diseases.

City Ends Care of Mental Defectives—New York City officially discontinued the treatment of mentally defective children as a municipal function July 31 with the transfer of a group of eighteen from the Children's Reception Hospital to the Newark State School, Newark. The children were once inmates of the old New York City Children's Hospital on Randall's Island, which was razed to make way for the new Triborough Bridge. Some years ago an amendment to the state mental hygiene law laid responsibility for care of mental defectives on the state but because of inadequate facilities transfers from the city institution had to be made gradually. Since the old hospital was torn down, some of its inmates have been moved from place to place until the final group was taken over recently. The mental hygiene clinics at Bellevue and Kings County hospitals will function as application bureaus.

for the state institutions Admission of mental defectives from New York City to state institutions has averaged about 700 a year for the past five years, according to the department of hospitals

Typhoid on German Ocean Liner—Twenty-four members of a crew of 400 were suffering from typhoid when the Hamburg-American liner *Hansa* arrived in New York August 28 with 993 passengers Within a few hours the number of sick had increased to twenty-nine The ship was cleared at quarantine by the new system of radio pratique under which the ship's physician radios his belief that no quarantinable disease exists on board It was thought that the men were suffering from a form of gas poisoning from fumigants used before the vessel sailed from Hamburg, according to a statement from the steamship company Investigation by the U S Public Health Service officials at quarantine and by the New York City Health Department proved that the disease was typhoid As a result the steamship officials canceled the entire passenger list of 325 persons and returned to Germany with the sick members of the crew, an extra physician and a corps of nurses Meanwhile the city health department conducted an investigation of the passengers who arrived on the *Hansa* Those who lived in New York would be visited by physicians of the department to watch for indications of the disease, and health departments of other cities represented by the passenger list were to be notified, it was said Before the *Hansa* left on its return trip the fresh water tanks were emptied and refilled and the water was then tested by the city laboratories According to the *New York Times* the public health service officials removed the ship's physician, Dr Helmuth Paul Otto Grieshaber, from the list of physicians eligible for medical clearance by radio and the *Hansa* will henceforth be required to stop at quarantine for examination

OREGON

Associate Dean Appointed—Dr David W E Baird Jr, assistant clinical professor of medicine, University of Oregon School of Medicine, Portland, has been appointed associate dean to succeed the late Dr Harold B Myers Dr Baird graduated at Oregon in 1926

PENNSYLVANIA

Deaver Road—A street in Wyncote has recently been named Deaver Road in honor of the late Dr John B Deaver, Philadelphia The street was formerly known as Wyncote Road

District Meeting—The annual meeting of the Ninth Council District was held in Indiana, August 26 On the scientific program were the following speakers Drs Ford M Summerville, Oil City, on "Gallbladder Infections with Reference to the Pancreas and Heart", Hollister W Lyon, Punxsutawney, "Diagnosis and Treatment of Chronic Prostatism", and William J Armstrong, Butler, "Meningitis—Differential Diagnosis and Treatment" Drs Frederick M Jacob and Chauncey L Palmer, Pittsburgh chairmen respectively of the committees on public relations and public health legislation in the Medical Society of the State of Pennsylvania, discussed activities and plans of their committees

Philadelphia

Personal—Dr Anthony Sindoni Jr has been appointed chief of the diseases of metabolism at the Philadelphia General Hospital—Merkel Henry Jacobs, PhD, professor of general physiology at the University of Pennsylvania and director of the Marine Biological Laboratory at Woods Hole Mass, has resigned from the latter position according to *Science*

TEXAS

Personal—Dr Levi C Wayland Plamview, has been appointed health officer of Hale County, to succeed the late Dr Edgar F McClendon—Dr George M Decherd Austin was recently appointed health officer of Austin to succeed Dr Eugene O Chumene, who resigned

Society News—Drs Julius McIver and William H Potts Jr will address the Dallas County Medical Society September 23 on "Analgesia in Obstetrics" and Recent Advances in Our Knowledge of the Vitamins respectively—The annual meeting of the Texas Public Health Association will be held in Dallas at the Hotel Adolphus November 1-3 Sessions the first two days will be for laboratory workers food and drug officials, health officers, public health nurses and sanitarians The third day's program will be open to the general public—Drs Walter G Reddick and William Lee Hudson, Dallas,

addressed the Kaufman County Medical Society, Terrell, Ju 8, on "Types of Heart Failure and Their Treatment" and "Congenital Duodenal Bands" respectively—Dr Roy G Loveless, Slaton, addressed the Lubbock-Crosby Counties Medical Society, Lubbock, July 6, on eclampsia

WISCONSIN

State Medical Meeting at Milwaukee, September 15—The ninety-sixth annual meeting of the State Medical Society of Wisconsin will be held in Milwaukee September 15-17 at the Milwaukee Auditorium Headquarters will be at the Hotel Schroeder Guest speakers who will address general sessions will be

Dr Ralph A Kinsella St Louis Principles Governing Treatment of Severe Streptococcal Infections
Dr Eldridge L Elason Philadelphia Surgical Aspects of Indigestion
Dr Chevalier Jackson Philadelphia Indications for Bronchoscopy
Dr Emery A Rovenstine New York Anesthesia
Dr Cyrus C Sturgis Ann Arbor Mich Modern Methods of Treating Lobar Pneumonia
Dr Fredrick A Willius Rochester Minn Treatment of Diseases of the Heart
Dr Charles A Aldrich Winnetka Ill Growth and Development of Babies
Dr Edward L Cornell Chicago Abnormal Vaginal Discharges
Dr Vincent J O Connor Chicago Stone Impacted in the Lower Ureter
Dr William C Menninger Topeka the Rogers Memorial Lecture Psychological Factors in Medical and Surgical Conditions
Dr Robert M Grier Evanston Ill Pain Relief in Labor
Dr Edward T Evans Minneapolis The History and Application of New Advances in the Treatment of Fracture of the Neck of the Femur
Dr John H J Upham Columbus Ohio President American Medical Association The Heart of Middle Life

One general session will be devoted to a symposium on "The Family Physician—A Unit in Preventive Medicine," in which the speakers will be Drs Frederick C Rodda, Minneapolis, Jay Arthur Myers, Minneapolis, and Fred G Johnson Iron River At another session there will be a symposium on endocrinology presented by Drs Edward H Rynearson Rochester, Minn, and Elmer L Sevringhaus, Madison Several of the guest speakers already named will also address section meetings and participate in round table luncheon discussions In addition, the following will address various sections

Dr Owen H Wangenstein Minneapolis The Role of the Surgeon in the Treatment of Acute Pyogenic Infections
Dr Cecil S O'Brien Iowa City Conjunctivitis Diagnosis Etiology and Treatment
Dr Paul H Garvey Rochester N Y subject to be announced

Dr Logan Clendening, Kansas City, Mo, will be the speaker at the annual dinner at the Hotel Schroeder, Thursday evening on "The Great Centers of Medical Thought in the Past" A new feature of the meeting is a "health exhibit," prepared by the council on scientific work for inspection by the public

GENERAL

Western Ophthalmological Meeting—The fourth annual meeting of the Western Ophthalmological Society was held in Denver, July 22-23, with the following speakers, among others

Dr Roderic P O Connor San Francisco Principles of Ocular Surgery
Dr Edwin M Nehrer Salt Lake City Utah presidential address Aniridia in Five Generations
Dr Maurice E Marcove Denver Origin and Significance of Detachment Bands in the Crystalline Lens
Dr Georgiana M Dvorak Theobald Oak Park Ill Radium in Treatment of Chalazion
Dr Edward Jackson Denver Mechanics of Cataract Extraction

At an evening session July 22 the speakers included Dr Edward H Cary, Dallas, Texas, on "Did Clinical Specialization Anticipate Scientific Medicine?"

Prevalence of Infantile Paralysis—The U S Public Health Service reported that 492 cases of infantile paralysis had been reported during the week ended August 21 compared with 455 the preceding week and an average of 303 for this season, according to the *New York Times*—Three deaths have occurred in Buffalo, where eighteen cases have been reported since August 14—Newspapers report that Illinois and Chicago have the largest number of cases at any time in twenty years, 221 cases in the state this year compared with ninety-five for the corresponding period of 1936 and sixty-eight in Chicago from August 1 to 22, compared with ten in the same period of 1936—Opening of schools was delayed a week in Omaha because of sixty-three cases from May 1 to August 24—A general quarantine of children under 16 was imposed in Mansfield, Ohio, August 17, following the death of a young woman playground supervisor—Twenty four cases have recently been reported in Kansas City, Mo and five in Jackson County outside Kansas City

Southern Tuberculosis Meeting—The annual meeting of the Southern Tuberculosis Conference and the Southern Sanatorium Association will be held at the John Marshall Hotel

Richmond, Va., September 29-October 1 Among the features of the program will be a symposium on collapse therapy, with the following speakers Drs Richard H Overholt, Boston, Frank S Johns, Richmond, Paul A Turner, Louisville Ky, and Champneys H Holmes Atlanta, Ga Speakers in a symposium on nontuberculous lung conditions will be Drs Louis Hamman, Baltimore Leroy U Gardner, Saranac Lake N Y, and David T Smith, Durham N C Dr Overholt Dr Jay Arthur Myers Minneapolis, president of the National Tuberculosis Association, and Dr Edward J Murray Lexington, Ky, president of the Southern conference will speak at a public session Wednesday evening September 29 Dr Myers and Dr John Donnelly Charlotte, N C president of the sanatorium association, will be the speakers at a banquet Thursday evening

Deduction of Medical Expenses for Federal Income Tax Purposes.—On the last day of the first session of the Seventy-Fifth Congress, Senator Bone of the state of Washington introduced in the Senate a bill, S 2997, proposing in part to authorize individuals to deduct in the computation of their federal income taxes (1) any amounts, not exceeding \$250 actually paid during the taxable year for medical dental surgical or nursing treatment, or hospitalization of the taxpayer or his spouse or of any dependent for whom a credit is allowed under the income tax law, and (2) amounts paid during the taxable year for the funeral and burial of a taxpayer's spouse, or a dependent for whom a credit is allowed under the law with a proviso that no such deduction shall be allowable if at the time of the filing of the return the expense has been claimed as a deduction for estate-tax purposes While this bill was introduced too late for any action to have been taken with respect to it before the adjournment of the Congress it was referred to the Senate Committee on Finance and consideration may be given to it when the second session of the Congress meets either in special session or on Jan 3, 1938

American Hospital Association.—The thirty-ninth annual convention of the American Hospital Association will be held in Atlantic City September 13-17 There will be general sessions section meetings on group hospitalization, dietetics tuberculosis hospitals outpatient service, trustees activities, children's hospitals, nursing, construction, social service mechanical division of hospital operation, purchasing agents administration and public hospitals Among the speakers listed on the program are

- Dr Gilbert J Dalldorf Valhalla N Y Incorporation of Modern Knowledge of Nutrition into Institution Dietetics
- Dr Carl M Peterson hospital inspector American Medical Association Chicago Intern Training in the Small Hospital and Discussion of the Relationship of the Medical Specialty Boards to the Small Hospital
- Dr Robert E Plunkett Albany, N Y Sanatorium and Tuberculosis Hospital Survey of the American Medical Association
- Dr Samuel W Becker Chicago The Place of the Social Worker in the Medical Team
- Dr Benjamin P Potter Secaucus N J Present Day Concepts of a Tuberculosis Hospital
- Dr Arthur W Bingham East Orange N J The Role of the Hospital in Reducing Maternal Mortality
- Drs Charles P Major and Theodore S Wilder Philadelphia Ultra violet Light for Air Sterilization in a Ward for Infants
- Drs Mary K Bazemore Merton Station Pa, and William M McEadden Jr Philadelphia Prevention of Ward Infections in Children's Hospitals
- Dr Carl E Vohr St Louis Group Hospitalization from the Medical Man's Point of View
- Dr Joseph W Mountain U S Public Health Service Washington D C Financial Support of Nongovernment Hospitals as Revealed by the Recent Federal Business Census of Hospitals

A feature of the meeting will be clinical demonstrations of such procedures as isolation hospital technic superintendent's staff conference, court appearances technic of obtaining consent for necropsy and fire protection

International Radiology Congress in Chicago, September 13.—The fifth International Congress of Radiology will be held in Chicago at the Palmer House September 13-17 Preliminary to the congress there will be a reception to foreign guests given by the Chicago Roentgen Society Sunday afternoon September 12 at the Palmer House followed by group dinners Monday will be devoted to meetings of the international executive committee and the international radiological committee, an official luncheon for officers directors delegates and committees of the congress, and the official opening of the technical and scientific exhibits

The opening session will be held Monday evening Dr Arthur C Christie Washington D C will be installed as president of the congress by Dr Hans R Schinz, Zurich Switzerland president of the fourth international congress Addresses will be delivered by Drs William J Mayo Rochester Minn C Gösta Abraham Forssell Stockholm, Sweden Schinz and Christie

Each morning from 8 to 9 o'clock lecture courses will be offered with the following instructors

- Dr Henri Contard Paris Roentgen Therapy in Cancer
- Dr George W Holmes Boston Problems in Roentgenologic Diagnosis
- Dr Hermann Holthausen Hamburg Germany Fundamentals of Roentgen and Radium Therapy
- Dr Byrl R Kirklin Rochester Minn Roentgen Diagnosis in Gastro-Enterology
- Dr Edwin A Merritt Washington D C Special Problems of Radiation Therapy Relating Particularly to Treatment of Cancer of the Cervix and Cancer of the Breast
- Dr Merrill C Sosman Boston Diagnosis of Brain Lesions
- James L Weatherwax Philadelphia Elementary Physics of Radiation

These courses will be given in English and will be open to physicians other than radiologists for a small fee

General sessions will be held each morning Among the speakers will be

- Dr Forssell The Role of the Autonomus Movements of the Gastro-Intestinal Mucous Membrane in Digestion
- Dr Gian G Palmieri Bologna Italy Radiologic Evaluation of the Size and Form of the Heart
- Dr Arthur Schuller Vienna Cerebral Cystography and Cisternography
- Dr Rene Gilbert Geneva Switzerland Treatment of Hodgkin's Disease by Radiotherapy
- Sir George Lenthal Cheatle London and Dr Max Cutler Chicago Racial Variations in the Incidence of Carcinoma
- Dr Russell J Reynolds London Cineradiography by the Indirect Method
- William D Coolidge Ph D Schenectady N Y Production of X Rays of Very Short Wavelength
- Robert J Van de Graaff Ph D Cambridge Mass Production of Penetrating Radiations by Means of Electrostatic Generators
- Dr Yser Solomon Paris France Recording the Quantity of Irradiation in Roentgen and Radium Therapy in R Units

Afternoon sessions will be divided into sections Three are on roentgen diagnosis with Drs James T Case Chicago Charles A Waters Baltimore, and Frederick M Hodges Richmond Va, as chairmen Three are on radiotherapy with the following chairmen Drs Albert Soiland Los Angeles Bernard P Widmann, Philadelphia and Arthur U Desjardins Rochester, Minn Gioacchino Failla D Sc, New York will be chairman of the section on radiophysics Dr Francis Carter Wood New York, of the section on radiobiology, and Dr Norman E Titus, New York, the section on electrolgy and light therapy

The national organizations in radiology in the United States will sponsor meetings for the evenings of the congress The American College of Radiology will have a dinner and convocation Monday evening before the opening general session Tuesday evening the American Radium Society will present the Janeway Lecture to be delivered by Dr Douglas Quick New York on Carcinoma of the Larynx Wednesday evening Dr George E Pfahler, Philadelphia, will give the Caldwell Lecture of the American Roentgen Ray Society on Treatment of Carcinoma of the Breast The Radiological Society of North America will sponsor the program for Thursday evening presenting the Carman Lecture, by Dr George W Holmes Boston on The Development of Postgraduate Teaching in Radiology Friday evening there will be a banquet for the entire congress with entertainment

A feature of the congress will be the simultaneous projection of pictures and text of all papers on screens in English, French and German

In addition to Dr Christie officers of the congress include Dr Benjamin H Orndoff Chicago general secretary Drs George E Pfahler Philadelphia and James Ewing New York and William D Coolidge Ph D Schenectady honorary vice presidents Information concerning the congress may be obtained from Dr Orndoff, 2561 North Clark Street, Chicago telephone Lincoln 0724

CANADA

Poliomyelitis in Ontario.—Between 350 and 400 cases of poliomyelitis have been reported in an epidemic in Ontario within the past three weeks it was reported August 29 Two thirds of the cases and nine deaths of twenty reported for the whole province have been in Toronto and the surrounding district It was announced August 23 that schools would not reopen until September 7, instead of September 1

CORRECTION

Bismuth Subsalicylate for Flat Warts.—In Queries and Minor Notes in THE JOURNAL August 21 page 610 the dose of bismuth subsalicylate used in the treatment of flat warts by intramuscular injection was given as 15 Gm and 2 Gm which was an error The dosage should have been indicated as the same amount in grams

Nonvenereal Syphilis

At the Royal Society of Tropical Medicine, Dr E H Hudson described a form of nonvenereal syphilis which is epidemic among the seminomad villagers of the middle Euphrates and is called bejel. Sexual promiscuity does not exist and the disease is usually acquired in childhood by contagion under the conditions in which a dirty, careless, poorly clad, closely huddled people live. Sixty per cent of adults acquire it in childhood and a majority of the remainder from children, often their own, later in life. Less than 1 per cent of adults acquire the disease in sexual intercourse. Of the adult population 75 per cent stated that they had had bejel, and that percentage gave positive serologic reactions. Surveys showed that 90 per cent were affected. That bejel is syphilis was shown by the early and late lesions, the uniform presence of an organism indistinguishable from *Spirochaeta pallida*, the positive precipitation and complement fixation reactions, and the response to treatment. Bejel resembles yaws in its nonvenereal acquisition in childhood, its community-wide dissemination, the morphology of the skin lesions, the predilection for the skin and bones, the relative escape of the eyes and the cardiovascular and nervous systems, and in the presence of gangosa, juxta-articular nodules and patchy depigmentations. Both diseases tend to disappear under civilizing influences. On the other hand, bejel resembles syphilis in its constant involvement of mucous membranes, in the alopecia, and in its extratropical location. It can be argued that the three forms of spirochetosis have an identical etiologic basis and that their differences can be explained on epidemiologic grounds if the influence of all environmental factors is known. Bejel is syphilis in its "lowest terms," the archetype of this spirochetosis. That syphilis has ceased to be a childhood disease and assumed a venereal character is not due to any tropism toward the genitalia but to the restriction of the bodily contact for its communication to sexual intercourse by the conditions of civilization. The existence of bejel is also strong proof of the identity of yaws and syphilis.

Persecuted Scientists and the Society for Their Protection

When the Academic Assistance Council was formed in 1933 to help the scientists and scholars expelled from their posts on the continent in consequence of political persecution, it was hoped that the need for such an organization would be only temporary. Unfortunately this hope has not been realized and in 1936 it was decided to continue the work of the council by means of a permanent body, the Society for the Protection of Science and Learning. The great body of the refugees come from Germany but political persecution on a much smaller scale is not unknown in some other countries—Austria, Russia, Italy, Spain and Portugal. Thus under our boasted civilization of the twentieth century it is only the smaller part of the European continent—the democratic countries of France, Netherlands, Scandinavia and Switzerland—that are free from this stain. In his book "Human History" the anatomist and anthropologist Sir Grafton Elliot Smith wrote "For the first thirty centuries of its career civilization was concerned with building up the state system. Then in the fifth century B C the Ionians opened up a new chapter in human history by removing the shackles. They showed that man was free to think." When he wrote these words some years ago Elliot Smith could not have foreseen that he would live to see the day when he could have added the postscript. This achievement of the Greeks was lost over a large part of Europe in the twentieth century.

According to the last report of the Society for the Protection of Science and Learning the total number of scientists and scholars displaced from German universities is about 1,600, of whom 70 per cent were married. Of about 800 scientists and scholars who have left Germany 464 have been permanently reestablished and 311 temporarily placed. These have been distributed in forty-three countries, of which Great Britain, with 228, and the United States take the lead. The civil war in Spain has led to the displacement of sixty scholars, who may never be able to return to their country. The society maintains a central bureau in London. It makes emergency grants to those who have secured what may become permanent employment and allots a limited number of research fellowships to those of unusual ability. It has assisted those engaged in all branches of science, but the majority are workers in medicine, chemistry, physics and economics.

The Insufficient Consumption of Milk

The desirable amount of milk in the diet of children has been given as from 1 to 2 pints daily, for nursing mothers about 2 pints, and for adults about half a pint. Our national consumption is not half that amount. An organization called the Children's Minimum Council, of which our greatest authority on diet, Sir Frederick Gowland Hopkins, is chairman and which has the support of twenty-six national organizations concerned with maternity and child welfare, has submitted to the Ministry of Health a plan for the provision of cheap milk for mothers and children under school age. The council points out that at present prices the milk for a family of three children, a mother again pregnant and a father would cost about \$3 a week—a usually impossible expenditure for a working class family. A survey was made of 587 working class households in Oxford not confined to the working class. In the families in which there were no children the weekly consumption of milk per head was 46 pints and the amount steadily diminished with the number of children until with six or more it became 185 pints. In Great Britain milk is much dearer than in any other country in northwestern Europe or in the United States. The council proposes that milk should be purchasable at 3 cents a pint for all expectant and nursing mothers and children of school age. At present it costs about 6 cents a pint, though it is sold at 11 cents a gallon for manufacturing purposes. The difference is partly due to the fact that the milk industry is a monopoly and prices are controlled by the Milk Marketing Board, a body appointed by the government. It is argued that some of this cheap milk should be diverted for the needs of mothers and children. This would involve a subsidy by the government.

Homosexuality and Divorce

In the House of Lords Lord Dawson (president of the Royal College of Surgeons) moved an amendment to the marriage bill providing that a divorce might be granted on the ground that since the marriage the respondent had been guilty of homosexuality. He said that homosexuality was now looked on as a pathologic condition. He was not at all sure that in the future it might not be regarded as a deficiency disease, and although it was true that the law must take cognizance of homosexuality and punish it in order to act as a preventive to potential offenders, the more reasonable view was being adopted gradually that it had, at any rate, one foot in the realm of disease and was not wholly in the realm of crime. For the purposes of the bill it would be entirely wrong to use any word that would confine homosexuality to one sex. It was time that there was equality of treatment between men and women. This offense was quite compatible with excellent qualities of mind and character. But such people would frustrate the purpose for which marriage existed and it would be a grave injustice to recognize any marriage in which homosexuality turned out to be existent in either one of the parties. When discovered, it ought to be a ground for divorce. The amendment was opposed by Lord

Atkin (lawyer) He did not think that these cases were of the nature of disease In his experience they were the result of wicked impulses which were susceptible of being controlled They did not appear to him to be of the nature of a permanent infirmity that was always likely to affect the married life The real answer probably at the present moment was that the subject required careful examination The amendment was defeated

\$18,000 Damages Assessed for Puerperal Fever

A woman was admitted to a cottage hospital for her confinement. After the birth of the child she was removed from the maternity ward to the general ward There she contracted puerperal fever from a woman who was found later to be suffering from this disease She brought an action for negligence against the hospital and the physician who attended her there In giving judgment Mr Justice Singleton said that the plaintiff was perfectly well when she entered the hospital and that one of its rules was that no infectious case was to be kept there The hospital authorities ought to have known that the hospital was dangerous but no warning was given to the plaintiff They failed in their duty when they placed her in a ward with a gravely suspicious case The physician was not responsible for her admission, but he had in the hospital a gravely suspicious case He ought to have isolated it in order to prevent the infection from spreading When he found that the plaintiff had been put in the same ward as that case he ought to have removed her and done everything to prevent her becoming infected He did nothing He did not protest to the matron nor did he give any warning of the danger of infection In that respect he failed in his duty to the plaintiff She was now crippled in the hips, one shoulder and one wrist No damages could compensate her for the pain and suffering which she had undergone The judge awarded \$18,000 damages against the hospital and the physician

Osteopsathyrosis as a Familial Disorder

The symptom triad bluish color of the sclerae, bone fragility in infancy and deafness, as first described by Lobstein, in its familial and hereditary aspects, was the subject of a paper presented at the June 8 meeting of the Academie de Paris by Carriere, Delannoy and Huriez They reported the results of the study of five families, in which thirty-four of eighty-six members presented symptoms of osteopsathyrosis over a period of five generations The disease is distinctly hereditary and is directly transmitted on both the paternal and maternal sides, attacking both boys and girls It does not follow the mendelian laws The principal clinical feature is the bluish color of the sclerae, being found in thirty-three of the thirty-four cases In order, however, to make a diagnosis of osteopsathyrosis the color ought to attain a certain intensity, present a familial character and be associated in at least one member of the family with osseous or auditory stigmas Although the bone fragility is the clinical feature which most often directs attention to the presence of the syndrome, it is inconstant Only seven patients had spontaneous fractures In two of the families that were studied, such an occurrence was never found by the authors The term "glass man, as exemplified by the multiplicity of the fractures, was applicable to only five cases The possibility of fractures of the spine subsequent to slight injury has not been sufficiently taken into consideration by clinicians Bone deformity, especially of the skull, is frequent, without any history of injury Kyphoscoliosis was found in five cases In general, bone development is inadequate and such a degree of looseness of the joints as to be followed by dislocations and sprains was noted in seven cases Endocrine dysfunction was observed in all the families It has been claimed that a hypo-

parathyroidism is responsible for this syndrome, but the authors found that the calcium content of the blood was usually higher than normal, especially in patients with a history of recent fractures Hypoparathyroid grafts, according to Hansen, have not been followed by any improvement and the injection of parathyroid extract has resulted in an exaggeration of the symptoms Parathyroidectomy was performed in two severe cases So far, the blood calcium content has been lowered but it is too early to evaluate the end results Stigmas of hereditary syphilis are frequently found, hence antisyphilitic treatment should be given as a routine measure It may not have much effect on an outspoken syndrome, but it acts favorably on future generations

Diagnosis of Hydatidiform Mole

At a meeting of the Academie de medecine, Brindeau and Hinglais of Paris presented a paper in which their method of diagnosis of the early stages of malignant deciduoma *in situ*, the fifth week after the miscarriage, was described It depends on the content of gonadotropic substance in the blood serum The normal varies from 1,000 to 15,000 units per thousand cubic centimeters of serum During the development of a hydatidiform mole, as well as in pernicious vomiting of pregnancy, it rises to 100,000 units or even higher A curve was shown representing the progressive diminution of the content of gonadotropic substance in an uncomplicated case of miscarriage due to hydatidiform mole A second curve was shown to illustrate the value of the Brindeau-Hinglais method The curve dropped to 2,000 units the tenth day after the miscarriage and remained at this point until the thirty-third day The curve then showed a sharp rise on the thirty-fifth day to more than 200,000 units, indicating acute malignant changes The diagnosis was verified, following hysterectomy, and the curve approached the normal ten days after the operation Seventy-two cases of miscarriage due to hydatidiform mole were observed at the Tarnier clinic Tests at frequent intervals by this method resulted in early diagnosis, followed by hysterectomy, in eight of the seventy-two cases

Causes of Regional Variations of Natality

At the June 8 meeting of the Academie de medecine, Dr Godlewski said that the natality rate is highest in communities whose population does not vary as the result of influx of foreigners or emigration of the members of the older families Hence the natality rate does not change in the mountainous portions of France The number of births among those who have come from foreign countries since the war has been disappointing Denatality is more or less generalized here, and the few centers of supernatality do not compensate for the decrease in number of births Concomitant with the steady migration from smaller to larger centers of population, a drop in the natality rate has been noted, especially since the crisis The chief causes of the denatality are the widespread use of contraceptive measures and the increasing number of abortions, which together are responsible in some regions for a 25 per cent decrease in the natality rate Tuberculosis in young girls and venereal diseases, especially gonorrhea, play a secondary part Fortunately, the struggle against infant mortality has partially offset the denatality To combat the latter it has been proposed that financial aid should be given to every family head and a diminution of the inheritance taxes, which at present are high in France In the discussion, Dr Sireday stated that the leniency shown by both judges and juries toward professional abortionists was a great handicap to the question of having a larger number of births in France

Death of the Ophthalmologist Felix de Lapersonne

One of the leading French ophthalmologists, Prof Felix de Lapersonne, has died here at the age of 84 He succeeded Professeur Panas as head of this department in 1901 at the Faculté de medecine His clinics became popular and many

foreign specialists admired his teaching methods. During the World War he took charge of the ophthalmologic service and organized centers all over France. He was elected a fellow of the Academy of Medicine shortly after the close of the war and became its president in 1931. As one of the editorial board of the *Presse medicale*, the weekly journal with the largest circulation in France, his service in keeping up the high standard of this publication was an important contribution to medical journalism. As head of the ophthalmologic clinic of one of the largest Paris hospitals, his influence on the progress of this specialty in the training of younger men has been extensive.

French ophthalmology loses its most distinguished representative in the death of Professor de Lapersonne.

Congress of Otorhinolaryngologists

This year's Congress of German Otorhinolaryngologists met at Cassel. The main topic was "Suppurations of the Pyramidal Cells." Prof. Otto Mayer of Vienna delivered the principal lecture. In recent years, he said, scientists of all lands have given more consideration to suppurations of the pyramidal cells. These disturbances, it has been determined, can be responsible for many intracranial complications. In some cases after a thoroughgoing removal of the mastoid cells (mastoidectomy) the surgeon believes that the focus of infection has been completely done away with until he is confronted with a manifestation of these sequels. In cases that terminated fatally despite a carefully performed operation, microscopic postmortem examination of the pars petrosa of the temporal bone disclosed foci of inflammation in the areas anterior to the semicircular canal, and because of the location of these foci they had not come within the scope of the intervention. A study of pyramidal cell suppuration is of especial importance as most of the present day fatal cases of meningitis following acute otitis media are based on purulent foci in the pars petrosa. The pyramidal apex syndrome as a clinical sign of the disorder was established by Gradenigo in 1904. This syndrome is characterized by an acute otitis media followed by violent temporoparietal pain and abductor paralysis on the affected side. Investigation of the way in which the inflammation reaches the pyramidal apex from the middle ear discloses the principal etiologic factor as a more or less pronounced pneumatization of the pars petrosa. Various types of pneumatization may be differentiated. All cell tracks can lead to the apex. The following should be kept in mind with respect to pyramidal cell suppuration. It may form a circumscribed focus, spread over the entire surface of the labyrinth or lead to an abscess, which may be either closed and hence incapable of discharging into the spaces of the middle ear or open to the extent that some influx of pus into the middle ear is possible. Abscesses may also occur in various cell tracks and, finally, pyramidal cell infection may assume the character of a proliferating inflammation and run its course without much suppuration. But if the suppurative process is sufficiently active it can perforate the posterior or middle cranial fossa, the labyrinth, the carotid canal, the foramen lacerum posterius or the pharynx. It is essentially a more favorable sign if perforation takes place in the last named region forming a retropharyngeal abscess. X-ray visualization is a valuable diagnostic aid. Operative treatment is usually indicated. Cases that come early to diagnosis are treated conservatively (by paracentesis), since in these cases the prognosis is favorable. Even cases in which the suppuration is of long standing may be cured, mastoidectomy with a thoroughgoing extirpation of the cells and above all those proximate to the labyrinth is here indicated. If sup-

puration persists, radical operation should follow. Only if the foregoing safe and tried procedures fail to produce results should one look for a focus in the apex.

Professor Zange of Jena has found that pyramidal cell suppuration and related processes which appear in the region of the inner ear, in the pars petrosa or in the adjacent meningeal spaces are capable of involving numerous other cerebral nerves. Most prominent among these nervous diseases are labyrinthine-vestibular disorders, namely, disturbances of the equilibrium, which, because of their peculiar character and the preservation of peripheral irritability of the labyrinth, can today be with certainty distinguished from labyrinthine inflammations.

Some other data of interest were contributed in the discussion. Report was made of the healing of a pyramidal abscess that had erupted spontaneously into the sphenoidal sinus. Similar conditions may also heal spontaneously, especially in child patients. But, on the other hand, there are the hopeless cases, especially the rapidly advancing osteomyelites. The latter are particularly apt to prove fatal if combined with the otitis of nurslings.

The Treatment of Epidemic Meningitis

Professor Bessau, ordinarius in pediatrics at Berlin, recently discussed epidemic cerebrospinal meningitis before the Berlin Society of Pediatrics. In recent years a slight increase in the incidence has been remarked. Diagnosis is established by lumbar puncture. As to therapy, antimeningococcus serum has been unsatisfactory. On the other hand it has been noted that exanthems, as in measles, for example, exert a favorable effect on meningitis. The serum exanthem appears likewise to exert a favorable effect on the course of the disease. Bessau treated three children with antimeningococcus serum and then induced a serum sickness by means of diphtheria sheep serum. Two of the children died, the third survived with an optic atrophy. Four children were inoculated with sheep serum alone from two to three times. A definite serum sickness was thus induced in all four patients. The effect was extremely favorable. Improvement was observed before the appearance of the serum exanthem and allergic symptoms. In the case of a 5 months old nursing who had received 80 cc of sheep serum in two days, a startling improvement appeared within five days, especially as evidenced in the cerebrospinal fluid. One case in which recidivation had followed the beginning of improvement came to prompt recovery after intramuscular administration of protosil. Another child was treated with immunized blood; this blood was abstracted from the patient's father, who had been immunized with the meningococcus strain of the sick child. Bessau believes that the use of specific serum should be abandoned in favor of the artificial production of an exanthem by means of sheep serum.

Care of Nurslings and Infants

Not long ago the national minister of the interior issued regulations designed to effect more satisfactory cooperation between the health officers of particular districts and cities and the National Socialistic bureau of public welfare. The new rules stipulate that health supervision and medical advice for mothers, nurslings and young children must be regarded as a principal function of the public consultative centers maintained by local health departments. The National Socialistic public welfare bureau is to expand the work of its consultation centers within the framework of the already extant "Mother and Child" Auxiliary by a program of dietary and economic assistance. It is thought that these guiding principles will establish a suitable foundation for collaboration of the party bureau and the local boards in the fight against infant mortality. As a result welfare work among mothers and children should become more fully standardized in all parts of the country. In carrying forward this large scale program of infant welfare the local

health bureaus will make use of the existing welfare and consultation centers maintained by the central party bureau. A comprehensive, finely meshed network of consultation centers is being evolved so that in the future no mother will forego necessary visits to the physician because of too great distances between the consulting center and her home. If need arises, traveling medical consultative centers will be organized.

Fertility of Parents of the Feeble-minded

Dr C Brugger has undertaken an investigation of the interrelation of hereditary endowment and fertility. He was especially anxious to apply the German criteria to a nation whose cultural, social and economic complexion differed from that of the reich. The survey material consisted of the families of (1) 611 students in the realgymnasiums, namely, secondary schools offering generalized academic courses; (2) 758 pupils in the common schools; and (3) 429 congenitally feeble-minded pupils of the special schools for backward children, all at Basel. Any pupil whose intelligence quotient was below 0.85 was classed as feeble-minded. All feeble-mindedness was considered as inherited if no proof of an exogenous production of the deficiency could be adduced. The statistical material dealt only with legitimate offspring and with families in which the eldest child had been born prior to 1926, that is, families which represented a marriage that had already endured for ten years. The children were grouped according to the year of birth: group 1 comprised all children born prior to 1911, group 2 all those born in the years from 1911 to 1920 and group 3 those born between 1921 and 1925. On this basis no further offspring could be expected from the parents of group 1 and

Average Number of Children Born to Each Couple Studied

Group	Real gymnasium Students	Common School Students	Combined	Feeble minded
1	3.2	3.4	3.3	5.7
2	2.1	2.2	2.2	3.2
3	1.7	1.7	1.7	2.3

only a few additional offspring might be anticipated from the parents of group 2. The accompanying table indicates the average number of children born to each married couple studied.

With regard to the occupation of the parents, merchants and manufacturers were most prominent (19.9 per cent) among the parents of realgymnasium students. Other callings were represented in fairly equal numbers among this parent group excepting that only 0.3 per cent were of the working class. In the parentage of group 2 (the common school students), various social classes were represented as follows: artisans 45.2 per cent, laborers 14.9, minor civil servants 14.5. The parents of the feeble-minded pupils were found to be in great measure of the employed artisan class (46.9 per cent) and of the unskilled laborer class (41.1 per cent). The representation of the minor civil servant class (4.6 per cent) and of the commercial white collar class (4.4 per cent) was much smaller and that of the independent artisans and tradespeople (2.9 per cent) even less. A further classification revealed that the differences in the number of offspring in particular social strata are much fewer than differences between the parents of normal and feeble-minded children within the same class of society. Brugger came to the conclusion that it is not the social milieu but the quality of hereditary endowment that is the decisive element in the restriction or lack of restriction of the number of offspring by a married pair.

International Congress of the Therapeutic Union

The Union Therapeutique, founded in Paris in 1934, held its first international congress at Berne recently under the presidency of Prof. Emil Bûrgi, pharmacologist of Berne. Dr. Toni Gordonoff served as secretary general. More than 400 physicians from many different countries were present. The congress was officially opened by Federal Councillor Etter on behalf of the Swiss government. Hans Horst Meyer of Vienna sent a message on "Experimentation and the Clinic," which was read by his pupil and successor E. P. Pick. Gustav von Bergmann, Berlin clinician, discussed the pathology of arteriosclerosis and Laubry of Paris read a comprehensive discussion on treatment. Max Bürger of Bonn discussed senile alterations of the aorta, and Leriche, Strasbourg surgeon, reported his investigations of surgical treatment of vascular disorders. Walther Frey, Berne clinician, discussed chemical regeneration of tissues. These exchanges of opinion amply demonstrated the need for more frequent authoritative discussions of the arteriosclerosis problem. P. Martini of Bonn, in a paper on clinical studies of the therapy of hypertension, furnished several illustrations of the prevalent attitude of reserved judgment toward much that is published with respect to vascular therapeutics. He pointed out that, if hypertension is subjected to a course of therapy from which medication with many numerous and much touted specifics is omitted but which in every other respect is correct and purposeful, the disorder will subside in the same way, within the same period of time and in equal measure as when the so-called specifics are employed. Handovsky and Goormaghtigh, both of Ghent, discussed the interesting interrelation of the thyroid body, arteriosclerosis and vitamin D.

Highly informative was the discussion of narcosis. De Quervain, the Berne surgeon, introduced this topic in a lecture which weighed the old against the new in a circumspect and helpful manner. Bouckaert of Ghent exhibited a film on the revivification of the higher centers following acute anemia. Wildbolz of Berne spoke on the operative treatment of prostatic hypertrophy. Bickel of Geneva spoke on the role of the hormones in cardiovascular therapy. Guggisberg of Berne discussed the importance of endocrine preparations, calcium and vitamin C for the medicinal therapy of functional uterine hemorrhages. Asher of Berne reported recent experiments on the pharmacodynamics of the resistance of the central nervous system to lack of oxygen. Paul Wolff of Geneva spoke on the problems of narcotism with particular reference to codeine. The program and the excellent organization caused the participants to feel that the congress had been a complete success.

Lausanne University's Jubilee

In June Lausanne University celebrated its quindicentennial. The institution traces its origin to the Akademie founded by the Bernese in the year 1537. The government of Berne which introduced the Protestant Reformation to this region envisaged a school at Lausanne wherein the promulgators of the new doctrine would receive training. During the nineteenth century the Akademie underwent a particularly drastic reorganization. Lausanne University maintains many international contacts. It is much beloved by students from Germanic Switzerland. The medical faculty is excellent. It boasts many illustrious names among its membership.

Prof. Eugen Bleuler 80 Years Old

Prof. Eugen Bleuler, former professor of psychiatry at Zurich University, recently completed his eightieth year. Especially by means of that research which found expression in his monograph (1911) on the group of disorders first designated by him the schizophrenias, Bleuler has stimulated psychiatric research and practice the world over. His textbook of psychiatry is widely used and has appeared in many editions since 1916. Bleuler is a leading representative of the so-called psychologic

trend in the treatment of mental disease, a movement which has furthered the understanding of previously incomprehensible psychic manifestations and evolved a systematized psychotherapy of the mental patient. Like his equally illustrious predecessor at Zurich, Auguste Forel, Bleuler has sought to serve medical science as a whole. In this connection his book "Autistic-Undisciplined Thought in Medicine" (1911) deserves particular mention, as this work exerted an enormous influence on the philosophy of the trained physician.

The Campaign Against Infant Morbidity and Mortality in Switzerland

The accompanying table indicates the decline in infant mortality in Switzerland. In spite of the great increase in population, child mortality has fallen to one fifth of what it was in 1876. Welfare services for both healthy and sick children have been extensively organized in recent decades. In Switzerland such service is administered by the cantonal governments. The canton of Vaud, for example, of which Lausanne is the capital, expends yearly more than 2,500,000 Swiss francs for child and

Infant Mortality in Switzerland

Year	Deaths of Children Aged from 0 to 14 Years	Total Population (in Round Numbers)
1876	23,628	2,700,000
1890	19,327	3,000,000
1900	20,495	3,300,000
1910	14,920	3,750,000
1922	8,142	3,890,000
1934	5,044	4,100,000

infant welfare services. Thus, in a population of approximately 332,000 there is a per capita expenditure of 37 Swiss francs. The Lausanne Children's Clinic is beautifully situated on high ground 600 meters above the city and thus enjoys the most favorable climatic condition obtainable. To this model institution there has recently been added a spacious new ward for nurslings, the Nestle-Saal, which is equipped with sixteen glass cubicles for isolation purposes. The clinic is under the direction of Prof. Jules Taillens.

The Inheritance of Endemic Goiter

Dr. J. Eugster of Zurich has investigated the problem of the heritability of endemic goiter by studying a small goiter-free district in comparison to regions in which the disease is endemic. Thorough investigation of family histories within the areas of endemic goiter and of persons emigrating from these areas, together with the research on 524 sets of twins, formed the basis for his investigations. He attaches special value to the significance of prolonged observations on individuals. It was established that in enzygotic twins the greatest variations in the course of the goiter appeared if discordant conditions had already been observed in this respect at birth, whereas in dizygotic twins the traits frequently consisted in various temporary manifestations of goiter by both twins of a pair.

The most important fact elicited by the investigation was that the difference between enzygotic and dizygotic twins lay within the limits of statistical error, given the same environmental surroundings. On the other hand, manifest concordance and manifest discordance followed in enzygotic and dizygotic twins with a ratio of 4 to 3. This observation had its foundation in the disparate conduct of dizygotic twins with respect to the localization and pathologic type of the goiter. Eugster concludes on the basis of his investigations that research on twins offers an additional proof of the great preponderance of environmental influence. Moreover, the results indicate that the usual question, "Is disease inheritable?" should be modified to express the question of whether and to what extent heredity is a pathogenic factor. In endemic goiter a hereditary predisposition is not to be sought in a varied suscep-

tibility within the same sex but is expressed both in the type of course assumed by the disease and in the localization and pathologic-anatomic form. A particular trait is not inherited but is rather an aggregate of reaction possibilities. The sexual predisposition at puberty may likewise be legitimately regarded as indirectly conditioned by heredity.

Prof. Otto Naegeli Has Retired

Prof. Otto Naegeli of Zurich University has retired because of ill health. Naegeli's activities are inseparably linked with the development of hematopathology and of constitutional studies. Hematologic diagnostic methods, leukemia and pseudo-leukemia are but a few of the subjects that he has discussed in his numerous contributions to the literature. Prof. Wilhelm Löffler, erstwhile director of the medical polyclinic, has been appointed to succeed Professor Naegeli.

Dr. Alfred Jaquet Is Dead

Dr. Alfred Jaquet, former professor of pharmacology, died at Basle, recently, at the age of 73. As a research scholar and as a man he had played a distinguished part within his special field and exerted influence far beyond the confines of his own university. Jaquet had received an excellent training in physiology and physiologic chemistry at Basle under Miescher and Bunge, and in pharmacology at Strasbourg under Schmiedeberg. While Jaquet was still an assistant to the last named, his discovery of a respiratory ferment in animal tissue was made, which came to be a point of departure for present day knowledge of cellular metabolism. Intensive study of the regulation of respiration in the blood led Jaquet to advance, among other things, the concept, generally applied today, of an "alkali reserve" in the blood. Further investigations undertaken with collaborators dealt with the physiologic effect of high altitudes. During his many years' service as assistant at the medical clinic, Jaquet obtained great insight into the interrelation of laboratory and clinic. An apparatus for the examination of the respiratory metabolism was invented by him and was known by his name. The metabolism of obesity, the relationship between muscular work and cardiac action, the physical therapy of circulatory disturbances are only a few of the numerous topics that have been investigated by Jaquet. He devised a recording apparatus for the venous and cardiac impulse. During his professorship in pharmacology, Jaquet kept in contact with clinical medicine—partly by consultations and partly through the sanatorium founded and directed by him. Jaquet was the author of various books, in his last, "La médecine qui guerit et la médecine qui tue" (medicine that cures and medicine that kills), he criticized unmercifully certain dangerous and uncertain medical practices.

Marriages

- EDWARD FULLER STANTON, New York, to Miss Margaret Gilmore Pendleton of Portland, Ore., June 19.
GEORGE H. STEIN, Harrisburg, Pa., to Miss Elizabeth Wheelock Doughton of Philadelphia, June 16.
WILLIAM JERVEY RAVENEL, Charleston, S. C., to Miss Kathryn Geer Martin of Anderson, June 19.
LEE RHODES REID, Norwich, Conn., to Miss Augusta Blanche Wein of Philadelphia, May 28.
JACOB HARRISON SHUFORD, Hickory, N. C., to Miss Roberta Fraley of Statesville, June 25.
WILBERT KENNETH ROGERS to Miss Mary C. Benton, both of Loris, S. C., in June.
EUGENE E. RAYMOND to Miss Marie Brady, both of Johnstown, Pa., June 26.
WILLIAM F. SEIFERT to Miss Kathleen Lewis, both of Chicago, in June.
HERMAN A. STRAUSS to Miss Jean Heller, both of Chicago, August 2.

Deaths

George H. Simmons, Editor and General Manager Emeritus of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION, died September 1, in St. Luke's Hospital, Chicago. Dr. Simmons was born in Moreton, England, Jan. 2, 1852. He came to the United States in 1870 and studied at Tabor College in Iowa in 1871 and 1872 and at the University of Nebraska from 1872 to 1876. He received his M.D. degree from the Hahnemann Medical College, Chicago, in 1882 and was awarded the M.D. degree by Rush Medical College following additional study, in 1892. In 1884, previous to his study at Rush Medical College, he served in the Rotunda Hospital in Dublin. From 1884 to 1899 he practiced medicine in Lincoln, Neb. In 1896 he established the *Western Medical Review*, acting as its editor and from 1895 to 1899 he was secretary of the Nebraska State Medical Society and also secretary of the Western Surgical and Gynecological Society. During this early period of his development he gave indications of the editorial genius which was later to bring him world-wide fame. While a freshman in the University of Nebraska he won an important prize for an essay on the sheep industry. At this time he was acting editor of the *Nebraska Farmer*, assistant city editor of the *Nebraska State Journal* and field correspondent of the *Omaha Republican* and the *Kansas City Journal*. With these odd jobs he aided in paying his way through the university and the medical school, and he developed a taste for the use of printers' ink which followed him throughout his life.

In Lincoln, Neb., he became known as a leader in reform movements. At one time he led an attack to take the government of Lincoln out of the hands of the machine politicians and to restore it to the people. A resolution adopted by the chamber of commerce of Lincoln indicated the willingness of the city fathers to admit the debt of that city to Dr. George H. Simmons for much of its political cleanliness and financial soundness.

In 1899, when the Board of Trustees of the American Medical Association was in search of a secretary for the organization and an editor for its periodicals, a number of leading figures in the medical literary and political world were given consideration. They appeared before the Board of Trustees, many of them with strong endorsements. After long consideration the Board of Trustees chose Dr. George H. Simmons for the position of General Secretary, which he filled from 1899 to 1911, and of editor, which he occupied until 1924. In 1901 he became also General Manager. Before its reorganization in 1901 the American Medical Association was not a truly representative body, and the method of administration of its professional affairs and its business were, to say the least,

disorganized. When Dr. Simmons became Secretary in 1899 he initiated the movement which led to the appointment of a committee, of which Dr. J. N. McCormack of Kentucky was chairman and he secretary, to consider ways and means of reorganization. At the meeting of the Association in St. Paul in 1901 the general principles and policies outlined in the Constitution and By-Laws presented by that committee were adopted. The present plan of organization of the American Medical Association is largely due to the work of that committee.

THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION was established in 1883. When Dr. Simmons took over the editorial supervision and management, its total subscription list was approximately ten thousand. From that time it showed con-

tinuous improvement. Furthermore, under his leadership it became a significant weapon in the initiation and progress of great movements for the advancement of medical education and medical science. In 1901 THE JOURNAL began the annual publication of information concerning the medical schools of the country. In 1903 it undertook publication of the results of the examinations of graduates in medicine for licensure by state examining boards. The next step was the organization of the Council on Medical Education and Hospitals in 1905. At the same time the Council on Pharmacy and Chemistry was developed and in association with it the chemical laboratory and the Department of Propaganda for Reform, which eventually became the Bureau of Investigation. Thereafter came other councils and departments, which were logically an outgrowth of the developments that have been mentioned. In the field of publication THE JOURNAL was supplemented by the American Medical Directory, which was an outgrowth of the Biographic Department, the various *Archives of Internal Medicine*, *Neurology and Psychiatry*, *Dermatology* and *Syphilology* and of *Surgery*, the *American Journal of Diseases of Children* and many other publications. It occurred to Dr. Simmons to begin publication of

GEORGE H. SIMMONS, M.D.
1852-1937

a quarterly cumulative index of leading medical publications as a means of providing physicians with up to the minute references to medical periodical literature in an easily accessible form. The success of this publication was so great that it eventually was combined with the *Index Medicus* into the *Quarterly Cumulative Index Medicus Hygeia*. Too was initiated under the leadership of Dr. Simmons as General Manager.

To tell the story of the services of Dr. Simmons in the period from 1899 to 1924 is in fact, to tell the history of the American Medical Association in that period.

In 1908 he was commissioned a First Lieutenant in the Medical Reserve Corps of the United States Army, in 1917 when the United States entered the war he was made Major in the Medical Reserve Corps and served diligently in the Personnel Division. In 1921 by order of President Harding he was awarded the Distinguished Service Medal.

As an editor Dr George H Simmons was alert and fearless. His attacks on quackery and fraud in the field of medicine brought on his unwearied head and shoulders the counter-attacks of those who saw their unscrupulous exploitations exposed and their incomes discontinued. It was his policy never to reply to any of the personal attacks made on him in the course of his service. Innumerable medical writers would testify to the manner in which he devoted himself personally to the education of younger men in editorial technique. His personal writings were few, but much of what he wrote and developed appeared anonymously in the pages of *THE JOURNAL*. His published papers include, however, one on medical education and preliminary requirements, which appeared in *THE JOURNAL* in 1904, one on the American Medical Association, published in *THE JOURNAL*, June 2, 1906, one on the commercial domination of therapeutics and the movement for reform, and another under the title "What the American Medical Association Stands For." In 1914 he read a paper before the Southern Medical Association, entitled "Work of the Council on Pharmacy and Chemistry. Its Effect on Medical Progress", and as president of the Institute of Medicine of Chicago, which position he held in 1921, he read an address under the title "Medical Periodical Literature."

In 1924 he resigned as Editor and General Manager of the American Medical Association and became Editor and General Manager Emeritus. At that time a number of leaders in American medicine arranged for the painting of his portrait, which was presented to him at a testimonial banquet in Chicago on June 9, 1924. Hundreds of physicians attended, and he received messages of appreciation and congratulations from all over the world.

This, then, is briefly the record of Dr George H Simmons as an executive and administrator. His work for the American Medical Association was characterized by intelligence, unselfishness, initiative, honesty and righteousness. In his personal life he had his share of physical and mental suffering. He weathered storms of unjust criticism and false characterization of his administration. He devoted himself almost objectively and completely devoid of personal interest to the public career which he had chosen. Unquestionably he was the greatest factor in his generation in the development of the American Medical Association and the profession that it represents.

After his retirement he traveled extensively for several years. Since that time he has resided in Florida but has spent some time every other year in Great Britain and in the intervening years in Chicago, frequently coming to the headquarters office and making available to his successors the experience of years and the brilliant insight which he brought into medical problems. The medical profession of the United States owes him a debt which it could never pay and which he never wished to collect.

Richard C Norris, Philadelphia, University of Pennsylvania Department of Medicine, Philadelphia, 1887, member of the Medical Society of the State of Pennsylvania, emeritus professor of obstetrics at the Medical Surgical College, Graduate School of Medicine, University of Pennsylvania, formerly assistant professor of obstetrics at his alma mater, at various times on the staffs of the Methodist Episcopal Hospital, Philadelphia Hospital and the Preston Retreat, at one time editor of the "Atlas and Epitome of Gynecology," and author of the "American Text Book of Obstetrics", aged 73, died, June 10, in Los Angeles.

Otto Von Huffman, Mount Kisco, N. Y., Columbia University College of Physicians and Surgeons, New York, 1903, member of the American Association of Pathologists and Bacteriologists, formerly associate professor of medicine at the New York Post-Graduate Medical School, Columbia University, New York, at one time dean of the Long Island College Hospital, and member of the state board of regents examiners, University of the State of New York, on the staff of St. Luke's Hospital, aged 55, died, June 9, of coronary thrombosis.

Milton P Overholser, Harrisonville, Mo., Kansas City Medical College, 1884, past president of the Missouri State Medical Association, past president and secretary of the Cass County Medical Society, formerly councilor of the fourteenth district of Missouri, for many years member of the state board of health and of the pension board of examiners, at one time superintendent of the State Hospital, Nevada, and the State Hospital St. Joseph, aged 77, died, June 19, of carcinoma of the prostate.

Henry Marion Neale, Freeland, Pa., Jefferson Medical College or Philadelphia 1880, past president of the board of trustees and formerly on the staff of the Hazleton (Pa.) State Hospital, on the staffs of the White Haven (Pa.) Sanatorium and the Mercy Hospital Wilkes-Barre, aged 78, died, June 17, of bronchopneumonia.

Samuel Downing, Newport News, Va., Medical College of Virginia, Richmond, 1914, member of the Medical Society of Virginia, served during the World War, fellow of the American College of Surgeons, formerly represented the U. S. Public Health Service and the Veterans' Administration in his district, on the staff of the Riverside Hospital, aged 44, died, June 14, in Richmond, of carcinoma of the stomach.

Harvey Edmund Webb, Milwaukee, University of Illinois College of Medicine, Chicago, 1914, formerly secretary and treasurer of the Medical Society of Milwaukee County, fellow of the American College of Surgeons, on the surgical staff of the Johnston Emergency and St. Luke's hospitals, on the visiting staff of St. Joseph's Hospital, served during the World War, aged 52, died, June 12, of coronary occlusion.

Albert Eugene Payne, Riverhead, N. Y., New York University Medical College, New York, 1898, past president of the Suffolk County Medical Society, member of the county board of health, physician to the county jail, aged 64, on the staffs of the John T. Mather Hospital and the Southampton Hospital, where he died, June 22, of diabetes mellitus and heart disease.

Frank Wandling Hornbaker, Occoquan, Va., University College of Medicine, Richmond, 1900, member of the Medical Society of Virginia, for many years connected with the Occoquan Work House and Lorton Reformatory, aged 62, died, June 11, in the Garfield Hospital, Washington, D. C., of tumor of the bladder and diabetes mellitus.

Henry Ecroyd, Jamestown, R. I., University of Pennsylvania Department of Medicine, Philadelphia, 1883, medical examiner of the city schools and member of the town council, formerly on the staff of the Newport (R. I.) Hospital, aged 79, died, June 4, of chronic myocarditis and chronic nephritis.

William Preston Patterson, Springfield, Mo., Vanderbilt University School of Medicine, Nashville, Tenn., 1885, member of the Missouri State Medical Association, county coroner, formerly member of the school board, at one time on the staff of the Missouri Baptist Hospital, aged 75, died, June 7.

James Howard Douglass, Arkansas City, Kan., Detroit College of Medicine, 1908, member of the Kansas Medical Society, also a pharmacist, served during the World War, on the staff of the Mercy Hospital, aged 55, died, June 10, in Larned, of arteriosclerosis and cerebral hemorrhage.

Benjamin L Sheldon, Cedar Rapids, Iowa, Rush Medical College, Chicago, 1902, fellow of the American College of Surgeons, past president of the Linn County Medical Society, on the staffs of St. Luke's and Mercy hospitals, aged 59, died, June 21, of arteriosclerosis and uremia.

Howell Towles Heflin, Birmingham, Ala., University of Maryland School of Medicine, Baltimore, 1893, member of the Medical Association of Alabama, fellow of the American College of Surgeons, aged 60, died, June 18, in the Birmingham Baptist Hospital, of portal cirrhosis.

George Edward, Canton, Minn., University of Minnesota College of Medicine and Surgery, Minneapolis, 1897, member of the Minnesota State Medical Association, served during the World War, aged 65, died, June 3, in Rochester, of coronary thrombosis.

Ernest Blake Minor, Traverse City, Mich., Barnes Medical College, St. Louis, 1899, member of the Michigan State Medical Society, aged 67, died, June 12, in the University Hospital, Ann Arbor, of periappendiceal and right subdiaphragmatic abscesses.

Reuben Levi Hurst, Winnipeg, Manit., Canada, University of Toronto Faculty of Medicine, 1909, M.R.C.S., England, L.R.C.P., of London, 1912, aged 55, died, June 3, in the Winnipeg General Hospital of coronary thrombosis and diabetic gangrene.

Samuel P. Oldham, Owensboro, Ky., Louisville Medical College, 1897, member of the Associated Anesthetists of the United States and Canada, served during the World War, on the staff of the Owensboro City Hospital, aged 63, died, June 17.

John James Gelz, St. Cloud, Minn., University of Minnesota College of Medicine and Surgery, Minneapolis, 1909, fellow of the American College of Surgeons, on the staff of St. Cloud Hospital, aged 53, died, June 26, of hemochromatosis.

Thomas Francis Judge, Troy, N. Y., Albany Medical College, 1901, member of the Medical Society of the State of New York, served during the World War, formerly county coroner, aged 64, died, June 1, of carcinoma of the colon.

Martha Burdick Newby, Denver, Harvey Medical College, Chicago, 1900, aged 72, died, June 14, at the Denver General Hospital, of ruptured ulcer at the pylorus and peritonitis.

Correspondence

INJURY TO THE RECURRENT LARYNGEAL NERVE

To the Editor—In the editorial "Total Thyroidectomy for Congestive Heart Failure," appearing in *THE JOURNAL*, July 17, the following statement occurs: "Injury to the recurrent laryngeal nerve was recorded in 8.2 per cent of the cases. In no instance was it bilateral or permanent." This statement includes an opinion widely held among clinicians even though it contains a gross anatomic ambiguity as well as, by implication, a definite falsehood. According to the BNA there is no recurrent laryngeal nerve. What is meant by the customary term is the left laryngeal or recurrent nerve, as there is only one recurrent nerve in the body. The reason for this asymmetry is that in the embryologic rotation and descent of the heart from the neck into the thorax the left laryngeal nerve is caught between its origin and insertion and pulled down with it, coming to rest in a loop around the aorta. This distinction is important, as it fully explains the observation of left—and only left, except in cases of anomaly—vocal paralysis which obtains in thoracic diseases involving the mediastinum—infections, growths, aneurysms.

JOHN F. QUINLAN, M.D., San Francisco

FORTY DAYS' CONSTIPATION

To the Editor—In the Correspondence section of *THE JOURNAL*, July 10, Dr. W. K. McCandless cites a case of obstipation in which a bowel evacuation did not occur for forty days.

In Samson Wright's textbook of Applied Physiology (ed. 6, New York, Oxford University Press, 1936) there appears the following (p. 565):

A case is recorded of a man who went from June 18, 1900, to June 21, 1901, without a motion. Towards the end of that time he belched a good deal and suffered from some pain; the abdomen was distended; he felt weak and lost some weight. After the colon was cleaned out he recovered rapidly.

LOUIS GOODMAN, M.D., New Haven, Conn.

PICROTOXIN IN THE TREATMENT OF BARBITURATE POISONING

To the Editor—In their paper on picROTOXIN in the treatment of barbiturate poisoning in *THE JOURNAL*, July 31, Kline, Bigg and Whitney state: "The importance of picROTOXIN in the treatment of this patient must be weighed carefully, as recoveries do occur in severe cases when nothing more than general supportive measures are employed."

Chang and Tainter (Unusual Case of Barbiturate Poisoning with Recovery, *THE JOURNAL*, April 18, 1936, p. 1386) reported a case in which recovery occurred from the effect of 270 grains (18 Gm.) of sodium barbital, and Gwathmey (The Barbiturates. The Safe Preliminary Medication for Surgical Operations, *ibid.*, Nov. 17, 1934, p. 1536) has reported a recovery from 172 grains (11 Gm.) of ipral. I have reported a case (Paraldehyde and Other Preliminary Hypnotics, *Anal. & Inal.* 15:14 [Jan.] 1936) in which the patient recovered after taking 168 grains (11 Gm.) of sodium amital and Alexander (Narcosis Therapy in Psychoses, *Rhode Island M. J.* 19:151 [Oct.] 1936) has administered 542 grains (35 Gm.) of sodium amital in an eight day period without deleterious effect.

These figures indicate the probability of recovery in Kline, Bigg and Whitney's case in which only 45 grains (29 Gm.) of amital was ingested irrespective of the use of picROTOXIN. Barring possible individual susceptibility, the estimated 2 to 3 Gm. as the fatal dose of amital underestimates the margin of safety of the barbiturate acid group.

ALBERT H. MILLER, M.D., Providence, R. I.

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

PREVENTION OF RICKETS BY SUN EXPOSURE

To the Editor—Please advise me with regard to the minimum skin surface that must be exposed to the sun in New York City during July and August and the minimum length of time for a normal 6 months baby to constitute adequate prophylaxis against rickets. Is there any variation between the white and the Negro?

HENRY LAYEN, M.D., Brooklyn

ANSWER—The simple questions here propounded are difficult to answer exactly. The simplest method of exposure of the skin surface to the sun is that practiced for many years by Rollier in Switzerland. During the late spring months when the infant can be exposed outdoors, the wrists and ankles are first exposed for short periods and gradually the arms and legs are exposed and then the trunk of the body. Tanning is the sign that ultraviolet radiation has been effective, though of course not all infants will tan, and overexposure may result in sunburn. The answer, therefore, to the minimum skin surface that must be exposed would be starting with the gradual exposure the maximum amount of skin that could be exposed without harm to the infant. As to the minimum length of time of exposure to the sun for a 6 months baby to insure adequate prophylaxis against rickets, no arbitrary answer can be given. A fair skinned child who will not tan naturally cannot be exposed as long as a dark skinned child who will tan easily. It is said that a Negro will require a longer exposure than fair skinned white children. There are many factors that interfere with the ultraviolet rays of direct sunlight in large cities: fog, haze and city smoke all tend to cut down the effective ultraviolet rays. It is also well to realize that not only the direct sunlight ("direct shine") but also the reflected light of the sun ("sky shine") possesses antirachitic power. The child in the shade receives only sky shine. When placed in the sun he receives both direct shine and sky shine. To receive all the sky shine possible there must be no obstruction between the child and the dome of the sky. Therefore a child on a narrow street cannot possibly receive as much sky shine as a child in an open park or on an open roof or balcony. Direct shine, as well as sky shine, is greatest in the middle of the day. Both can produce tan, and the dust and smoke of cities—like-wise clouds and fog—will cut down or completely eliminate the ultraviolet rays in each. From experience with a group of infant welfare babies for whom only direct exposure to the sun was relied on as prophylaxis against rickets during the summer months, it was found that nearly 50 per cent of the babies showed clinical signs of rickets in September. In cities in the temperate zone such as New York, it would seem advisable, if possible, to supplement the sunlight with small amounts of additional antirachitic agents in order positively to prevent the development of rickets.

DEAFNESS IN EARLY CHILDHOOD

To the Editor—In the past two years four cases of deafness in early childhood have come to my attention. The oldest patient was 4½ years of age; the youngest 17 months. I am unable to find much information on diagnosis or treatment. Please inform me as to methods of diagnosis. Also can you tell me how early in life the sense of hearing develops?

M.D., Colorado

ANSWER—The diagnosis of deafness depends on tests, most of them subjective in character and hence fallible. The accuracy of the test is dependent on the age of the person; his intelligence; his interest and his self interest. In very young children the diagnosis of deafness is difficult because it is often impossible to obtain cooperation. In the case of very young children the first thought one should have in an instance in which a child does not begin to speak at the proper time is that the child may be deaf. Most persons are mute because they were born with a profound hearing disturbance and hence have not learned to speak, or they became deaf at such an early age that they forgot what speech they had acquired. It is true that there are cases of mutism primary in character wherein the person has good hearing but these are exceedingly rare and for the present discussion need not be considered. Further, some children do not learn to speak because they are backward mentally. Here a pediatrician or child psychologist can demon-

strate the mental retardation in other ways. Such a child for instance in addition to other things does not learn to feed itself or to perform those other duties which normal children of that age are capable of performing.

There are a number of objective tests that will determine the presence of hearing in infants and very young children among these one highly recommended consists of striking a c-4 (4096 double vibration) fork very loudly behind the patient and observing whether he blinks (oculopalpebral reflex). A positive result means that the patient can hear the high tones and therefore has no deafness of the cochlear or perceptive type. This test is not infallible. There are variations of this test, instead of looking for blinking one observes whether the pupils dilate.

The sense of hearing is probably fully present at birth.

NONSPECIFIC URETHRITIS DURING INFLUENZA

To the Editor—Can a nonspecific urethritis with hematuria frequency urgency and dysuria arise from influenza? A married man aged 52 whose general health was good had had no serious illness since 1917 when he was taken with a sudden attack of chills. He was treated by a competent physician who diagnosed influenza. It required five weeks convalescence for complete recovery in 1917. The present illness began with fatigue for about two weeks then headache and rhinitis. December 28 he became very weak with headache and went to bed. An hour later he felt a little better. His wife uses a diaphragm. Coitus at this time caused pain at the glans. He had headache and a fever of 102 F. Shortly after ward he got up to telephone and the cooling off in the ball white telephoning he believes caused a chill. This chill became so violent that his bed shook. After taking hot milk and brandy he vomited. This broke the chill and perspiration started. Two hours after he took to bed the family doctor called. He was taken to the hospital in an ambulance. He remained there five days and several attacks of chills were controlled by febrifuge medication. On the second day in the hospital the backache grew worse and there was an annoying ticklish sensation in the perineal urethra but no discharge however there were frequency and urgency about every three hours. He used the urinal from the ward next door. He was urged to drink much water and this increased the frequency. On the third day out of the hospital eight days after the acute onset he injected into the urethra a very hot solution of strong potassium permanganate which he thought would stop the ticklish sensation as well as the urgency and frequency. A few hours afterward he passed blood in the urine and urgency became worse than before and in addition he now felt pain at the end of urination. Frightened he consulted a urologist. The urologist found nothing alarming by rectal examination. A preparation containing oil of santal was ordered. The pain was almost at once relieved and in three days the bleeding stopped. The frequency urgency and dysuria also abated within a week. The second week after consulting the urologist he was put on alkalis. Ten days after the administration of oil of santal he went out on a hike caught cold and passed blood again with frequency and urgency. Oil of santal relieved the symptoms again but coagulated blood was now passed and in four days a small epididymitis formed on the right side there was no pain but the testicle was tender. The patient tells me that the urologist gave him a prostatic massage two days prior to the swelling of the right testicle and he wants to know if the massage may not have started the epididymitis. He comes to me thinking I shall be a bit less rough in examination. I cannot claim any expert knowledge and do not know what else to prescribe than rest suspensory oil of santal and a mild diet. I advised also hot baths several times daily. In addition to the foregoing questions please answer the following. The prostate is very slightly enlarged but soft in consistency and the gentlest manipulation produces a profuse bloody discharge by way of the urethra. Is this a nonspecific case of urethritis? Laboratory examination of several smears failed to show any typical cocci but many pus cells were seen in one specimen. What is the best treatment in a case of this kind? Bacilli with clubbed ends were reported in one specimen. What is their significance? Is it safe to do any manipulation such as prostatic massage and emptying of the seminal vesicles? The patient passed clotted blood until a short time ago when he had coitus after which blood ceased to come. Does this indicate that intercourse should be interdicted? Can coitus normally performed be regarded traumatic? He cannot remain entirely off his feet. What is the next best thing to tell him? M D New York

ANSWER—It has been shown that, in many cases of respiratory infection cocci may be found in the urine without giving evidence of any infection in the genito-urinary tract. With a lowered resistance or in the presence of virulent bacteria the prostate gland and urethra not infrequently become actively infected and are the cause of urinary symptoms such as are here described. It may be difficult to identify the infecting organism in a case of this kind. Infection with *Neisseria gonorrhoeae* should of course be excluded in every case without regard to the previous history. This is best done by culture of the urethral or prostatic secretion even though the gram stain may be negative. The bacilli with clubbed ends in the secretion are probably due to secondary contamination and are of no clinical significance.

The treatment of infections of this kind consists largely of rest. Exercise coitus or hard work should be strictly forbidden. Medication other than oil of santal is not of much value. The application of heat by sitz baths or rectal Elliott treatment should be tried. Prostatic mass age is contraindicated

in the acute stages of the disease, particularly as long as there is hematuria following massage. After the acute stage has subsided, massage may be cautiously employed at intervals of a week, with gradually increasing pressure and frequency. Injections of any kind into the urethra would be contraindicated until the acute stage has passed and should then be employed only under the guidance of a specialist.

SEBORRHEIC DERMATITIS OF EYELIDS

To the Editor—I would appreciate information on the therapy of a seborrheic dermatitis involving the upper eyelids in a woman aged 17 years. The blood the urine and the rest of the examination are normal with the exception of an endocervicitis (with leukorrhea) and an acneiform eruption on the face and rest of the body. The patient receives pills of ferrous carbonate for an anemia which she had when I first saw her. The cervix is to be treated by electrocoagulation (with a short wave diathermy machine). She is getting close range ultraviolet therapy to the acneiform lesions (to the point of scaling). I have regulated her diet to exclude large amounts of fats and carbohydrates. In addition, she receives lotio alba treatment to the body lesions after the face is freed by boric acid compresses twice daily to the affected areas. Would the following remedies suggested for the treatment of seborrheic dermatitis of the scalp cause ocular injury should some trickle into the eye?

	Gm or Oz
R Salicylic acid	1 0
Ammoniated mercury	2 0
Rose water ointment	to 30 0
	Gm. or Oz.
R Mercury bichloride	0 01
Chloral hydrate	8 00
Spirit of formic acid	15 00
Castor oil	0 50
Alcohol (80%)	180 00
Oil of bergamot	enough to perfume

I would appreciate prescriptions containing ingredients that will not injure the eyes. M D Illinois

ANSWER—The ointment can be used on the eyelids without any fear of ill results. The lotion, while unobjectionable for the scalp, is likely to be rather strong for the eyelid. The trouble is not so much with any one of the ingredients as with the fact that 80 per cent alcohol is too strong for application near the eye. If one leaves out the castor oil and the bergamot oil, which while useful on the scalp are not needed on the eyelid, one can dilute the preparation with 4 parts of water which would possibly lessen the therapeutic value but also the liability to produce disagreeable irritation in the eye, should some inadvertently enter the conjunctiva.

TOXICITY OF TRICHLOROETHYLENE

To the Editor—The following information is desired concerning the use of trichloroethylene: 1 Toxic effects because of its use in industry as a degreasing agent. 2 Skin reaction resulting from a defatting process. 3 Toxic properties when inhaled. 4 The safe exposure to workmen in parts per million. 5 Safeguards if any against overconcentration in air. Please mention available literature.

HAROLD M JAMES M D Dayton Ohio

ANSWER—Publications descriptive of the toxicology of trichloroethylene have now become so voluminous as to prohibit listing in this department. An apt presentation on trichloroethylene may be found in Hamilton's "Industrial Toxicology" (New York, Harper & Brothers 1934) which will provide extensive literature materials. The specific questions presented are now briefly answered.

1 When trichloroethylene is used as a degreasing agent there arise no peculiar manifestations as to toxicity, setting this apart from others giving rise to vapors. In this use trichloroethylene is often kept boiling and in open tanks. Evaporation is prevented in marked degree by coils of piping around the tank periphery, through which cold water is circulated. This protection is far from perfect. Workers are prone to lift baskets of articles submerged in trichloroethylene for degreasing prior to complete draining and drying. Qualitative tests for trichloroethylene vapors will be positive anywhere in a workroom in which an open type degreaser is in use. The toxic problem becomes one of inhalation.

2 No specific property is possessed by trichloroethylene setting it apart from other skin defatting agents of equal potency. Exposed skins may become dry, scaly, fissured papillated and at times infected. However, there is some reason to believe that trichloroethylene may produce systemic disease following absorption by the skin.

3 Although trichloroethylene is chemically closely related to carbon tetrachloride manifestations after exposure may be quite dissimilar. Gross exposure through the inhalation route may lead to active narcosis. This agent has been proposed as a

surgical anesthetic because of its narcotic action, but unfortunate results militate against its use. While the action of carbon tetrachloride is principally on the liver, respiratory tract, gastrointestinal system and kidneys, trichlorethylene stands out as affecting the central nervous system, particularly the cranial nerves. The fifth and optic nerves are apparently vulnerable to an exquisite degree. Psychic disturbances are well known, hysteria is common, trichlorethylene addiction is well established, personality changes take place. Minor effects include headache, dizziness, loss of appetite, tachycardia, vomiting and loss of weight.

4 The upper limit of safe use is perhaps not above 200 parts per million and 100 parts per million is accepted by some as the threshold of danger. If exposure is a matter of hours, lower limits should be enforced.

5 The chief safeguard in avoiding danger from this substance is to limit its use to completely enclosed systems, such as in dry cleaning. This vapor is measured quantitatively only with difficulty. No less every use of trichlorethylene in appreciable amounts should be associated with adequate testing so that the threshold of danger is never reached. Fortunately, the cost of this excellent solvent is so high as to necessitate conditions of use that are unfavorable to evaporation losses of great extent.

DIAGNOSIS AND TREATMENT OF LEAD POISONING

To the Editor—I was recently consulted by a man, aged 27, who complained of pain in the feet and knees and weakness of the legs. The patient dated the onset of the symptoms to August 1933. At this time he had some pain in the right thigh and testicle and because he feared this might be due to a previous gonorrheal urethritis he consulted a highly competent urologist and was assured that there was no remaining gonorrheal infection. The patient's history disclosed that he had had progressive weakness of the legs with pain at times in the feet and ankles. During the three weeks prior to consulting me he had developed pain in the legs. In August 1936 he had suffered a moderately severe gastro-intestinal upset and from that time until the present had complained of vague epigastric pains that were not related to food intake. There had been increasing constipation and for about three months he had been regularly taking liquid petrolatum. For the same length of time the patient had not been sleeping well and had complained of a metallic taste in the mouth. In the last two years there had been a weight loss of about 12 pounds (5.4 Kg.). For about ten years the patient had been employed in a local newspaper office where his work was limited to the preparation of lead plates for the advertising cuts and he was each day exposed to the fumes of molten lead. Physical examination revealed that he was 5 feet 6 inches (168 cm.) tall and weighed 130 pounds (59 Kg.). He appeared slightly anemic. The teeth appeared quite normal; there was no evidence of a lead line on the gums. The heart, lungs and abdomen were entirely normal. The genitalia showed only slight tenderness of the right epididymis. The extremities appeared normal. There was slight pain on full motion of the knees and ankles but there were no evidences of arthritic changes and no history of swelling or redness of the joints; however, a diagnosis of infectious arthritis had been previously made by another physician. There were some sensory nerve changes and slight pain over the course of each sciatic nerve. The blood count showed a hemoglobin of 90 per cent, erythrocytes 4,760,000, leukocytes 8,900, differential count normal. Smears were examined in three laboratories and none of these showed any basophilic stippling of the red blood cells. Urinalysis was entirely negative. A tentative diagnosis of subacute lead intoxication was made and a twenty-four hour urine specimen which was analyzed for lead showed 0.198 mg. of lead. The patient was put on a low calcium high phosphorus diet. In addition he is receiving 4 Gm. of sodium phosphate, 3 Gm. of ammonium chloride and 15 cc. of 50 per cent magnesium sulfate daily. Naturally the patient is not at present working. 1 In your opinion is this diagnosis correct? 2 Should this patient eventually return to his previous work, what prognosis is to be offered concerning the return of the symptoms in the same or increased form? 3 In such a case when the symptoms are subacute would it be more advisable to attempt to fix the lead rapidly than to attempt to delead the patient as I have done?

M D, Indiana

ANSWER—1 So protean are the manifestations of the action of lead on the human body that it is sometimes quite impossible to make a diagnosis without reservation. In the present instance the quantity of lead mentioned suggests the reasonableness of a diagnosis of lead poisoning but the making of quantitative determinations of lead in the urine is fraught with difficulty and frequently associated with error. In an earlier day, the making and manipulation of lead type and cuts was a rather prolific source of lead poisoning. Lately, lead poisoning has distinctly lessened in newspaper and other printing plants. A desideratum for the diagnosis of lead poisoning is the quantitative determination of lead in the atmosphere at the work place. Epididymitis as a manifestation of lead poisoning is known but is a rarity.

2 If the patient recovers to the point that he is able to work, the most practical step that may be taken is to remove further exposure at the work point and then permit him to resume duties. The prognosis as to recurrence of lead poisoning, if, in fact, such disease has existed primarily depends on the elimination of future exposure. It is possible, but unlikely,

that recurrences of lead poisoning might arise from lead already present in the body. On the assumption that it has been several months since the last exposure, this becomes improbable.

3 At the present time there exists distinct controversy as to the respective merits of attempting to delead patients on the one hand and entirely avoiding deleading or fixing of the lead on the other. Unless the patient can be placed under a hospital regimen deleading probably should not be attempted. Left alone, spontaneous elimination of lead will take place to some extent.

FATIGUE WITH LOW METABOLIC RATE

To the Editor—An old patient and friend of mine aged 60 has always been a hard worker inclined to take life seriously and somewhat neurotic. For many years he complained of rather unusual and marked fatigue but in spite of that continued strenuous work with considerable responsibility. About three years ago the fatigue became so marked that careful investigations were made and it was found that he had a low basal metabolism minus 32 minus 30 and minus 28 on different occasions and with cholesterol 270 mg. He was put on thyroid with immediate and rather marked beneficial effect. The symptoms returned after several months and other basal metabolism tests were made showing always minus 32 to minus 20. The dose of thyroid was increased somewhat and it was advised that the dose be balanced against subsequent tests but he was called out of the city and remained about a year. On his return I found him taking 1½ grains (0.1 Gm.) of thyroid extract with a metabolism reading of about minus 20. The fatigue is still quite marked, his endurance is considerably limited and his activities are cut in half. A very annoying symptom is burning in the feet and back of the legs and at times slight cramping. These symptoms have been present more or less during the past two years but have become more marked in recent months. The temperature when observed has ranged from 96 F in the early morning to 97.8 in the afternoon. There is now and has been for several years a marked periodic insomnia. Can a balanced ration of thyroid be expected to relieve these symptoms? If not what other measures could be used to bring relief from the symptoms especially the burning of the feet and legs?

M D, Texas

ANSWER—In cases of fatigue associated with a low metabolic rate there is always the question of how much the fatigue is due to the low metabolic rate or whether the low metabolic rate is due to fatigue. With a rate as low as this, however, it would appear possible that a hypothyroidism was present. The presence of a burning sensation in the feet and cramps in the calves of the legs may be due to a circulation impaired because of a hypothyroidism, to changes in the cardiovascular system consequent on some other factors than hypothyroidism, or possibly to some change in the calcium or chloride metabolism. Other conditions aside from the hypothyroidism should be ruled out as, for instance, anemia. It is to be expected that symptoms of hypothyroidism would be relieved by an adequate dose of thyroid if the symptoms are entirely due to that condition. A good vacation, with complete rest and relaxation while taking desiccated thyroid, may be more efficacious in bringing the basal metabolic rate into the normal range than merely giving more thyroid alone.

The peripheral circulation can also be improved by the use of the theobromine derivatives, such as the alkaloid theobromine or theobromine with sodium acetate given in 0.5 Gm. grain doses three times daily with some or complete relief of symptoms. In selected cases, insulin free tissue extract in small doses intramuscularly gives relief while in others it may merely make the symptoms worse. Patients who have an impaired peripheral circulation to the extremities should be warned of the dangers of traumatic injuries to the extremities.

MERCURY POISONING

To the Editor—What are the ordinary tests for mercury poisoning by ingestion? What pathologic changes are shown in the stomach lining and what tests are made on the gastric contents? How long after the ingestion of 10 or 20 grains (0.613 Gm.) of mercury chloride does death occur? Has a minimum lethal dose ever been determined?

W W BOYNE M D, East St. Louis, Ill

ANSWER—The most serviceable test for mercury in the stomach contents is based on the fact that metals which are more electropositive than mercury (such as copper, zinc, iron and aluminum) liberate metallic mercury from solutions. The test is performed as follows:

To a portion of the stomach contents add one-sixth volume of chemically pure hydrochloric acid. Place in this mixture one or two small strips of bright copper foil and boil the mixture for a few minutes. If mercury is present in the material, the copper foil will receive a silvery deposit. Remove the foil, wash with water, alcohol and ether, and dry between filter paper. To prove that this deposit is mercury, cut the copper foil into small bits, place in a reduction tube and heat the lower end over a free flame until the copper glows slightly. The mercury sublimes and collects on the cool portions of the tube. Microscopic examination of the sublimate reveals the

characteristic globules of mercury. For further verification of mercury, one may remove the copper foil place in the tube a crystal of iodine and stopper with a cotton plug. After standing for a while the sublimate becomes red from the formation of mercuric iodide.

A grayish white eschar is found on the lips, mouth, pharynx and esophagus. The stomach is firm and contracted and looks as if cooked. The mucosa is of a uniform pale violet, which is the result of the mouse gray tint of the coagulated blood in the vessels blending in with the white coloring of the escharotic epithelium.

Death usually occurs after from five to ten or even twenty days. Death within a few hours is most exceptional. Even less than 0.1 Gm may cause death in a sensitive person while 0.5 Gm and even 5 Gm have been recovered from.

ORAL TREATMENT OF DIABETES—CHANGE IN LIFE EXPECTANCY WITH INSULIN

To the Editor—Five of eight patients use insulin the other three refuse it but adhere strictly to their diet. Is there any adequate treatment by mouth? In Beckman's General Practice myrtillin is mentioned but none of the drug houses seem to carry either a tincture or a fluid extract of it. Many years ago (over fifty) a Swiss family in my town made a tea from blueberry leaves which it used for diabetes. Could the myrtillin which it contained have been of benefit?

M D Pennsylvania

ANSWER—There is no adequate treatment of diabetes by mouth today. What will happen tomorrow no one can predict. Myrtillin has not been used for years. Those most interested in it and competent to use it have dropped it.

At the present time insulin injected parenterally affords the only treatment specific for diabetes. One must insist that insulin be taken by those patients whose diabetes is so severe that their urine is not sugar free when they are on a diet necessary to maintain their weight and strength. In talking with patients averse to the idea, one should contrast the mortality today with that prior to 1922. Before the introduction of insulin (1) children despite rigid dieting died within twelve months (2) the mortality of diabetic coma among children was 100 per cent and (3) in all diabetic persons, young and old, the duration of life after the onset of diabetes was only from four to five years. Today (1) the life expectancy of a diabetic child at age 10 is 31.7 years (estimated by the Metropolitan Life Insurance Company) (2) the mortality from coma in children (if not hopelessly far advanced before treatment is begun) has been reduced to almost zero in the better hospitals and (3) there has been a threefold increase in the duration of life of all persons with diabetes.

If patients who need insulin but have refused it are not open to these arguments or to persistent persuasion always without success, it is best to advise them to select another doctor in whom they have more confidence. At the same time the physician should concentrate on patients who do take insulin so that their superiority in comfort, health and efficiency may be noted by every one.

FRIEDRICH'S MODIFICATION OF PREGNANCY TEST

To the Editor—I have been interested in Friedrich's modification of Visscher and Bowman's chemical pregnancy test abstracted on page 80 in the January 2 issue of THE JOURNAL. Will you let me know if there has been any confirmation of this work and also your opinion concerning it. I have done quite a number of these tests using the bunsen burner method described in the abstract and I am so far pleased with the results obtained.

*WILLIAM C. STEPHENSON, JR. M D Roanoke Va

ANSWER—The modification of the Visscher-Bowman test as described by Friedrich (*Monatsh. f. Geburtsh. u. Gynak.* 103:185 [Oct.] 1936) has not as yet been verified by other workers although the original test has been reported on rather favorably by Dodds (*Brit. M. J.* 2:224 [Aug. 1] 1936) who in an investigation on 100 pregnant women found the test to be correct in ninety and on the urine of 80 nonpregnant women there were nine that responded as positive a correct reading having thus been made in 89 per cent of the cases tested. Wiesener (*Zentralbl. f. Gynak.* 60:1588 [July 4] 1936) on the other hand states that the titration method is unreliable but reports that his glass mortification reaction gave a 93 per cent correct diagnosis in early pregnancy and a 91 per cent correct result in nonpregnant women.

Although the modification of the test as described by Friedrich is simple it seems that the color distinction as described is too fine.

In extensive series the original Aschheim-Zondek test has been found to be reliable in about 99 per cent of cases tested while the Friedman modification is correct in about 98 per cent.

Because of the reliability of the latter tests it is felt that at the present time none of the more simple reactions can be used with a sufficient amount of security to replace the Aschheim-Zondek or Friedman test.

PSYCHOSIS IN MALARIA

To the Editor—I have been consulted with regard to an acute mania which occurred in an American woman aged 47 located in a tropical country. There was an indefinite preceding history of malaria, with no undoubted attacks for four years except that she said she had a fever one and one half days before hospitalization. She was however afebrile on admission and no plasmodia were found in the blood and showed no subsequent symptoms of malaria. In spite of this she was given the usual antimalarial treatment consisting of quinine for five days followed by atabrine for several days. The third day after discontinuance of atabrine she had one dose of plasmochin. On the next day and to some extent before the plasmochin she began to develop an acute maniacal condition which increased in severity for several days. She was placed in a mental hospital under British physicians and pronounced in an extreme maniacal condition. This lasted nineteen days and she was in the mental hospital three months and was then discharged apparently in good condition. Is it reasonable to suppose that this was a toxic psychosis from drugs administered or that it occurred entirely independent of the malaria or the treatment?

M D Kansas

ANSWER—Psychotic states have been described following the administration of atabrine and apparently due to a toxic effect of the drug (Kingsbury, A. N. *Lancet* 2:979 [Nov. 3] 1934). This would seem to be a rare occurrence however. In the case described the psychosis might have been due to malaria if this is believed to have been present, or to the atabrine or have been an independent occurrence. There is nothing to guide one in the history given as to which is the correct explanation. A history of the events preceding the psychosis would probably be of assistance in deciding as to the latter possibility.

CONTACT DERMATITIS

To the Editor—A white married woman aged 23 has annual recurring blisters on her legs and feet. For the past thirteen years (she has lived in New York for five years previous to that time being a native of Connecticut) these blisters have returned the early part of June and have disappeared in late September or early October without medication. The onset is as follows: Several mosquito-like bites on both lower extremities usually the forelegs and feet develop which quickly progress with the formation of an area of erythema about 1 cm in diameter. In the center of these lesions a vesicle forms which contains a clear serous fluid. This vesicle within twenty-four to forty-eight hours grows until it measures from 1 to 2.5 cm in diameter. There is itching. At this point, owing to trauma the vesicles or bullae rupture with subsequent oozing of serous fluid. They quickly close and refill again. Such a lesion may stay throughout the three to four months period. On the thighs and hands are similar lesions appear but never progress beyond the mosquito-bite stage. These itch slightly. A brother is sensitive to barn dust. A sister is asthmatic and is being desensitized. Physical examination for a focus revealed nothing pathologic. The patient has flaming red hair and tender white skin and is only moderately covered with freckles. I was under the impression that I was dealing with either a food sensitivity (pollen or grass sensitivity). I therefore scratch tested her for the common foods which one usually eats for the first time in June, viz. strawberries, plums, apricots, cherries and peaches. I have also scratch tested her for sensitivity to lamb's quarter, bluegrass, orchard grass, timothy, redtop, sweet vernal grass, ragweed, both dwarf and giant, and cocklebur. These have all been negative. I withdrew some of the serum from the bulla and injected it intracutaneously without reaction. I made a smear of the serous fluid and found many eosinophils, lymphocytes and polymorphonuclear cells. There were no microorganisms. The white and differential blood count revealed 6,000 white blood cells of which 44 per cent were lymphocytes, 46 polymorphonuclears, 2 eosinophils, 6 monocytes and 1 basophil. Am I justified in assuming that these lesions are due to a sensitivity? I would appreciate any further suggestions as to procedure and therapy.

M D New York

ANSWER—The fact that the vesicles have occurred each year in the summertime, from June until September or October, and the fact that there are more on the lower extremities associated with itching, strongly suggests that the patient has a contact dermatitis sometimes called true eczema. Such persons are not allergic in the sense that there is a family inheritance and they do not show any other signs of allergy such as other allergic manifestations, cosmophilia or positive passive transfer tests (Prausnitz-Küstner reaction).

This patient is almost certainly sensitive to some weed with which she comes in contact as by walking through vacant lots especially if she goes barefooted or barelegged through such weeds. It is a simple matter to find out which weed it is by contact or patch tests should be made with the leaves themselves of such weeds as the various grasses, timothy, redtop, orchard grass, June grass, and also of short and giant ragweed and barnyard marsh elder. These are the most common causes but any other weed or grass may be responsible.

The leaves should be moistened and placed against a clean part of the skin, such as the back, and left for from twenty-four to forty-eight hours. Redness and vesiculation indicate a positive reaction.

As far as treatment is concerned, mere avoidance of weeds, either by keeping away from them or by wearing heavy shoes and stockings, should suffice. If not, injections with an extract of the oily fraction of the responsible weed has given success in some hands, in others, disappointing results have been obtained by this method.

Ordinary skin tests carried out in such cases are usually negative because the materials used contain the protein fraction of the weeds, whereas the sensitivity in contact dermatitis is due to the oily fraction. Furthermore, the contact must be of sufficient duration to allow redness and vesiculation to form.

HAIR TONIC

To the Editor—Is there any incompatibility in the following for use as a hair tonic?

	Gm or Cc	
R Pilocarpine hydrochloride	0.65	
Tincture of cantharides	7.5	
Tincture of capsicum	15	
Castor oil	2	
Quinine bisulfate	2.6	
Mercury bichloride	0.065	
Alcohol	ad 125	
Oil of rose geranium	0.18	
Oil of bergamot	0.5	
Dissolve and filter.		
Label	Poison	Sig
daily or every other day		Message into the scalp
		M D New York

ANSWER—The mixture precipitates because of the tincture of cantharides which contains principles that are insoluble in alcohol. It is perfectly compatible if the tincture of cantharides is omitted. Should one insist on employing the tincture of cantharides the solvent should be the same as the menstruum employed in the manufacture of the tincture which is 10 per cent of glacial acetic acid in alcohol. This would, however, make the application probably rather strong in acetic acid. It is therefore best to eliminate the tincture of cantharides from this preparation. It would then be quite unobjectionable excepting, of course, that it should be labeled "for external use only."

HENNA AND INDIGO IN HAIR DYES

To the Editor—I have an inquiry for trade names of vegetable hair dyes that contain a combination of henna with the powdered leaves of Lawsonia inermis and reng and also powdered leaves of indigo. Fera argenta. These dyes were recommended in Queries and Minor Notes in THE JOURNAL some time ago.

M D Minnesota

ANSWER—The article from which the information regarding the combinations of henna and reng as hair dyes was derived gives no trade names under which such hair dyes are sold and we have not been able to find any such commercially made dyes. Adelaide O'Brien, of the magazine *Modern Beauty Shop* in answer to an inquiry writes:

"I regret that I am unable to give you the name of any commercial dye consisting of henna and indigo. The mixture is seldom used in modern hair tinting because the process of application is a tedious one and the long continued use of such a mixture makes the hair rather harsh and brittle and obscures its natural luster."

"The henna and indigo powders are mixed in varying proportions that is about 80 parts of indigo to 40 of henna for a light brown shade, 90 of indigo to 30 of henna for a dark brown. A few ounces of this mixture were then mixed with warm water, and the paste allowed to remain on the hair as a pack for several hours."

The comparatively harmless dyes are not satisfactory. Individual reaction plays an important part in the dyeing of hair and good results can be obtained only by expert work.

TOXICITY OF GREEN ROUGE OR CHROME GREEN

To the Editor—I would appreciate information as to the nature of the substances used in the polishing and coloring of electrical fixtures. There is one particular substance used in this industry called green rouge that I am especially interested in as a cause of toxic symptoms. Please list references also.

M D New York

ANSWER—Green rouge' is the term widely applied to chromium sesquioxide Cr₂O₃, chrome green. Apart from its pigment properties this chemical is somewhat extensively used as an abradant for the very fine polishing of steel and other metals. In a paste or liquid form it may be used to impart an arti-

ficial patina. Both of these uses appear to be involved in the conditions of work mentioned in the query. Exposure may lead to the well known 'chrome holes' particularly if the green rouge comes in contact with breaks in the integument. However, chromic acid, chromates and chromium oxides will attack unbroken skin, particularly in the presence of moisture leading to a persistent dermatitis. The breathing of chromium oxide dust may induce nasal perforation or widespread nasal inflammation. Very rarely workers become sensitized to the action of chromium compounds leading to gross dermatoses with manifestations suggesting systemic disease.

PERVERSION OF TASTE SENSATION

To the Editor—I have a patient who has been complaining for the past three years of a peculiar taste in his mouth. His tongue is always heavily coated and he reports that he can feel pus exuding from one side of his cheek. All tests are essentially negative. Is it possible to have a suppurative discharge from the salivary or parotid glands without any swelling or other clinical evidence?

M D New York

ANSWER—Two possibilities deserve exploration. Cultures should be made in brain broth from saliva taken aseptically through a cannula inserted into the parotid duct on the suspected side in order to rule out definitely infection of a low grade without obvious symptoms. The teeth should be examined for large metallic restorations. If two or more different metals are found, especially if a tooth under such circumstances is found bearing a large metallic filling adjacent or near to the origin of the perverted sensation, this clue should be followed up. Otherwise this must be classified as a poorly defined neurosis characteristic of a patient in the decades of life.

CARDIAC ANEURYSM

To the Editor—I recently had a case that came to necropsy showing a large aneurysm of the left ventricle of the heart. Pick's disease was also found. Will you please inform me how rare aneurysm of the heart is also please give references.

M L PINDELL M D Los Angeles

ANSWER—Cardiac aneurysm is comparatively rare. In a review of 12,000 necropsies by Lucke and Rea the instance was 1.25 per thousand. Most such aneurysms follow coronary occlusion but occasionally are traumatic as when the ventricle wall is just nicked by a bullet. There is a good review on the diagnosis with the report of two cases by Sigler and Schneider in the *Annals of Internal Medicine* (8 1033 [March] 1935). This article gives many references.

ALDRICH DYE MIXTURE FOR BURNS

To the Editor—Will you please give me the formula of the Aldrich dye mixture for the treatment of burns?

W F CANTWELL M D International Falls Minn

ANSWER—The use of gentian violet in a 1 per cent aqueous solution was suggested by R H Aldrich (*Role of Infection in Burns New England J Med* 208 299 [Feb 9] 1933) as a primary treatment for burns. The solution is applied either as a swab or as a spray and is repeated every two hours for twenty-four, at the end of which time a firm eschar is formed.

TONICITY OF ATROPINE

To the Editor—Kindly advise me as to the effects and dangers common particularly to the eyes of large doses of atropine by mouth. One thirtieth grain (0.002 Gm) three times a day. These doses are being used in an effort to reduce the spasticity in a case of parkinsonism. Will the continued dilatation of the pupils produce glaucoma? Is it possible for this patient to develop an immunity to atropine? Is the effect of one seventy-fifth grain (0.0008 Gm) three times a day over a long period as dangerous as the previous dose mentioned? Is it possible to become so immune to either dosage mentioned that the eyes will be able to accommodate and the mouth will lose its dryness?

M D Florida

ANSWER—Such atropine therapy would be decidedly dangerous for a person predisposed to glaucoma otherwise not. Tolerance so that the therapeutic effect is lost may develop earlier than tolerance to the untoward effects. When this occurs a change to scopolamine is advisable. The interesting suggestion has been advanced to combine the mydriatic drug with an antagonist such as pilocarpine proper dosage of which must be worked out as required in each individual case.

Book Notices

Public Medical Services. A Survey of Tax Supported Medical Care in the United States. By Michael M. Davis. Cloth. Price \$1.50. Pp 170. Chicago: University of Chicago Press, 1937.

The subject of medical services supported by taxation is now receiving considerable attention. As the author indicates, such services developed out of the attempt to combat poverty in contrast to public health work, which had its origin in the endeavor to control pestilence.

Part I is a review of the kind and extent of public medical services. Four major types are discussed: 1. General medical care as a governmental responsibility for dependent persons (indigents and near-indigents); 2. Governmental hospital care for dependent and other persons (general and acute diseases, mental and tuberculous patients, and tax-supported care in nongovernmental hospitals and clinics); 3. Medical services for special groups (soldiers, sailors, marines, veterans, Indians, prison inmates and college students) and for special rural areas; 4. Medical care for dependent and other persons afflicted with diseases or conditions bearing a public health interest (communicable diseases and other than communicable diseases, such as school medical inspection, baby clinics, maternity services, cancer, heart diseases and pneumonia). The information and statistics gathered on these topics are not exhaustive but do serve to outline the trends and problems in public medical services.

In part II, Summary and Comments, the development of public medical services is pictured as a broadening of the social base "from the concept of dependency to the concept of need" and a broadening of the medical base to a recognition of more diseases "as infused with a public health interest." The causes for the widening in the scope of public medical services are stated to be "(a) the public interest in dependency, (b) the public threat of diseases, (c) the costliness of diagnosis and treatment."

Despite the growth in the amount of medical services in governmental hospitals and institutions, the author recognizes the increasing importance of personal medical care. Both for medical and for economic reasons the care of the indigent, the rehabilitation of the mentally ill and the treatment of tuberculous patients are returning to a person or "home" service basis as contrasted with custodial care. It is also noted that there is "an increasing emphasis upon the medical as distinguished from the charitable, aspect." It follows that increased responsibility is being placed on physicians in the expenditure of governmental funds for public medical services.

The amount of public medical services is estimated at between \$400,000,000 and \$500,000,000, or about one seventh of the total bill for all forms of medical care. The development of this extensive public medical service has not been based on any general policy and as a result has been largely haphazard and lacking in coordination. Primary problems in the administration of such a service have to do with quality, adequacy and economy of the intended service. New projects for public medical service to meet some reported need often ignore these primary problems and consider only the costs of the service in relation to available revenue. The author states that "probably the most important single factor in maintaining and improving the quality of service is professional participation in determining the qualifications and appointment of professional personnel and in controlling the procedures through which professional service is furnished."

The three major problems of relationship in the organization and administration of public medical services are: (1) the relations between physicians and patient, (2) the privileges and status of the patient in relation to public medical services, and (3) the relation of the governmental authority to the medical and allied professions. With regard to these problems it is noted that "a relation of mutual confidence between patient and physician is essential," that the extension of public medical services varies with localities and with the type of service supplied, and that "the freedom of the professions and their

control of professional standards and procedures is vital to the care and promotion of health."

The author has expressed in this publication a more tolerant attitude than in some of his previous writings toward the medical profession as the qualified agency to maintain and advance the quality and adequacy of medical services.

Le venin des araignées. Par J. Vellard. Préface du Professeur Cuillery. Paper. Price 45 francs. Pp 311 with 63 illustrations. Paris: Masson & Cie, 1936.

This monograph, from the Pasteur Institute of Paris, is written by a physician-naturalist who has traveled extensively in the wilds of South America, has been associated with the Institut antiofidique de Butantan at São Paulo, Brazil, and has prepared antivenomous monovalent and polyvalent serums against the principal poisonous spiders of South America. The book is a comprehensive treatment of the subject based mainly on the author's experience with South American species. It is divided into three major parts. The first is a history of araneism, beginning with Aristotle and Pliny, and includes a discussion of tarantulum. The Spanish dance, the tarantella, had its origin in an epidemic collective neurosis, derivable from the convulsive symptoms and cries of patients suffering from the bites of the tarantula (*Lycosa tarantula*). The more accurate accounts of this disorder led the author to the opinion that the larger and better known tarantula got all the credit for tarantulum, whereas a definite part of the symptoms observed were in reality attributable to the smaller, less often observed *Latrodectus* *l3-guttatus*, the European analogue of our black widow spider. There is a brief discussion of the poisonous spiders of Australia, New Zealand, Madagascar, Africa and Asia, of the structure of the poison glands and their ducts, of the mechanism of injection of the venom, and of the use of the venom in the capture of insects used as food by spiders in general. The author gives a full account of the physicochemical properties of the venoms of spiders, of their toxic, gangrenous, hemolytic, coagulative and proteolytic action and of the relation of these properties to the types of alimentary spiders. The bodies of adult spiders and their eggs when macerated and extracted yield additional hemolysins and proteolytic ferments. Their own blood contains toxic substances, their salivary glands a highly proteolytic ferment, and the hairs on their body an urticating substance. The second part contains an exhaustive study of the classification, structure and habits of the many dangerous spiders of South America with clinical observations on the effects of their venoms on experimental animals and man.

The major interest for physicians in this country attaches to the notorious black widow spider *Latrodectus mactans*, which is widely distributed throughout the United States and extends south as far as Patagonia. The effects of its bite are severe and sometimes fatal. Clinical observations in reputed human cases coincide with those in controlled experimental cases in man and experimental animals. The symptoms begin with local pain, later becoming general and more severe, delirium, perspiration, salivation, vesicular and intestinal paralysis, cutaneous hyperesthesia, muscular pains, trembling, convulsions and intellectual fatigue and are followed by weeks of slow convalescence. In fatal cases death ensues in from twenty-four to forty-eight hours. Necrosis at the site of the bite does not occur as in bites of some other spiders. The black widow is found in shrubbery, among the bases of plants, in rubbish and in out-houses, especially privies. A number of cases of bites on the penis have been recorded. The Eurasian *Latrodectus* *l3-guttatus* causes extensive losses among camels (32 per cent), horses (16 per cent) and sheep (12 per cent), with a death rate of 4 per cent in man at times of great abundance of this species in Asiatic Russia. As in the case of many insects, spiders exhibit the phenomenon of recurrent waves of great abundance. Recent reports of widespread occurrence of the black widow spider in various parts of the United States suggest such a wave in this country of this species.

The author has prepared for distribution from the Institute of Butantan serums for treatment of persons bitten by certain poisonous spiders. A single subcutaneous injection of the appropriate serum is sufficient to arrest the intoxication in man and also to prevent necrosis after bites by *Lycosa*. There is a high degree of specificity in the antiaraneidan serums.

A Workbook in Health for High School Girls By Gladys B. Gogle
MS Paper Price \$1 Pp 267 New York A. S. Barnes & Company Incorporated 1937

This health workbook is one of many devised for similar purposes, namely, to make health attractive to those who have a reasonable share of it. One wonders whether the author really expects to make health attractive to the adolescent girl by putting greatest stress on the teaching of health during the first three days of the menstrual period or by giving to health a grudging few minutes of the time of the physical educator "while the gymnasium class is dressing," and a few more at the end of the gymnasium period "when the gymnasium class is again dressing." Moreover, she says "Ideally, the school arranges for a health examination for each pupil once a year. When it is impossible to do this, the pupils may be educated to have the family physician make a careful examination." Ideally it is quite the other way around. The proposal advanced by the author is neither good health procedure nor good education, it teaches the student to depend on some one else first for the initiative toward health examinations and to be self-reliant only as a second choice. It should be said, however, that the author is not alone in this but follows common practice, which has been allowed to gain a firm foothold in many instances by the failure of physicians to cooperate with school authorities in making examinations promptly and recording them according to prescribed instructions, when offered the opportunity. The health charts in the workbook, while complicated and voluminous, and therefore discouraging to those for whom health is to be made attractive, are for the most part sound. One notes, however, as a good health habit "my breakfast always contains fruit and whole-grain cereal," some girls should not have both every morning, and some should never eat whole-grain cereals at all. In the same list (health chart 1) are the following items, which would have been modified if the consensus of medical opinion had been followed: "each day I have one or more elimination of waste from the intestinal tract without use of a laxative" (some persons naturally eliminate only once in thirty-six hours or more and are healthy), "I drink at least 3 glasses of milk" (when eating a full diet this is not always possible or desirable), "each day I take a full bath" (some skins will not tolerate this), "each morning I take a cold bath" (there are some who should never take cold baths). The human body is so variable, and rules are so difficult to formulate, that the wiser teachers are now abandoning hard and fast rules for health. There are so many exceptions that students with alert powers of observation will not be influenced as intended, because they will see for themselves that some of these things just are not so. The chapters on the menstrual period, on teeth, on food and on the problem of clothing are good. The units on advertised medicines are excellent, with a well-considered appeal to the girl's own judgment on the basis of material selected from authoritative sources, in which it is gratifying to note that the American Medical Association is prominently mentioned. On the whole, this should be a useful book in the hands of a teacher who can inspire her students, but she will need more time than the intervals when there is nothing better to do or the days when the girl student menstruates.

Die Nomina anatomica des Jahres 1895 (B. N. A.) nach der Buchstabenreihe geordnet und gegenübergestellt den Nomina anatomica des Jahres 1935 (I. N. A.) Von Dr. Fr. Kopsch. Boards. Price 2.50 marks. Pp 103. Leipzig: Georg Thieme 1937.

The aim of this book is to enable anatomists, students and physicians to become more familiar with the revised *Nomina anatomica*. The original list of anatomic names authorized by the Anatomische Gesellschaft at its Basel meeting (1895) was an enormous improvement over the previously existing chaos. It was not even then, however, a perfect list. It has been revised by committees appointed by the Anatomische Gesellschaft of which Dr. Ross Harrison of Yale was recently president, in cooperation with the anatomic societies of Great Britain and Ireland and the American Association of Anatomists, and representative anatomists from France and Italy. The new list (*Jena Nomina anatomica I. N. A.*) reduces the number of terms from 5,291 to 5,124. Changes have been made to bring human nomenclature into conformity with that of com-

parative anatomy. The terms cranialis and caudalis are frequently substituted for superior and inferior, ventral and dorsal for anterior and posterior. Names of individuals are entirely omitted. Some new names were necessitated by discoveries. On philologic grounds some names have been slightly modified, for example, articulus for articulo, fibularis for peroneus, and pharyngicus for pharyngeus. Dr. Kopsch has arranged the names of the B. N. A. and those of the I. N. A. side by side, in alphabetical order. In the I. N. A. list he has marked with one, two or three asterisks all the changes that have been made—the greater the change, the greater the number of asterisks. This will be of considerable convenience to anatomists and students who are seeking to become familiar with the revised nomenclature. The changes are for the most part a decided improvement. Undoubtedly they will be generally adopted, and when the new nomenclature appears in the editions of the atlases of Spalteholz, Toldt and Sobotta and in the newer textbooks of anatomy, they will pass into current use as easily as did those of the B. N. A. forty years ago.

Allgemeine Elektrokardiographie Von Professor Dr. Eberhard Koch, Vorstand der Abteilung für experimentelle Pathologie und Therapie des Kerkhoff Herzforschungs-Institutes zu Bad Nauheim. Mit einem Anhang: Wie analysiert und beschreibt man zweckmässig ein EKG? Von Dr. Elisabeth Koch-Momm, Bad Nauheim. Second edition. Boards. Price 3 marks. Pp 40 with 37 illustrations. Dresden & Leipzig: Theodor Steinkopff 1937.

This pamphlet is an attempt to present the physiologic and physical background of electrocardiography in elementary language. This is accomplished by correlating the text with well-chosen illustrations. It should help the medical student and general practitioner to obtain a clear idea of the theory behind electrocardiography, provided he can rid himself of the mental hazard which so many students have who enter this field. The presentation is of necessity dogmatic, and yet the majority of authorities will find little to take exception to. The appendix on the manner in which to analyze and describe the electrocardiogram is out of place and should have been omitted. It can serve no useful purpose for the student who has no previous knowledge of electrocardiography, for whom the pamphlet was written, and is too sketchy for the experienced. Many of the illustrations are refreshingly different from those in monographs covering this subject and should interest more experienced electrocardiographers.

Sexual Power By Chester Tilton Stone, M.D., Clinical Assistant Surgeon in the Urological Department, Bellevue Hospital, New York. Cloth. Price \$1.50. Pp 172 with 7 illustrations. New York & London: D. Appleton Century Company Incorporated 1937.

The advertisement for this book states that it is "a book on sex written primarily to help men understand fully the factors which determine male sex efficiency." In other words it is a book intended for the public, and it is therefore not surprising that it contains no new scientific matter and that whatever scientific material it contains can readily be found in the standard works on the subject. But even as a book for the general public, it has marked and serious defects. How, for instance, is an ordinary nonmedical mortal supposed to understand that the brain center sends impulses to the erection center in the spinal cord, and that this in turn sends impulses to the arteries and muscular structures in the penis? The book is full of statements of this kind, and the occasional illustrations do not help matters much. Aside from all this, some of the statements are misleading and the advice given may even be harmful. In one paragraph, for instance, the author obviously confuses impotence with sterility. He makes the statement that after epididymitis, both vasa may be obstructed and that in such cases the result is the same as castration, whereas it is well known that the obstruction of both vasa will cause sterility but has no bearing on sexual power in the vast majority of cases. In fact, the Steinach operation does this very thing on one or both sides with the avowed purpose of improving sexual power. As a result of misleading statements that have long since been disproved, the author makes really harmful deductions. Among these may be mentioned his statement that "absolute continence is so rare that with few exceptions it only applies to the impotent, to chronic onanists—masturbators—and to inverts." Again, he repeats the long forgotten fallacy that the sexual glands and muscles need regular exercise to prevent them from becoming disabled. The following statements

in the book are exceedingly dangerous and might be used by many readers as an excuse for sexual immorality. "It is just as much a woman's privilege, however, to enter a life of sexual freedom if she feels so inclined after considering the consequences." Again "If, in such a case, the woman does not care for the sex act and submits to it reluctantly at rare intervals, the man is fully justified in seeking extramarital relations, if he can do so without causing those at home to suffer." The book is full of generalities, conflicts and psychoanalytic statements and, in the majority of cases, fails to state the remedy. Too much stress is laid on the emotional side and too little on the influence of the prostate and other sexual organs as causes of impotence.

Lehrbuch der röntgenologischen Differentialdiagnostik der Erkrankungen der Bauchorgane Von Dr. med. habil. Werner Teschendorf, Chefarzt des Strahleninstituts der allgemeinen Ortskrankenkasse Köln. Paper. Price 42 marks. Pp. 477 with 929 illustrations. Leipzig: Georg Thieme 1937.

The excellent book by Matthes on the differential diagnosis of the internal diseases inspired his pupil Teschendorf to write a roentgenologic differential diagnosis, since the roentgenologic aspect was neglected in the Matthes work. This treatise should serve as a supplement to Matthes's textbook. In general, by differential diagnosis is meant the consideration of all pathologic changes that will help to explain the symptom complex and arrive at a final diagnosis. Teschendorf, however, insists on the use of x-ray examination exclusively, from which considerable difficulties must result. One should expect from the roentgenologic method that a differential diagnosis which follows morphologic and topographic-anatomic aspects would be successfully discussed. The various applications of contrast mediums as used for the examination of the stomach, colon, kidney and gallbladder may be helpful for this purpose. Also the concretions as far as they can be visualized within the abdomen may guide our diagnostic efforts. Combined examinations of different organs, furthermore, assist in establishing the differential diagnosis. These investigations are necessary for a correct interpretation of a roentgenologic differential diagnosis. Teschendorf's book, however, can be considered as an attempt only in spite of the abundant material. The author has not succeeded in solving the problem of a roentgenologic differential diagnosis of the diseases of the abdominal organs. In spite of the misinterpretation of the subject, the book is stimulating because of the abundant material. The work has to be considered as a textbook of roentgenologic diagnosis of the abdominal organs and only as such is it of value.

Diagnóstico anatómico topográfico de la obstrucción arterial coronaria Por el Doctor Guillermo A. Bosco, profesor adjunto de semiología y clínica propedeutica en la Facultad de ciencias médicas de la Universidad Nacional de Buenos Aires. Paper. Pp. 755 with 245 illustrations. Buenos Aires: Artes Gráficas Modernas 1935.

This bulky work, devoted to an important subject is divided into three parts: (1) anatomic description of the coronary arterial system, (2) graphic representation of the coronary arterial system and (3) symptoms and topographic signs of coronary arterial obstruction. The author believes that he has solved one of the most difficult problems of diagnostic medicine. He refers to recognition of the site of the necrosis of the myocardium in acute coronary obstruction. Clinically this is not easily established by the present diagnostic means. The first investigators of the subject of this work relied too much on the electrocardiogram for localizing the site of myocardial infarcts, it finally developed that the fibrous plaque was a sequel of the ventricular parietal cicatrix and that the electrocardiographic tracing does not pursue the same curve in all cases of parietal necrosis of the myocardium even in the same patient, during the short or long period of anatomic-clinical evolution of the anatomic alteration. Due credit is given Barnes, Whitten, Bell and Pardee for work done in this country. The illustrations are reproductions of photographs, line and wash drawings, and roentgenograms of anatomic specimens after injection of the arteries with opaque material. The author has made a detailed study, the results of which ought to be of value to all physicians interested in the heart from the clinical, radiologic and pathologic points of view. The author believes that his studies have proved the establishment

of new myocardial zones nourished by coronary branches which until the present have not been mentioned. He suggests that the left coronary artery marks out three myocardial regions which correspond to the anterior descending branch, to the diagonal of the left ventricle, and to the left circumflex, sometimes called the left auriculoventricular branch.

Anatomy of the Fetal Pig By John G. Sinclair, M.S., Ph.D., Professor of Histology and Embryology, the University of Texas Medical School, Galveston, Texas. Paper. Price \$2. Pp. 80 with 51 illustrations. Ames, Iowa: Collegiate Press, Inc. 1936.

The full term pig fetus offers many advantages as the mammalian type for study in comparative anatomy and its use has spread widely in recent years. The present dissection manual is timely and adequate, giving a good account of the important features characteristic of mammalian anatomy. It is stated that the work outlined can be done in thirty laboratory hours, but the mass of detail presented could hardly be mastered in so brief a time. The plan of work is particularly adapted to the needs of the premedical student and there are frequent comparisons between the pig and man. The anatomic description of each system is included with the instructions for dissection and is illustrated with line drawings which are for the most part excellent. Where clarity has been sacrificed in favor of detail the student can remedy the situation by coloring the figures with crayons. In most cases the structures are labeled directly and in full, so that there is no annoying legend to decipher. There are tables of muscles into which the student may insert the function of each muscle.

The description of each system of organs is followed by an "interpretation", i.e., a brief statement of its fundamental morphology and physiologic significance. This is an especially valuable feature in spite of the occasional unavoidable inaccuracy. On page 80 for example it is stated that the nerve impulse is an "electrical impulse." The details presented in this section on the nervous system are far beyond the scope of a course in comparative anatomy. As they stand, they would not be adequate for even a brief elementary course in neurology. The introductory embryologic chapter dealing primarily with placentation is followed by accounts of the various systems beginning with the external form and the skin and ending with the nervous system. The lymphatic system is not mentioned, and the consideration of the reproductive system is necessarily superficial. In the "interpretation" of the latter system a section of the text appears to have been inadvertently omitted by the printer. While the embryologic point of view is an important feature of the whole presentation, there are some lapses which create false impressions and introduce inconsistencies in the text. Thus the optic "nerve" is said to "enter" the retina, and the fila olfactoria are described as "extensions of the olfactory lobe."

Kurzwellentherapie in der Praxis Von Dr. Ernst Raab. Mit einem Vorwort von Prof. Dr. Erwin Schleichmann. Boards. Price 5.80 marks. Pp. 173 with 97 illustrations. Leipzig: Georg Thieme 1937.

Although there is no dearth of monographs on short wave diathermy, the present small and inexpensive volume is in many respects a worthy addition to the literature. Raab fully realizes that the early overenthusiasm has led to many disappointments and that a number of theoretical concepts have been erroneous. He has sifted facts from fancy on the basis of his own extensive clinical experience, and while he has made extensive use of the literature—he includes 149 articles and monographs in the bibliography—he has accepted nothing as granted. Moot problems, such as the selectivity of certain wavelengths for special tissues, have been treated objectively and conservatively. He stresses the need for thorough familiarity with the underlying biophysical fundamentals, which he presents in the first sixty-two pages. To be clinically successful the method must be applied intelligently in the sense of proper indications, dosage, selection of electrodes and their technique of application. The bulk of the book is devoted to therapy, the diverse diseases having been grouped both regionally and according to their pathologic similarity. Electropneumonia is considered separately at the conclusion of the clinical part and is properly evaluated. The text proper is concluded with a brief critical review in which the author endeavors to show that different results by various observers are ascribable

to differences in technic, the latter being the sine qua non for success of a method that has been applied too often in haphazard fashion. A good index enhances the well prepared table of contents. The book may safely be accepted as a reliable guide to short wave treatment of the many disorders in which modern thermotherapy is indicated.

Les spasmes de la face et leur traitement. Par Th. Alajouanine et R. Thurel. Paper. Price 12 francs. Pp. 88. Paris: Masson & Cie. 1936.

This monograph describes briefly and concisely the varieties, nature and origin of facial spasm. The tics are divided into two groups depending on whether the irritative focus is peripheral or central. This differential diagnosis can be made by a morphologic analysis of the muscle groups that enter into the spasmodic movement. A spasm due to peripheral involvement of the facial nerve involves only the muscles innervated by that nerve. A spasm of central origin may include movements of muscles supplied by nerves other than the facial. Facial spasm due to involvement of the facial nerve is caused by a focus of irritation affecting this nerve after its emergence from the brain stem. Not infrequently voluntary twitching occurs during recovery from a paralysis of the facial muscles (Bell's palsy). Otitis media, a cerebellopontile angle tumor, and vascular, neoplastic or infectious lesions along the course of the nerve may result in a facial spasm. Occasionally, for want of a better explanation, an intrinsic irritative factor in the nerve itself can apparently produce the same result. The only effective treatment in the relief of such a spasm is the injection with alcohol of the peripheral branches of the facial nerve that run to the muscles involved. The causes for central irritation of the facial musculature are less clear. A facial spasm often accompanies the severe, lancinating pain of major trigeminal neuralgia, undoubtedly an involuntary response to the painful stimulus. Spasmodic movements of the face following almost reflexly on certain stimuli may be due to constant repetition of certain facial movements as seen in actors or mimics. Jacksonian convulsive movements due to cortical irritation often involve the facial musculature. Rhythmic myoclonic movements of the face, which not only include the face itself but also the eyes, palate, pharynx and larynx, not infrequently extending to the arms, follow a lesion in the olivary or dentate nuclei. Finally the lesions of a postencephalitic syndrome produce a well defined quivering of the lips or cheeks, while much more rarely choreic or athetotic facial movements are seen, usually in conjunction with similar involuntary purposeless movements of the extremities. A fairly complete bibliography is appended to this monograph. While adding nothing new to our knowledge of the various types of facial spasm, what is known is concisely described without undue speculation as to the underlying physiopathologic mechanism.

Life Saving and Water Safety. Prepared by the American Red Cross. Cloth. Price 60 cents. Pp. 267 with 141 illustrations. Philadelphia: P. Blakiston's Son & Co. Inc. 1937.

This is an excellent and timely release. As its title indicates, it covers the water-front from the angles of life saving and safety. The coverage is complete, concise, clear, fully illustrated, and free from notions or unsupported theories. It gives full and common sense reasons for the commonly repeated and uncommonly respected rules about not swimming alone, about not swimming too soon after meals, and about sensible precautions to take when swimming at night. It deals with personal safety in swimming bathing places (including the old swimmer's hole) and what they ought and ought not to be like, safety and self rescue in the use of small craft, drowning and elementary forms of rescue, swimming rescues and how to avoid being a second victim instead of a rescuer, recovering a submerged victim resuscitation, special forms of rescue and ice accidents (prevention and rescue). The full and clear descriptions with accompanying illustrations of the various procedures involved especially in handling small craft, in rescues and in resuscitation should be of inestimable service to instructors and supervisors of life-guards, to boys and girls camp directors and workers to emergency crews in industry (a growing group) and to physicians who may be called on not only for medical treatment but for cooperation in rescue work. This book should take its place beside the Red Cross Manual on First Aid as a standard reference and textbook in its field.

Nogle Undersøgelser over Widalreaktionen ved Tyfus og Paratyfus. M. Chresten Faarup. [Studies on Widal Reaction in Typhoid and paratyphoid.] (With an English summary.) Paper. Price 8 d. Kr. Pp. 141. Copenhagen: Levin & Munksgaard. 1937.

This dissertation for the degree of doctor of medicine at the University of Copenhagen describes in detail the author's observations on specific agglutination in typhoid paratyphoid fever with special reference to H and O agglutinins. It will be recalled that H, or flagellar, agglutinin reacts with motile bacilli and gives rise to a floccular, large flake agglutinate, while the O, or somatic, agglutinin reacts with nonmotile forms and gives rise to a granular, small flake agglutinate. To secure the most reliable results, tests should be made for both H and O agglutinins. The dissertation, which is in Danish with an English summary, will be of value to workers with typhoid and paratyphoid agglutinations.

Der klinische Blick. Von Dr. Erwin Rissak. Privatdozent für Innere Medizin der Universität zu Wien. Paper. Price 4.80 marks. Pp. 141. Vienna: Julius Springer. 1937.

This booklet attempts to outline to the medical student in a brief manner some fundamental bedside observations. Clinical impressions to be gained by the eye, ear and nose are recorded and illustrated by practical examples. Some of the author's statements may be criticized. For instance the doctor should observe the manner in which his female patient is disrobing. If she does it in a modest way, she is not seriously ill. If she does it in a shameless way, she is gravely ill. As a whole, however, the book fulfils the purpose for which it was written. It does not record original observations but offers to the student an evaluation of impressions gained at the patient's bedside.

Nutritive Aspects of Canned Foods. A Bibliography of Scientific Reports and Helpful Tables of Food Data. Compiled by the Nutrition Laboratory Research Department of the American Can Company. Cloth. Pp. 110 with illustrations. New York: American Can Company. 1937.

The canning of foods began more than a hundred years ago as a result of the need by Napoleon to preserve food for his armies. Today the canning of foods is an enormous peace time industry, but textbooks on nutrition have largely neglected to discuss the nutritional significance of these products. This little volume contains information about the human dietary requirements and on the nutritional, bacteriologic and other public health aspects of canned foods. There are interesting chapters on the manufacture of cans and the various canning procedures. The appendix provides information in tabular form about the chemical composition and dietary value of canned foods. A selected bibliography is appended.

Digitalslibel für den Arzt. Von Prof. Dr. Ernst Edens. Paper. Price 1.80 marks. Pp. 39. Berlin: Julius Springer. 1937.

The primer gives a sketchy history of the digitalis bodies (51 pages), an equally sketchy discussion of their chemistry and pharmacology (seven pages), a discussion of their clinical use, and emphasizing especially the use of strophanthin in certain conditions. Those who are familiar with efforts to popularize the routine intravenous use of strophanthin are acquainted with the work of Edens and Fraenkel, who recommend the use of strophanthin in many conditions in which digitalis is preferable. It is nevertheless surprising to find no less than twenty references to the papers of these two authors in this booklet. It is not probable that this primer will serve any useful purpose in promoting the scientific treatment of cardiac disease.

Etudes sur les maladies de l'enfance. Par A. B. Marfan. Professeur honoraire à la Faculté de médecine de Paris. Paper. Price 30 francs. Pp. 191 with 6 illustrations. Paris: Masson & Cie. 1936.

This book consists of clinical essays, each about twenty pages in length on scrofula, rickets, lymphatism, intermittent albuminuria, headache of school children, involuntary defecation, spasmodic paraplegia, varicella, pericardial puncture, and extubation. The discussions are mainly clinical and are based on the writer's experience. Throughout the book more than in most American writings greater emphasis is laid on syphilis and tuberculosis as etiologic factors. Some of the author's hypotheses are not widely known in this country. He believes that infections are important in the causation of rickets. It

feels that the value of the ergosterol in our tissues lies in overcoming chronic infections when it is activated by sunlight. Intermittent albuminuria, although frequently postural, has its real origin in a mild kidney infection which has healed but left the kidney with slight functional damage. For the mature pediatrician, the excellent clinical descriptions and observations make stimulating reading. The book can well be read by any one wishing succinct clinical lectures by an authority of another land.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Dental Practice Acts Injunction to Restrain Enforcement of Legislative Ban on Advertising—The plaintiff, a licensed dentist, owned and operated a chain of dental offices in Iowa. In connection therewith, he advertised extensively in the newspapers. In 1935 the legislature of Iowa forbade all advertising by dentists other than the use of professional cards and window or street signs at the licensee's places of business. The plaintiff thereafter instituted proceedings against the state commissioner of health and others to enjoin the enforcement of the ban on advertising. The trial court dismissed the plaintiff's petition and he appealed to the Supreme Court of Iowa.

The appellant did not apparently question the right of the state, under the police power, reasonably to regulate the practice of dentistry but urged strenuously that the legislation must bear a fair relation to the public health, morals, safety or general welfare of the people, and that so long as there is nothing untruthful in advertising matter the public welfare is not adversely affected. He contended, further, that the legislature in attempting to regulate the practice of dentistry, had destroyed his right to practice. But, the court said the restrictions placed on advertising have the sanction of the dental profession as a whole. They are intended to preserve the profession, not to destroy it. Such laws are not enacted for the benefit of any class of individuals but in the interest of the general public. In the sense that they tend to prevent an unseemly rivalry in a race for business and preserve a rational, reasonable and ethical approach to the public and aid the profession in maintaining its service on a high plane of efficiency, such laws may be said to be beneficial to the profession as a whole. But this is not the primary purpose of the law. It is but one of the beneficial and beneficent fruits of the law. By making unlawful all methods of advertising calculated to bait or allure the public, the quack the charlatan and the exploiter are deprived of any means of plying their art. Likewise the member of the profession who would seek to commercialize it by boosting himself through extensive use of methods of publicity, extolling the superiority of his services, thereby forcing his competitors into a race for business, to the demoralization of the high standards and established ethics of the profession—all of which worketh ill to the public—is successfully thwarted in his purpose. It is true, said the Supreme Court, that the authorities are not uniform in relation to this matter of truthful advertising, and many of the earlier cases may be cited to the effect that legislation of this character can only be directed toward eliminating advertising which is false and fraudulent and intended to deceive the public. More recent cases, however, seem to go deeper into the philosophy and purpose of such legislation.

The experience of mankind said the court, has shown that human greed and avarice, untrammelled and uncontrolled by law, will not hesitate to prey on the frailties of overcredulous human beings. Those affected by real or imaginary ills are an easy prey. The unscrupulous as well as some of the more honorable but avaricious members of the profession, in disregard of the ethics of their profession, are many times overcome by the great temptation to become rich at the expense of humanity, with all its afflictions. They have resorted to all the devices of the faker on the street corner and of the skilful

artisan of expert advertising and radio propaganda, some even going beyond the borders of the United States with their broadcasting stations, where they may exploit their victims without hindrance. Such methods are demoralizing to the profession and detrimental to society. While the object of the statute is to strike at the charlatan and unscrupulous practitioner, no legislation can be upheld which would apply alone to the quack. Such legislation must be general in its application and rest alike on all members of the profession concerned. The best interests of the public demand that members of a profession affecting the public health stand or fall on the merits of their services, not on their skill in advertising.

It was for the legislature to say whether or not it was necessary that all advertising except that designated in the statute be prohibited. That is the real pith of the controversy in this case. There is no claim that in itself there is anything harmful in advertising prices for dental work or displaying signs illustrating bridgework, or running stories in the newspapers. It must, however, be admitted, said the court, that there are some dishonest and disreputable members of the profession who are not willing to abide by what is commonly called the ethics of their profession, and who make use of such methods of advertising. The unsuspecting public and overcredulous members of society, unable to distinguish the true from the false, or the honest from the dishonest, are lured to the offices or lairs of the professional charlatans, who point to their array of expensive office equipment and overstuffed furnishings to convince their unsuspecting patients of their superiority, and use this as an excuse for "fleecing them." In order to reach this evil and attempt to correct it, in the interest of the public welfare individual rights must give way to the greater rights of the whole people. While under the Iowa statutes the limitations on advertising are rigid, they are not too rigid when the purpose or aim of the law is considered. The law, in the opinion of the court, bears a fair relation to matters of public health and the moral and physical welfare of the people.

The Supreme Court did not agree with the appellees' contention that the plaintiff had no standing in a court of equity. The enforcement of this law, the court said, will undoubtedly constitute a serious restraint on the plaintiff's prior methods of conducting a lawful vocation and will result in a financial injury. If the law is unconstitutional and void, he has a right to restrain its enforcement. He is not required to take the risk of forfeiting his license before he may proceed in equity to challenge the constitutionality of the law. It would be an unjust and arbitrary rule which would require him to proceed first openly to violate the law and thus place himself and his property rights in jeopardy in order to place himself in a position to have determined the question of the constitutionality of the statute.

While holding that the plaintiff had a right to proceed in equity, the Supreme Court was of the opinion that the decree of the trial court denying the plaintiff's petition for an injunction was correct. The decree was therefore affirmed.—*Craven v. Bierring, State Commissioner of Public Health, et al (Iowa), 269 N. W. 801*

Malpractice Physician an Independent Contractor, Not an Employee of Corporation—One of the defendants, a physician, was employed on a part time basis by the New York Telephone Company, a self insurer under the workmen's compensation act of New York, to render medical services to employees in emergency cases and to examine employees in connection with its disability benefit plan and its pension system. The plaintiff, an employee of the company, consulted the physician-defendant because of a pain in her foot. The condition, osteomyelitis, had no connection with her employment. She later sued the company and the physician, contending that because of the latter's negligent treatment she sustained injury. The trial court gave judgment against both defendants for \$40,227.39 and they appealed to the supreme court of New York, appellate division.

The defendant company was held liable on the theory that the physician was the servant of the company for whose negligence it was responsible. But, said the appellate court, the doctrine of respondeat superior has no application to the facts presented by the record. A physician employed under the cir-

cumstances of this case is not a servant of his employer but is engaged in an independent calling and his status is that of an independent contractor. Furthermore, the court continued, the evidence against the physician-defendant showed, without contradiction, that the plaintiff at the time she first saw the physician had a disease condition of the bones of her foot which had existed for at least two months and which grew progressively worse thereafter. The only damage for which the physician could be held responsible was for an aggravation of the existing condition resulting from his failure to treat the plaintiff properly. This issue, however, was not presented to the jury. The only issue presented was whether the alleged malpractice of the physician was responsible for the entire condition which developed. The finding of the jury in the plaintiff's favor on this issue was, in the opinion of the appellate court, clearly against the weight of the evidence.

The judgment against the telephone company was reversed and the complaint against it dismissed. The judgment against the physician was reversed and a new trial ordered—*Schneider v New York Telephone Co et al (N Y)*, 292 N Y S 399.

Malpractice Loss of Eye Attributed to Negligent Treatment of Gonorrheal Ophthalmia.—The plaintiff consulted the defendant, a specialist in diseases of the ear, eye, nose and throat, because of a badly infected and swollen eye. A diagnosis of gonorrheal ophthalmia was made and a course of treatment instituted. After eight days of treatment, the plaintiff consulted a specialist in another city who found the eye full of pus and badly swollen. There was a perforation of the cornea and prolapsus of the iris. Since sight from the eye was destroyed and could not be restored, this specialist removed the eyeball. Subsequently, the plaintiff sued the defendant, attributing the loss of the eye to his negligence. The trial court directed a verdict for the defendant and the plaintiff appealed to the district court of appeal, fourth district, California.

The degree of skill and care required of the defendant as a specialist, the court said, is stated succinctly in Ann Cas 1915D, 1124, as follows:

One who holds himself out as a specialist in the treatment of a certain organ injury or disease is bound to bring to the aid of one so employing him that degree of skill and knowledge which is ordinarily possessed by those who devote special study and attention to that particular organ injury or disease its diagnosis and its treatment in the same general locality having regard to the state of scientific knowledge at the time.

The plaintiff based his allegation of negligent treatment on the contention that the defendant failed (1) to cap the uninfected eye, (2) to hospitalize the plaintiff, (3) to take and test a smear from the infected eye and (4) to use more energetic treatment on the eye. Even if good practice required the defendant to cap the uninfected eye the court said, that eye did not become infected and the failure to cap it was neither a proximate nor a contributing cause of any injury suffered by the plaintiff. Furthermore there was no evidence to show that hospitalization of the plaintiff was required by the standards of good practice in and around the community. The specialist who enucleated the eyeball testified that hospitalization in such cases is desirable and that he himself did not see how a patient could properly irrigate his own eye. This fell short in the opinion of the court, of proving that the standard of care in the particular community required hospitalization of patients suffering from gonorrheal ophthalmia. There was testimony to the effect that good practice required the defendant to take a smear from the infected eye to determine the nature of the infection and the type of treatment required, the nature of the treatment being dependent on the nature of the infection and its virulence. The defendant, however, recognized immediately the nature of the infection on his first examination. The only merit to this particular contention would depend, therefore, the court said on the propriety and efficacy of the treatment administered by the defendant.

According to the record, the defendant, after diagnosing the condition as gonorrheal ophthalmia irrigated and cleaned the eye painted the lids with a 1 per cent solution of silver nitrate, and placed two drops of atropine solution in the eye. He administered this treatment daily during the eight days that

the plaintiff was under his care. He also advised the plaintiff to apply ice compresses continuously, to keep the eye clean with frequent irrigations of a salt or boric acid solution, and prescribed a one-half of 1 per cent solution of zinc sulfate with directions to place two or three drops in the eye every two hours. Subsequently, the zinc sulfate solution was discontinued and a 15 to 20 per cent solution of neosilvol was substituted. The specialist who operated on the eye, testifying for the plaintiff, said "If I were treating such a case, I would want to have more energetic treatment. In this serious disease the outcome might be grave in any event." He admitted, however, that "there is a great difference in the opinion about the use of drugs" and that each step in the treatment administered by the defendant was proper. Thus, in the opinion of the court, did not prove that the defendant did not bring to the case the required degree of skill and knowledge. The evidence only tended to prove that in the opinion of the witness a method of treatment other than that employed by the defendant might have produced a better result. Such evidence was not sufficient to make out a case for the plaintiff.

The judgment of the trial court for the defendant was therefore affirmed—*Jensen v Findley (Calif)*, 62 P (2d) 430.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

- Incidence of Trichomonas Vaginalis Infections. S B Potter Denver—p 169

Eclampsia and Its Sequels—Teel and Reid present a study of 173 patients with eclampsia who were treated at the Boston Lying-In Hospital from 1915 through 1934. The uncorrected mortality was 26.6 per cent. The mortality for patients who had attended the clinic prior to the development of eclampsia was less than for those admitted as an emergency measure. The mortality was higher in multiparas than in primiparas and was also higher in patients more than 30 years of age. Of the 127 survivors of eclampsia, eight have subsequently died, three of recurrent pregnancy toxemias, two of severe hypertension with cerebral lesions, one of cardiac decompensation, one of lobar pneumonia complicated by hypertension and possibly chronic nephritis, and one of cancer of the cervix. In eighty patients who survived the eclampsia and who have been followed for more than from one to twenty-one years (average 7.6 years) the incidence of hypertension was 27.5 per cent and the incidence of albuminuria 8.75 per cent. Evidence of significantly impaired renal function was found in only one case. A significant number of these patients had hypertensive disease or nephritis prior to the eclampsia, and both the immediate and the remote outlook for them was considerably poorer than for those known to have been normal before the eclampsia. In the twenty-nine patients followed who were known to have been healthy prior to the eclampsia, the incidence of subsequent hypertension was 10.3 per cent and that of albuminuria was nil. Such symptoms as were encountered at follow up examination were largely explicable on the basis of hypertensive disease.

Gonorrhea in Female Treated by Combined Heating Technique—The procedure that Bierman and Horowitz now follow in the treatment of gonorrhea in women is first to elevate the systemic temperature by short wave currents while the patient lies in a cabinet heated by electric lamps. After the systemic temperature has been elevated to about 106 F they apply the additional local heating to the pelvis, principally by means of diathermy, supplemented for an hour or two by ultra-short waves. At the same time the systemic temperature is maintained at its elevated level. The treatment (121 cases during the last six years) is strenuous and not without danger. It is a hospital procedure. Adequate apparatus, trained personnel and continuous watchfulness are necessary. Physically induced fever is combined for six hours with pelvic diathermy and for two hours with pelvic short waves, so as to produce

a vaginal temperature of about 109 to 110 F, while the body temperature is held between 105.5 and 106.5 F and continued for a period of about twelve hours. While usually from one to three such treatments may be required to eradicate all gonococci, the average number found to be necessary in the authors' last series of fifty-four patients was 1.4 per patient.

Treatment of Obstructed Fallopian Tubes in Sterility—Mintz finds that diathermy treatment combined with insufflation exerts a reparative influence on some chronically diseased tubes, leading to the restoration of patency, and is followed by pregnancy in many instances. The beneficial effects of diathermy are produced by the action of heat. The heat is generated by a high frequency current passing through the tissues between two metal electrodes, the greatest concentration of heat being near the smaller electrode. Of the forty-four patients treated, patency was reestablished to some degree in twenty-five, nine of whom became pregnant and gave birth to normal children. Ectopic pregnancy occurred in two patients, necessitating operation. In fourteen instances no pregnancies have been noted as yet. Each patient received diathermy treatments from one to three times a week, the total ranging from fifteen to fifty-nine treatments. Each treatment lasted from thirty to forty-five minutes, and from 2,500 to 3,000 milliamperes of current with the abdominal and sacral electrodes was used. When the abdominal and vaginal electrodes were used, the current employed was from 2,000 to 2,500 milliamperes. The electrodes were a concave vaginal electrode, and for the abdomen and sacrum ordinary Cook's malleable tin metal, 5 by 8 inches long, 22 gage.

Roentgenologic Diagnosis of Cardiac Compression—Freedman points out that the roentgen diagnosis of cardiac compression due to pericardial scar tissue formation is made by the utilization of several signs the most conclusive of which is the pericardial calcification. Aside from the latter only the finding of several of the individual signs justifies one in making an unequivocal diagnosis. The roentgenoscopic examination is of greater importance than the roentgenographic because important respiratory changes in the position and configuration of the heart and diaphragm can be elicited with ease. The knowledge of the clinical history is important, because it leads to a search for some of the signs which are not obvious and have to be elicited. One of the most important signs is the marked discrepancy between the clinical symptoms of cardiac decompensation and the absolutely or relatively small shadow of the heart. A marked enlargement of the cardiopericardial shadow is rare. The cardiac configuration is variable. The triangular heart is common, while others show an abnormal bulging on either the left or right contour. The cardiac pulsations are abnormal. They are either diminished in amplitude or absent throughout the entire heart or throughout certain sections as seen by roentgenoscopy and by kymographic studies. Similarly, abnormal pulsations can be found in pericardial effusions and in cases of decompensation due to cardiac dilatation. However, the compressed heart is rarely large enough to suggest

either of these two conditions. The lack of plasticity and the presence of fixation of the heart are determined by examination during the inspiratory and expiratory stage with the patient in the erect postero-anterior and lateral positions and in both lateral recumbent positions in the postero-anterior direction. Calcification of the pericardium, the most conclusive single sign, is present in only the minority of cases.

Changes in Lungs and Pleura Following Irradiation—In fifty-one consecutive patients with malignant tumors of the thoracic wall treated intensively by means of x-rays, radium and radon, Hsieh and Kimm observed that definite roentgenographic evidence of postirradiation changes was demonstrated in the lungs and pleura of twelve patients. The series included forty-seven cases of carcinoma of the breast, two cases of recurrent fibrosarcoma of the back, one case of hemangioendothelioma of the supraclavicular region and one case of recurrent fibrosarcoma of the upper part of the wall of the chest. The postirradiation changes were all observed in patients treated for carcinoma of the breast. These changes included pleural thickening, increased lung markings, contraction of the lung and shifting of the mediastinum. The postirradiation changes were believed to be due to a late fibrous tissue reaction following a more acute congestive change, and to be comparable to the irradiation reaction which may occur elsewhere in the body. Acute congestive reactions, as evidenced by pleural effusion soon after the irradiation, were observed in two cases. Chronic pulmonary tuberculosis, the infiltrative type of pulmonary metastasis and interstitial pneumonia were considered in the different diagnosis. In all the cases in which definite changes occurred in the lungs and pleurae signs, symptoms and laboratory evidence of the foregoing diseases were not encountered.

Shock Following Intravenous Neosarsphenamine—Weinberg presents three cases of shock following intravenous therapy with neosarsphenamine. All three patients exhibited a typical clinical picture of shock. The first two patients remained in shock for about six hours each, while the third patient maintained this state for about six days. All three were admitted to the wards with palpable peripheral pulses and unobtainable blood pressures. Patients 1 and 2 at first presented signs and symptoms characteristic of the nitritoid crisis, but none of the three responded in the least to epinephrine or similar stimulants. They did, however, respond well to the usual shock therapy, patients 1 and 3 receiving intravenous fluids, while patient 2 was treated with heat to the extremities and oxygen. Patients 1 and 2 presented marked cyanosis. All three suffered from persistent vomiting and cold sweats with cold clammy skins. Patients 2 and 3 showed marked increase in the concentration of hemoglobin and erythrocytes in the peripheral blood. The nonprotein nitrogen determination was greatly increased in patient 1 seven days after admission. All three showed an elevation in temperature during the first few days, and this, accompanied by nausea and vomiting has been described by Boardman as in itself a characteristic sign of intolerance to arspenamine and its derivatives. The mechanism of the production of shock in general and by the arspenamines

in particular is discussed briefly. It is suggested that arsenoxide plays a part in this toxic manifestation, but in addition there appears to be an α factor yet to be discovered.

Typhoid H Antigen Vaccine in Treatment of Neurosyphilis—Kulchar and Anderson used typhoid H antigen in the treatment of thirty-eight unselected patients (nine women and twenty-nine men) with various forms of neurosyphilis. All except two patients had previously received considerable amounts of antisyphilitic treatment, and fever therapy seemed indicated because of the unsatisfactory clinical or serologic response. The H antigen suspension was prepared by adding 0.5 per cent phenol in physiologic solution of sodium chloride to a twenty-four hour broth culture of motile typhoid bacilli. On filtration the somatic (O) antigen is blocked off, resulting in a water-clear saline filtrate containing the flagellar (H) antigen. The filtrate is standardized so that each cubic centimeter contains the flagellar antigen obtained from two billion typhoid bacilli. A preliminary dose of from forty to fifty million organisms (killed bacilli equivalent) was given intravenously by means of a 26 gage hypodermic needle. Usually, but not always, a moderate chill lasting from ten to thirty minutes occurred from one to two and one half hours after the injection, at which time the patient was closely wrapped in woolen blankets and the temperature taken every half hour until it returned to normal. Increase in temperature usually began at the time of the chill and required from two to three hours to reach its peak, which varied between 103 and 105.6 F. The temperature remained at the maximal level from one half to one hour, following which it gradually declined, returning to normal in from six to twelve hours. The rise in temperature was accompanied by an increase in pulse rate, never above 120 per minute. Except for the feeling of warmth, the patients were fairly comfortable for the most part. Sedatives of the barbiturate series were used to control any unusual restlessness during the period of fever. The doses for subsequent injections were determined by the febrile response to the preceding dose. The increases varied from 25 to 600 million per injection. After the first day, doses were divided into two portions, the second injection of the slightly lower dosage being given as soon as the temperature started to rise. Fever was induced daily by this method until the patient had received a total of from ten to eighteen days of treatment, a day of rest usually being given after each six days of fever. Each day as the temperature returned to normal the patients were allowed up about the ward. Aside from the slight loss of weight and the frequent occurrence of herpes labialis, no ill effects were observed and the patients were able to leave the hospital two or three days after completing treatment. Patients were observed for periods varying from five to twenty six months after receiving fever therapy. There were 28.5 per cent of reversals and 57.1 per cent of instances of marked improvement in the spinal fluid formula. This compares favorably with the 36.7 per cent reversals and the 20.7 per cent instances of improvement in the spinal fluids reported by Solomon and Epstein following malarial therapy. Fever therapy with typhoid H antigen provides a method that may be carried out in the home by a nurse under the supervision of a physician.

Unsteadiness of Heart Rate in Psychotic and Neurotic States—Whitehorn and Richter find that psychotic patients, even when reacting with so-called affective behavior in a personal interview, maintain a steadiness of heart rate greater than that of normal subjects, whereas neurotic patients tend toward a greater unsteadiness of heart rate. The average unsteadiness of heart rate as measured by the percentage change per beat was 29 per cent for the psychotic patients, 6 per cent for the neurotic patients and 44 per cent for the normal subjects. The different groups overlap each other. Another point of distinction which rates psychotic persons as less variable is brought out by the comparison of the amplitude of waves on the heart records. On the basis of this comparison of wave amplitudes, normal and neurotic persons are nearly alike.

Prevention of Sequels of Meningitis—Eagleton suggests that physicians attempt to prevent the ocular sequels of meningococcal meningitis by treating the various lesions causing the ocular disturbance at the site of the embolic infarction in a manner similar to that now employed in the treatment of suppurative meningitis. The optic nerve is involved as a perineurosis. There is no papilledema from pressure. The impairment of hearing associated with pyogenic meningitis is due to effusions in the arachnoid space, the deafness is never complete, because the eighth nerve withstands pressure well. On the other hand, the deafness associated with meningococcal meningitis is generally complete, because the disease involves the vessels of the nerve tissue itself either in the labyrinth or in the brain. With the embolic process of meningococcal infection, nystagmus is present for some time immediately after the invasion of the labyrinth. The author suggests that the

therapist from the beginning of meningococcal meningitis try to differentiate (1) embolic lesions of the blood stream (such as the intra-ocular effusions) from (2) those due to cerebral meningoencephalitis, and that serum be applied as near the site of the lesion as is possible. In cases in which there is vertical nystagmus, putting serum into the basal cistern should be tried as in all such cases up to the present time the condition has terminated fatally. If emboli lodge in the eyeball the injection of serum into the anterior chamber or even into the vitreous might be tried, as in all such cases the condition ends in blindness and is known to be of blood vessel origin. Increased intracranial pressure due to meningococcal meningitis can be relieved surgically.

Verruca—Hutton introduces a new method for the treatment of warts, which consists of the injection of a small amount of some sclerosing agent into the base of the wart. The injection is made with a tuberculin syringe and a fine gage needle and is accompanied by a surprisingly small amount of pain. After a few days the wart becomes dry and hard very much like a callus and after ten days, two weeks or longer, depending on the size of the wart and the thickness of the surrounding skin, the wart comes off or can be trimmed off, leaving a practically normal skin underneath. The following solutions have been used: quinine and urethane, 50 per cent invert sugar, equal parts of 50 per cent dextrose and 30 per cent sodium chloride, sodium morrhuate and potassium oleate. The heavier solutions have a distinct advantage in that they remain localized at the point of injection with less infiltration of surrounding tissue and therefore cause less pain. This increased localization seems also to increase the chance of curing the wart. The sclerosing solution should be injected into the wart rather than into the corium or the subcutaneous tissues underneath the wart. This aids greatly in keeping the injected solution localized by preventing infiltration into the surrounding tissue and minimizing not only the pain but also the resulting reaction within the tissues produced by the foreign substance.

Production of Hyaline Arteriosclerosis and Arteriolonecrosis by Means of Proteolytic Enzymes A R Rich and G L Duff Baltimore—p 63

Lead Encephalitis in Children—Blackman describes twenty-two cases, all occurring in children, in which the evidence of lead poisoning was clear in each instance. In most cases lead was ingested by nibbling painted articles, usually furniture. Paint may be swallowed in this manner for many months (from five to eighteen months in this series) before the onset of neurologic disturbances. Lesions are found throughout the entire central nervous system. They are most abundant in the cerebral hemispheres and cerebellum. All the changes are patchy in distribution, but examination of many sections shows the presence of numerous lesions. The microscopic changes are those of a serous inflammation. Vascular lesions are found, including capillary necrosis and thrombi, together with abundant exudate, tissue damage and evidence of repair. Most of the injury to the nervous tissue seems dependent on the accumulation of exudate. Fresh serous exudate and the older droplets cause distortion of the architecture of the brain, depending on the location and quantity of the fluid. Fields in the gray and white matter diffusely saturated with exudate contain many damaged and necrotic nerve and glial cells, and there is marked tearing and necrosis of fibers. In patients who recover after the initial convulsions, functional disorders varying from mental retardation to spastic paralysis may be expected, depending on the intensity and location of the injuries. Microscopically, there is a corresponding loss of tissue in the gray and white matter of the brain and cerebellum. Remnants of old coagulated exudate are found, basophilic in appearance like calcium, and basophilic plaques in the walls of blood vessels.

Classification of Monilias—Martin and his colleagues studied 153 unidentified strains of *Monilia* isolated from various sources and compared them with nineteen "known" species types obtained from other investigators. They classified 150 of these organisms into one of six species. The methods used in classification are comparatively simple and the criteria on

which identification is based are easily recognizable and the technic described is rigidly followed. An outline of the procedures necessary for identification is as follows. The fungus is isolated on Sabouraud's dextrose agar slant, transplanted to Sabouraud's dextrose acid broth and incubated at 37 C for forty-eight hours. After the type of surface growth has been noted, the tube is shaken to suspend the sedimented organisms and streaked on a beef extract blood agar plate of pH 7.4, which is incubated at 37 C for ten days, the type of colony is noted, and a well isolated colony is picked and transplanted to a Sabouraud dextrose agar slant. This is incubated at room temperature or 37 C for twenty-four or forty eight hours. Some of the growth is transplanted to a carrot plug, which is kept at room temperature and subsequently examined for ascus. The rest of the material is streaked on the surface of a beef extract agar slant pH 7.4. The growth is subcultured on this medium for two or three generations and a loopful is streaked on a corn meal agar slide culture, which is incubated at room temperature in a moist sterile chamber for several days. The slide is then fixed, stained and examined microscopically for details of mycelial growth. Four beef extract broth tubes, containing 1 per cent of dextrose, sucrose, lactose and maltose respectively, are inoculated with a pipet containing a saline suspension of the last transplant of the fungus on the beef extract agar slant.

Effect of Ammonium Chloride in Mountain Sickness—Barron and his associates consider the disturbances produced as a consequence of rapid ascents to high altitudes. The alveolar air and the arterial oxygen saturations which they determined in subjects suffering from mountain sickness revealed only that in rapid ascents up to 4,700 meters the development of mountain sickness has no simple dependence on the arterial oxygen saturation and the alveolar oxygen pressure. Arterial

nium chloride offers a handicap rather than an advantage (Haldane) in acclimatization. Since mountain sickness may be due to diminished oxygen utilization by certain tissues, the factors concerned with the maintenance of a suitable oxygen supply to the tissues are the vascular oxygen transport system (blood hemoglobin), the efficiency of which is regulated by the arterial oxygen capacity and saturation and by the alveolar oxygen, and the tissue oxygen transport system (myoglobin and part of the cytochrome complex), the efficiency of which is regulated by the blood flow, the state of the capillaries and the like. Since mountain sickness may occur when the vascular oxygen transport system is still within normal limits, it is suggested that the tissue oxygen transport system plays an important part in determining the appearance of mountain sickness, because it contains and transports the molecular oxygen, which will be immediately utilized by the oxidizing enzymes, i. e., the enzymes concerned with cellular respiration.

Rheumatic Fever as Familial Disease—From the genetic analysis of their data (112 families observed from three to eighteen years) Wilson and Schweitzer conclude that the susceptibility for rheumatic fever is transmitted as a single autosomal recessive gene. This may be said with some assurance, since it is based on quantitative agreement between observed incidence and the value predicted from this hypothesis. A consideration of penetrance is of importance in diseases in which hereditary factors play a part. In the case of a recessive disease, the best method of estimating penetrance is from the progeny of positive parents. In the authors' series, four families in which both parents were positive had fifteen siblings. Of these, thirteen were rheumatic. Of the remaining two children, one is now 7 years old and the other is 15. The penetrance is therefore 86 per cent. Of thirteen additional siblings examined in five similar matings, ten were rheumatic, taking all these cases together there is a penetrance of 82 per cent. The failure of a dominant factor to be expressed in any generation may be attributed to poor penetrance. The high penetrance observed in families of positive parents in these families excludes this possibility for the authors' cases. If penetrance is found to be lower in different geographic localities or economic groups, or following particular changes in the environment, important progress will be possible in the prevention of this disease. In clinical investigation it would be advisable to select not a sample of the general population but a series of subjects whose genetic constitutions are known. The evaluation of the efficacy of proposed treatment would be the ratio of positives in the series compared with the predicted incidence for their known genetic background. Accepting the hereditary transmission of a susceptibility to rheumatic fever, it is interesting to consider whether every susceptible individual will necessarily develop rheumatic fever, or whether the development of the disease is dependent on other factors. From what is known of the disease, it is more likely that other contributing factors are involved, such as environment and exposure. Should comparable studies of the familial incidence of rheumatic fever in families of the well-to-do, living under more favorable climatic conditions, reveal a diminished incidence of the disease among susceptible individuals of the family, a preventive therapeutic method would be available in this disease. There was no direct relation between the type and source of exposure and the resulting activity. The incidence of rheumatic fever following "active exposure" and "inactive exposure" was comparable. Intimate contact ("familial exposure") and casual contact ("extrafamilial exposure") were equally effective.

Vitamin B₁ in Cardiovascular Diseases—Clinically, the thirty patients with cardiovascular disease whose diet Jones and Sure supplemented with vitamin B₁ were easier to manage, were contented and used less medication than any group they have had under their supervision. With the exception of three patients, all stated that they felt better than they had in years. Respiration average of the thirty patients for the first week was 21 and the average for the last week under treatment was 18½. Pulse rate average for the first week was 89, the last week 79. Blood pressure showed definite improvement, with exception of one case, and the blood pressure gradually increased in this one instance. The patients were walking from two to four miles a day at the time of discharge from the hospital and reported no undue ill effects. Their respiration and pulse rates and blood pressure showed improvement over admission to this hospital after indulging in exercise. Whether this improvement is entirely due to vitamin B₁ therapy or not the authors are unable to say. There were no deaths and the average length of hospitalization was 114 days.

Recovery After Second Attack of Meningococcal Meningitis—The dividing line between relapse and fresh infection is difficult to establish. For practical purposes Schaffer and Freeman consider a patient as recovered when, while ambulant, examination of the cerebrospinal fluid shows a normal number of cells, persistent negative spinal fluid culture under lowered oxygen tension, normal spinal fluid sugar and chloride values, normal temperature and pulse, and absence of abnormal neurologic signs. Newer immunologic agents may yield opportunities for certainty, and active immunization may lower the incidence of second infections as well as primary infections. Since it is not possible at this time to be certain when an infection with the meningococcus is ended, patients who have had the disease must be regarded as potentially liable to additional attacks. In their two cases the second attack of the disease was proved each time.

Fever Due to Exercise—Hawke bases his remarks on a study of 2,500 temperature readings from thirty children varying from 3 to 14 years of age. The children selected were those with no physical defects other than the common dental or visual abnormalities. Each child had been admitted because of behavior problems due to maladjustment at home or at school. The temperatures were taken rectally at 6 a. m. before

arising, at 11 a m before lunch, at 4 p m before supper and at 8 p m before retiring. In addition to recording the temperature, a note was made of the type of exercise and the activity of the child for an hour or so before his temperature was taken. No specific exercises were given and the children followed out the usual routine of the home. The exercise was, for purposes of analysis, divided into two types: mild, which consisted of school, cinema, council or walking about the wards, and severe, which consisted of sleighing, skating, basket ball and baseball. There is definite proof that exercise will raise the body temperature. The average resting temperature for all the children was 98.2 F and varied from 97.3 to 99.8 F. When the results are considered after mild exercise it is found that the average level was 99.2 F and that 90 per cent of the children had a temperature above 99 F. The average reading after severe exercise was 100.2 F and in 70 per cent of the children more than 100 F. Every child showed some elevation in temperature after exercise. The height reached in most cases depended on the activity of the child, but in a few cases this correlation was not true, and one must suspect some constitutional factor probably involving the heat regulatory centers. The response of the individual to exercise is fairly constant, although occasionally there were marked differences in the readings obtained after similar activities on different days. There is apparently no relation to sex or age and some of the highest values were obtained from children of 12 years or older. In order to see how long the temperature would remain up after exercise, some of the 4 p m readings were checked every thirty minutes until the children were in bed. The time taken for it to fall to 99.2 F, the level of mild exercise, varied with the routine chosen. If the children were allowed to carry on the ward routine, only a few reached that level within sixty minutes and most temperatures were up until bedtime or later. If the children were put to bed at 4 p m, most temperatures reached that level within sixty minutes.

Care of Skin of the New-Born—Owing to the fact that the frequency of skin lesions in the new-born infant is still unknown, Sanford began a study in 1930 by examining the skins of new-born infants at birth and each day thereafter. All lesions of any type were noted. The lesions were classified into three groups: (1) irritations, including all erythematous macules and papules, as erythema toxicum and all forms of intertrigo; (2) pustules, including all vesicles and pustules, as the so called benign pustulosis, impetigo and pemphigus neonatorum; and (3) pustules with exfoliation, that is exfoliative dermatitis, but there was no case of this in the series covering six years. There was no seasonal incidence for either irritations or pustules. There is no apparent relationship between irritations and pustules, that is, an increase in the frequency of irritations does not mean an increase in pustules. There is no doubt that some internal factor acts as a cause of toxic erythema. The incidence appears to be about the same irrespective of the external treatment. It may be that something in the colostrum in the nature of hormones may be responsible, and it has been suggested that this is a pregnancy reaction. Babies with this condition show no other symptoms of any kind. Other erythemas and intertrigo are due to outside mechanical irritations. For the first few days, improperly laundered linen is the commonest cause. After the first week, circumcision was the chief cause of irritations. The skin of some new-born infants is sensitive to the antiseptics used to sterilize the field, and the skin of others is sensitive to the petrolatum used in the dressings. There was but little difficulty with intertrigo. Buttocks reddened from loose stools healed promptly when exposed to air and the heat from an ordinary incandescent bulb at a distance of 20 inches. Irritations caused by rubbing the face with the hands responded quickly after encasing the baby's hands in silk mittens. Nursing technic and the isolation of infants with initial lesions is one of the greatest factors in the control of skin lesions in the new-born. Beginning in 1935, with some hesitation the author decided to leave the skin of the new-born infant entirely untreated. The excess blood was gently wiped off and nothing further was done for nine days. This method has been so satisfactory that it has been continued. The number of irritations is practically the same as it was with the olive oil alone, ammoniated mercury and olive oil,

and ammoniated mercury and water, but the most astounding result was the practical absence of pustules. During the entire year only one pustule was found on one baby. It is apparent, therefore, that the skin of the new-born infant, if left alone and not injured by rubbing with an antiseptic or irritated with washings, tends to clear itself and seems to give some immunity to infection. After the first nine days, olive oil or liquid petrolatum may be used for the daily bath. From a physical standpoint the skin of these new-born infants is much more pink and healthy appearing than is the skin washed with oil or water.

New England Journal of Medicine, Boston

217 45 84 (July 8) 1937

- *Lymphogranuloma Inguinale. Clinical Study of Thirty Cases of Syphilis. Venereal Disease in Natives of New England. E. M. Chapman and E. P. Hayden. Boston—p. 45.
- Surgery of Prostate, Open and Closed, with Especial Reference to Technic. J. F. McCarthy. New York—p. 57.
- Progress in Anesthesia. R. F. Sheldon. Boston—p. 64.

Venereal Lymphogranuloma—In the last three years at the Massachusetts General Hospital and in private practice Chapman and Hayden saw the several manifestations of venereal lymphogranuloma in thirty white persons of all social level, most of whom have never been outside New England. Furthermore, the confusion of this disease with other venereal disease, malignant tumors, tuberculosis, Hodgkin's disease or simple traumatic infection gave them startling evidence that this disease entity is passing unrecognized in white people. These facts predict a wider recognition of a condition that can no longer be regarded as climatic, racial or rare. Venereal lymphogranuloma is venereal in origin, having its onset with a genital lesion that may pass unnoticed, from one to three weeks after exposure. This lesion may be a fleeting herpetic lesion resembling herpes praeputialis, an ulcerative lesion, a nodular lesion or a nongonococcal urethritis, the discharge showing only polymorphonuclear leukocytes without organisms. Nonvenereal and extragenital infections are extremely rare but possible. The thirty patients described had Frei tests positive to human antigen. In the entire group of cases a previous history of gonorrhea was obtained in six and the gonococcus complement fixation test was positive in three. The routine Hinton and Wassermann tests revealed the presence of syphilis in four, only one of these four patients was cognizant of his disease, and he had received some treatment after it was acquired in 1915. In the authors' experience with the acute disease, bed rest, nursing care, local heat applied to the bubo to hasten abscess formation and simple aspiration of the pus are most important in returning the patient as quickly as possible to a useful life. He will, however, continue to harbor the disease. At best, the patient can be told that the disease comes on over a period of weeks, is in full bloom for a few weeks and subsides in the course of the following months or more. The most serious effect of this disease, and the most difficult to treat, is the involvement of the lower part of the rectum and of the vulva and perineum. Surgical incision and drainage are necessary in late cases with fistulas. An instance may occasionally arise in which the perianal infection is so widespread and intractable that colostomy is indicated in an effort to reduce the amount of infection by directing the fecal current from the involved area.

Progressive Muscular Dystrophy—Berman studied certain biochemical characteristics of progressive muscular dystrophy and the response to endocrine therapy intended to affect these biochemical abnormalities. Pathologically not much can be gleaned as to the nature or causation of the disease process. Consequently attention was turned to the study of the metabolic

hism and the regulators of metabolism, the endocrine glands, in these patients. It was at first thought that the seat of the disease was primarily in the nervous system, but the study of the nervous system has failed to reveal changes comparable in extent or gravity with those in the muscles. In the studies conducted by the author, the following metabolic changes have been discovered to be constant characters of the disease: (1) a hypoglycemia, more marked than that which occurs in any other form of myoneural disease, (2) a disturbance of the blood sugar tolerance, (3) a hypocholesteremia and (4) a creatinuria, with a disturbance of creatine tolerance. On the theory that the hormones most definitely involved in the disturbances of sugar and phosphocreatine metabolism in progressive muscular dystrophy were those of the parathyroid and adrenal cortex, parathyroid extract and adrenal cortex extract were administered to twenty-two patients in various stages and ages of the disease. Marked clinical improvement occurred in fifteen: there was a rise in the blood sugar and blood cholesterol and a normalization of the blood sugar tolerance curve together with a reduction in creatinuria and an increased creatine tolerance, signifying an increased ability of the muscles to handle creatine and apparently as a result of the treatment. These observations, correlated with recent studies concerning the relation of the parathyroids to phosphocreatine metabolism and of the adrenal cortex to sugar metabolism in muscle, would seem to indicate that progressive muscular dystrophy represents a muscular dysplasia occurring on a basis of an endocrine dyscrasia centering around a deficiency or imbalance of the parathyroids and adrenals.

Retropharyngeal Abscess in Children—Dintenfuss maintains that in all children with acute sore throat and especially with large projecting tonsils a thorough search should be made behind the posterior pillars for the presence of a retropharyngeal abscess. Early diagnosis is important because retropharyngeal abscess is always a dangerous condition, and neglected cases frequently lead to death. Cases have been reported in which death ensued as a result of hemorrhage from erosion of the internal carotid artery and still others in which the jugular vein had become thrombosed with consequent bleeding or sepsis. The bacteriology of retropharyngeal abscess gives evidence that the predominating exciting micro-organism is the hemolytic streptococcus, less frequently the staphylococcus and pneumococcus. A number of conditions should be differentiated from retropharyngeal abscess, chief of which are enlarged thymus, meningitis, laryngeal diphtheria, severe adenitis, foreign body in the larynx, osteomyelitis and tuberculosis of the cervical spine. The treatment of retropharyngeal abscess in the beginning stage consists of the application to the neck of hot moist compresses, which are changed frequently. In addition steam inhalations and hot gargles whenever possible and the injection of nonspecific protein may prove of value. When the stage of suppuration is reached, the one curative treatment is operation. Suction is employed to complete the evacuation of the abscess. Improvement following the

initial discharge of pus may be only temporary, and renewal of symptoms may occur as the result of the closing together of the wound edges. This necessitates a further introduction of closed forceps followed by more suction. The procedure may have to be repeated for several days until a cure results. If the retropharyngeal abscess has broken through into the parapharyngeal space and an incision in the pharynx is inadequate to drain the abscess cavity properly, an external incision is necessary. External incision should always be made if the abscess is tuberculous in character and has its origin in the vertebrae. In cases of hemorrhage from a ruptured carotid artery or jugular vein, or septic phlebitis of the jugular vein, ligation of the particular vessel is indicated. Case reports emphasizing the difficulties that may be encountered in the diagnosis and treatment of the condition are presented.

Disappearance of Injected Epinephrine in Animal Body—As an alternative hypothesis for the rapid disappearance of epinephrine from the blood, Weinstein and Manning suggest the following from a critical consideration of their problem. Epinephrine is not destroyed by the blood or to any significant extent by specific organs but passes rapidly through the capillaries into the tissues, where it is oxidized to a physiologically inactive substance, possibly protocatechic acid. In the present experiments, rabbits were kept on a strictly controlled diet for forty-eight hours prior to the injection of epinephrine, and the phenolic content of the urine was determined in a twenty-four hour specimen. An increase in phenolic substances was obtained after injection of epinephrine equivalent to 80 per cent of the injected drug. A portion of the urine was acidified, hydrolyzed and concentrated under reduced pressure, the residue extracted several times, the extract reduced to dryness and the dark brown mass extracted with ether produced on evaporation of the ether extract, a small quantity of crystalline material which gave characteristic tests for protocatechic acid.

Early Differential Diagnosis of Breast Tumors—Scott believes that a definite tumor fixed to the adjacent breast tissues, adhering to the chest wall and to the overlying skin, presenting a retracted nipple, a deep dimpling of the skin and massive axillary nodes, need not be broken down into a foul smelling ulcer for any one to make a diagnosis of cancer. Early differential diagnosis of the malignant breast is frequently possible by careful search for the beginning of those signs which are so pathognomonic in late cancer. Enlarged and firm axillary lymph nodes may occasionally be found early in the lower axillary area, if the tumor occupies the upper outer quadrant of the breast. The earliest effect in tissue change is manifested in increased firmness, diminished elasticity and restricted motion. Skin adhesions and dimpling may be observed in early cancer when the breast is examined by a dim light glancing across the spherical surface of the breast and the tumor is slowly moved in such a manner as to cause dragging or pulling of its fibrous attachments to Cooper's ligaments, they, in turn, pulling on the overlying skin, causing it to become flattened or dimpled long before the usual skin adhesions and dimpling are to be observed by the customary examination. This early dimpling is significant of malignant change and can best be recognized by the use of oblique rays of a spotlight, which are directed across the surface of the breast during manipulation of the tumor in a darkened room. The resulting shadows magnify the dimples and make them clearly visible. The upward pressure of a tumor in the outer half of the breast, though benign, may exaggerate the normal creases, which run transversely across the anterior axillary fold and should not be mistaken for dimpling. It is often helpful to make comparison with a normal breast, which, under manipulation, preserves its smooth spherical surface. A study has been made of 178 cases, and the shadow test was applied in the diagnosis of eighty-nine of this number. Of these eighty-nine cases, forty-six were diagnosed benign. The shadow test, showing absence of dimples, was correct in forty-two cases, or 91.3 per cent. A dimple was found within the areola in three of these cases. In one, the dimple was found external to the areola. However, this dimple was small, deep and sharply defined, and it contained scar tissue evidently due to some previous inflammatory process and not produced by manipulation. Of the forty-eight cases diagnosed malignant, the shadow test, showing definite dimples, was correct in forty-one, or 97.6 per cent. Dimples within the areola are not to be relied on in determining a diagnosis, either in favor of or against a malignant

change, and while dimples outside the areola usually may be depended on as pointing to malignant manifestation, an occasional error may occur by reason of some previous trauma, incisional scar or inflammatory process. Dimpling, as demonstrated by the shadow test, makes possible a differential diagnosis at an earlier stage of the disease than any other sign. It is particularly applicable in cases that have not advanced to the stage of demonstrable adhesions to the skin or the chest wall, and it has been of inestimable value in differentiating malignant tumors of the breast prior to demonstrable axillary metastasis.

Significance of Bleeding After Menopause—By examining the records of all the patients (349) entering the Johns Hopkins Hospital with postmenopausal bleeding between Jan 1 1919, and Jan 1, 1935, in which complete pathologic and clinical data were available, TeLinde hoped to determine the pathologic lesion causing the condition. The most frequent lesion responsible for postmenopausal bleeding was carcinoma of the cervix which occurred in 32.4 per cent. If the cases of carcinoma of the cervix are added to those of the body of the uterus (14.9 per cent), it is found that the cause of postmenopausal bleeding is due to cancer of the uterus in 47.3 per cent. If to this are added the other malignant growths (eleven cases of malignant ovarian tumors, five cases of sarcomatous change in myomas, three cases of sarcoma of the endometrium and one case each of sarcoma of the vagina and secondary carcinoma of the vagina), a total of 53.3 per cent of the cases of postmenopausal bleeding are due to malignant changes of the genital tract. Therefore every woman bleeding a year or more after her last menstrual period has more than an even chance of suffering from some malignant process. This warrants the demand for a complete diagnostic study of all such patients. It is impossible to guess as to the malignant or benign source of the bleeding from the amount or character of the bloody discharge. Some of the cases with the least bleeding proved to be due to malignant lesions, while in others the most profuse bleeding was due to benign lesions. Bimanual and speculum examinations should be a routine procedure in every case. When these measures fail to reveal the cause, a diagnostic curettage will establish the diagnosis in most instances. On following a patient with postmenopausal bleeding in whom these diagnostic measures have failed to reveal the cause, one should regard an increase in the size of an ovary, suggesting beginning neoplasm as an indication for a laparotomy, provided there is no medical contraindication.

Urea Clearance Test in Psychotic Patients—Wylie examined eleven cases of epilepsy and thirty-four cases of melancholia by the method of Addis modified by Van Slyke intended to measure the renal efficiency in terms of the number of cubic centimeters of blood cleared of urea by the urine per minute, in other words, the volume of blood which contains the same amount of urea as is excreted per minute in the urine. There were two figures for almost every patient, the first being calculated on the excretion during the first hour and the second on the excretion during the second hour. The renal efficiency fell below the standards adopted for normality in only two of the thirty-four melancholic patients and in one of the eleven epileptic patients. In seventeen of the cases in which a slight albuminuria was noted at the time of the test, six showed a renal efficiency above 130 per cent. The results indicate that albuminuria occurring in patients suffering from melancholia or epilepsy is rarely associated with renal deficiency. The two melancholic cases that showed marked renal impairment had bad prognoses.

Death from Agranulocytosis After Treatment with Prontosil Flavum J G G Borst—p 1519

Menstrual Fistulas—Malphand reports a case of uteroparietal fistula, which followed the drainage of a tuberculous pelvic abscess. Uteroparietal fistulas are of two types. In the first there is direct connection with the uterine cavity, and the fistula is usually the sequel of cesarean section. The second type is seen in conjunction with pelvic inflammation, and communication with the uterine cavity is indirect by one of the fallopian tubes or tubal stumps. In about one third of the recorded cases indirect uterine fistula has been associated with peritoneal or adnexal tuberculosis. The free transtubal men-

struation often conspicuous in cases of tubo-abdominal fistulas signifies a breakdown of the sphincteric mechanism at the uterotubal junction. Chronic inflammation, by disturbing normal tubal physiology, may play an important part in the causation of pelvic endometriosis.

Agranulocytosis After Treatment with Prontosil Flavum—Between September and December 1936 Borst treated thirteen cases of *Bacillus coli* pyelocystitis with prontosil flavum, and toxic symptoms developed in five of these. One patient became dyspneic and developed Cheyne-Stokes respiration, she was seriously ill for one day, but not cyanotic. The blood was not tested for sulfhemoglobin and methemoglobin. Three patients complained of paresthesia of the face and hands, two of them at the same time had sensory disturbances, while doing their hair they could not actually feel it. None of these patients received more than six tablets of 300 mg of prontosil flavum daily, and after administration of the drug was discontinued the symptoms disappeared in a few days. The fifth patient developed agranulocytosis. During her stay in the wards this patient had no remedies except prontosil flavum, some dilute hydrochloric acid to facilitate its absorption, and 15 Gm of castor oil. There can be no doubt about the close connection between the use of prontosil flavum and the occurrence of agranulocytosis, but the patient's unusual previous history of thrombopenic purpura may indicate some predisposing disease of the bone marrow. As a result of the unfavorable experience prontosil flavum treatment was stopped, and sulfanilamide was given to eleven other patients. This drug also caused toxic effects, but these were fairly harmless.

Iron as Causative Agent of Kaschin-Beck's Disease—In previous papers Hiyeda and his associates have reported not only the epidemiology, pathologic anatomy and the clinical observations of Kaschin-Beck's disease but also the results of experiments made on laboratory animals by feeding them on various inorganic irons. From these studies it was verified that the iron of the drinking water in the endemic area is very high, the blood iron of the patients is sometimes three times more than normal, the various internal organs show an appreciable siderosis, and ulceration of the surface of joint cartilage and dilatation of the marrow cavity of the bones occurs in animals experimented on. From these data it is inferred that iron taken habitually in large amounts is the cause of Kaschin-Beck's disease.

Sequels of Splenectomy in Cirrhoses of Liver—Bergeret and Caroli report observations on several splenectomized patients, who were kept under careful observation after the operation. The first patient was hospitalized on account of a hepatosplenomegalic cirrhosis for the first time in 1928. A search for etiologic factors remained negative. From this time on, the size of spleen and liver increased steadily. The general condition became aggravated, ascites developed and severe intestinal hemorrhages necessitated copious blood transfusions. During this critical state splenectomy was done (July 1931). Following the operation, the patient's condition improved considerably. The number of erythrocytes remained practically normal and ascites did not recur. Nevertheless, in November 1934 the patient had recurrent intestinal hemorrhages and severe attacks of pain in the hepatic region. The authors express the opinion that the late results demonstrate that in certain hypertrophic cirrhoses of the liver favorable results can be obtained by means of splenectomy. They agree with Carnot and Harvier, who formulated in 1935 that in these cases it seems to be a question of a primary hepatolienal disease, of a splenogenic hepatic cirrhosis, and that the splenectomy must be considered as a palliative intervention rather than a curative operation. It intervenes especially, if not to suppress completely certain complications, such as hemorrhages, at least to diminish the fatal risks and dangers. These conclusions seem confirmed to the authors by some unpublished observations which they analyze particularly from the point of view of the late results. One case demonstrates that if the spleen is hypertrophic, even if the hepatic cirrhosis develops in the form of an atrophy, splenectomy is likely to produce favorable results as regards the recurrence of hemorrhages of the digestive tract and the general condition of the subject. Two other reported cases concern hepatic cirrhoses which, in the absence of a biopsy at the time of the intervention, appeared not to have developed until after the splenectomy, in spite of a considerable improvement in the general condition of the patients.

Opacification of Gallbladder by Black Bile—Fliessinger and his associates show that gallbladders which show spontaneous opacity in the roentgenogram and which contain no calculi derive their opacification from two chemical phenomena: either the bile is white and charged with calcium carbonate and calcium phosphate, or the bile is black and charged with calcium carbonate and bilirubinate. The authors review two cases belonging to the second group. In the first case a long clinical history seemed to favor the diagnosis of calculi in the gallbladder. A roentgenogram that was made without preparation showed a round homogeneous shadow. During the intervention, black bile was discovered, which contained several rare small calculi. The second observation is another example of opaque gallbladder of the same nature. The opacity of the gallbladder to x-rays is due in these cases to the abnormal richness of the bile in calcium, which forms a type of sediment and behaves in the roentgenologic examination as does a contrast medium. Most often it is calcium carbonate which determines the white aspect of the bile. If the precipitation is in the form of calcium bilirubinate, the bile remains hyperpigmented, presenting by its color and its consistency the appearance of tar, as was the case in the two reported cases. The authors point out that Bianchi likewise reported two cases of opaque gallbladders with black bile. In all published observations obstruction of the cystic duct existed either by a calculus of cholesterol or, in exceptional cases, by an epithelioma. In the described cases the cystic duct was likewise obstructed. All authors consider this obstruction the cause of the calcareous deposits. The roentgenologic examination, although

possible, is not easy. To make a diagnosis, the examination must be made carefully and repeatedly. Bianchi, in a detailed study of this problem, distinguished two different roentgenologic aspects. 1 There is a uniform shadow, more or less dense, reproducing the outline of the gallbladder and perhaps also that of the cystic duct. 2 There is a semilunar opaque outline, which partly reproduces the form of the gallbladder in its lowest portions. From the clinical point of view it is interesting that diagnostic errors are frequent. Most frequent is the diagnosis of vesical calculi. In the first reported case the abnormal shadow, the familial antecedents and the considerable eosinophilia would have made the authors think of the possibility of a hydatid cyst of the liver if the lithiasic symptomatology had not determined the diagnosis.

- Electrocardiogram of Arrested Heart R Lutembacher—p 1031

Familial Occurrence of Osteopsathyrosis—Carrière and his collaborators state that their interest in Lobstein's disease (osteopsathyrosis) was first stimulated by a young woman with deep blue scleras, who sustained a fracture of the fifth lumbar vertebra from an insignificant cause. Although the patient was not deaf, she doubtlessly had osteopsathyrosis because, when her family history was investigated, seven analogous cases were detected. The disorder, which is generally designated as Lobstein's disease, is characterized by the following triad of symptoms: blue coloration of the scleras, fragility of the bones and deafness. In further investigations on this problem the authors detected five families with eighty six members, of whom thirty-four had signs of Lobstein's disease. They give diagrams of the genealogical trees of these five families. The diagrams clearly demonstrate the hereditary character of osteopsathyrosis. The authors state that from the clinical point of view the blue coloration of the scleras is the most important symptom, by reason of its frequency and of the ease with which it can be detected. They observed it in various degrees of intensity in thirty-three of thirty-four patients. However, they think that in order to be a diagnostic sign of Lobstein's disease the blue coloration of the scleras must have a certain intensity, be of a familial character and be associated, at least in one member of the family, with osseous or auditory defects. Further they give their attention to the osteo articular symptoms of Lobstein's disease, discussing the fragility of the bones, the skeletal deformities and the articular luxations. They say that they detected deafness in seven of the thirty-four patients. Then they take up the endocrine disturbances, which they observed in many members of the five families. They found that the function of the thyroid is frequently impaired in the patients with osteopsathyrosis. All the members of one family had hypothyroidism. In another family myxedema was observed in a woman and her daughter. On the other hand, two of the patients exhibited signs of hyperthyroidism. Ovarian dysfunction, pancreatic disorders and parathyroid disturbances were other signs indicative of endocrine involvement. In answer to the question as to what might cause both the pluriglandular symptoms and the osseous dystrophy, the authors suggest that hereditary syphilis might play a part. The probability of such an etiology is proved by the frequency of the symptoms of hereditary syphilis among the patients. The authors think that, if their hypothesis of the role of the glandular disturbances and of the etiologic significance of hereditary syphilis is accepted, endocrine as well as antisyphilitic treatments are justified in the therapy of osteopsathyrosis.

- Studies on Chemical Modification of Cerebrospinal Fluid After Operations S Tzouvaru and D Theodoresco—p 1039

Intradermal Injection of Histamine-Histidine Solution—A review of the previous literature on the action of intradermal injections revealed to Aron three important points. First, the intradermal injection of all substances at the point

area has an analgesic action. In discussing this point he directs attention to the observation made by Lenormand, namely, that substances which influence disturbances in the sympathetic nervous system act most intensively when they are injected into the skin. The author thinks that the richness of the skin in sympathetic elements and its common embryologic origin with the nervous system are points which help to explain the therapeutic efficacy of the intradermal injection. The second point stressed by the author is that the intradermal route augments the rapidity and the efficacy of the action of the neurotropic substances (histidine). Third, the intradermal injection of histamine by its special vasodilator effect and by its general action is an efficacious method in the treatment of the pain and the contracture of rheumatic disorders. These points were corroborated by three series of experiments which the author carried on in recent years. He employed a histidine solution of 4 parts in 100, which contained 0.1 mg of histamine per cubic centimeter. The intradermal injection of this solution is not painful, provided it is rendered neutral or slightly alkaline. The technic is simple. It requires no special needle but a syringe of 1 cc, and needles that are used for subcutaneous injection are sufficient. The needle is placed parallel to the skin and its beveled edge is inserted, when the beveled edge is covered by the dermal membrane the injection is made. The author never injected more than 1 cc of solution and rarely gave more than one or two injections at one time. The patient himself usually indicated the painful area of the skin. The total number of injections was from six to twelve. One injection was given either daily or every other day. The results so far obtained encourage the further use of the method on a larger material, which will be necessary for a definite evaluation of the method. The author gained the impression that the combined use of histamine and histidine is more constant and lasting than is the separate use of the substances.

Function of Musculature of Renal Calices—According to Hennig the function of musculature of the renal calices plays an important part in the circulation of the urine through the renal parenchyma and in the excretory mechanism from the renal canal system. A knowledge of this function is of value for the interpretation of certain pathologic conditions of the urinary apparatus. An accidental observation in the course of a retrograde pyelography proved to the author the sphincter-like action of the ring musculature of the calices. After reviewing Henle's description of the musculature of the renal calices, he says that the action of the ring musculature of the renal calices had never before been observed directly on a living human subject and then he describes his observation of a pyelovenous reflux, which was localized in one calicine system, and of the sphincter-like closure of a renal calix. The roentgenogram of the right, healthy kidney revealed that the ureteral catheter had penetrated into the upper calix. Whereas the median and lower calices showed only rather weak shadows and smooth outlines, the upper calix showed a strong shadow and appeared laced in toward the renal pelvis. In trying to explain this phenomenon the author points out that by the accidental penetration of the point of the catheter into the upper renal calix the iodine preparation exerted such an irritating effect on the mucosa that the calix was closed against the renal pelvis by reflex of the ring musculature. Before the irritation could become completely effective, a small part of the contrast medium entered the other parts of the hollow system. If the wall of the calix did not contain ring-shaped contractile muscular elements, the contrast medium, according to the laws of

hydrostatics, would have spread uniformly through the entire hollow system, so that a shadow of uniform intensity would have been the result. The author thinks that his observation furnished the proof for the existence and lacing in effect of the ring fibers on the renal calices. He suggests that under normal physiologic conditions it is probably the suction of the calix bell which forces the urine stream periodically from the renal canals. The periodic play of the musculature of the renal calices, which is manifested in contraction and suction, was corroborated also by the roentgenograms following intravenous urography. This more physiologic procedure of renal visualization revealed that the muscular action of the renal calices does not take place simultaneously in all calices but alternates from side to side.

Calcium Prophylaxis of Postoperative Pulmonary Embolism—Muff reports on prophylactic injections of calcium chloride for the prevention of fatal pulmonary embolisms. He says that this treatment was first introduced in Bier's clinic. Two cases of fulminant postoperative pulmonary embolism, which occurred at the author's clinic shortly after Martin had reported on the prophylaxis in Bier's clinic induced the author to try the calcium prophylaxis. The technic of this method called for the daily subcutaneous injection of 1 cc of a 0.01 per cent solution of calcium chloride intramuscularly into the thigh or the gluteal muscle, this is less painful than the subcutaneous method of administration. According to Martin's directions the injections are given daily for eight successive days after operations or injuries. If signs of thrombosis or of pulmonary infarct appear, the injections are continued for two weeks. The author illustrates the effectiveness of the calcium prophylaxis in a tabular report which reveals the comparative incidence of embolisms in two groups of over 2300 surgical cases each. He does not assert that calcium prophylaxis alone will prevent every fatal embolism. However, since the fatal embolus usually originates in a symptomless distant thrombosis, he thinks that a measure which increases the adhesiveness of such thrombi appears valuable.

- *Clinical Value of Indicanemia L Pinelli—p 371
Perspiration Insensibilis in Edema G Rocchini—p 399
Bronchiectasis and Pulmonary Tuberculosis G Gianni—p 425

Clinical Value of Indicanemia—Pinelli states that the increase of indican in the blood is common in acute and chronic renal diseases and in other diseases in which the kidneys are normal. He found hyperindicanemia in acute diseases of the respiratory tract, chronic and acute liver diseases, diabetes, chronic constipation and grave anemia. In all cases azotemia is normal. The amount of indican in the blood becomes normal as the disease regresses. In acute and chronic nephritis there is hyperindicanemia and normal azotemia. The increase of indicanemia in renal diseases is of poor prognosis, especially if azotemia also increases. The intensity of hyperindicanemia in renal diseases depends on the intensity of renal insufficiency. Uremia is independent of the presence and intensity of hyperindicanemia. The determination of indicanemia during fasting has no specific clinical value in showing pathologic conditions of the kidneys.

Short Wave Treatment in Disturbances of Gastric Secretion—Benassi and Montagnini applied a local short wave treatment to nineteen patients suffering from disorders of the gastric secretion. During administration of the treatment no medicine was given and the patients followed their usual habits of life and diet. The modification of the gastric secretion was determined at intervals in the course of treatment and, in some cases, after discontinuation of the treatment. The waves were 6 meters long of a modulated type and average intensity which produced a slight feeling of local warmth.

The electrodes (12 by 18 cm and 27 by 18 cm, respectively) were applied at opposite points at the epigastrium and the back in order to include the stomach in the electric field. The treatments were given daily, on a fasting stomach or at a time remote from meals. Each treatment lasted thirty minutes (except in the cases in which the condition of the gastric secretion, such as changes induced by the treatment, were verified during one of the applications). The number of treatments varied from twelve to fourteen. In all patients the treatment controlled pain and regulated the gastric secretion, which decreased in hyperchlorhydria and increased in hypochlorhydria. The effects were lasting. In some cases the treatment induced a complete clinical cure. The authors state that the mechanism of action of the short wave treatment on the motor and sensory phenomena of the stomach is complicated. The action takes place especially through the sympathetic. Local hyperthermia and the stimulation of local nerve fibers are secondary factors.

*Intraspinal Anesthesia and Prevention of Following Headache M Margottini—p 1385

Fever of Malarial Type in Syphilis Associated with Chronic Malaria A Spanu and M Piga—p 1397

Spinal Anesthesia—According to Margottini, spinal anesthesia with a 10 per cent solution of procaine hydrochloride is the method of choice in performing all operations in structures lower than the diaphragm. It is not advisable to resort to this type of anesthesia in children less than 13 years of age. It is contraindicated in persons with low blood pressure, as well as in those suffering from toxic conditions, infections, circulatory disorders, syphilis and headache. The intraspinal injection of 12 or 16 cc of a 1 per cent solution of dextrose shortly after the intraspinal injection of procaine hydrochloride greatly reduces the frequency, intensity and duration of headache following intraspinal anesthesia. The author's conclusions are based on results of 3,500 cases in which procaine hydrochloride intraspinal anesthesia was used.

Hay Fever in City of Bahia Blanca L G Bouzat—p 1359

Appendicitis from Oxyuris—Battaglia and di Fiore found appendicitis caused by Oxyuris with a frequency of 2 per cent. It is more frequent in children than in adults. Only two patients out of a group of eleven suffering from oxyuris appendicitis complained of symptoms of oxyuriasis (occasional dizziness with unconsciousness). A microscopic study of the removed appendix was performed in three cases. The appendix was the seat of chronic inflammation and typical oxyuris lesions. The hemogram in three cases showed eosinophilia (4, 5 and 8 per cent, respectively). The appendix was intensely parasitic (twenty-nine, sixty-two and eighty-three oxyurids, respectively). The largest number of oxyurids isolated from the appendix were female. The examination of the feces for parasites and of the lumen of the appendix for eggs gave negative results.

*Sacralization of Fifth Lumbar Vertebra and Its Clinical Significance O Wenzl—p 493

Chorionepithelioma in Males—Chorionepithelioma in males, Bankoff states, is usually localized in the testicles or in testicular teratomas; the extragenital localization is probably only apparent or at least extremely rare. The histologic aspects

of the chorionepithelioma in males correspond morphologically with those of the chorionepithelioma in women. In its behavior toward the general organism, the chorionepithelioma of males likewise resembles that of women. The author describes the history of a man, aged 27, in whom a chorionepithelioma was removed from the right testicle. The patient recovered and as yet there have been no signs of metastasis. The author concludes that there is a morphologic similarity between chorionepithelioma in men and in women. However, this similarity is no proof that these tumors are of the same type, for it is known that tumors with the same histologic aspects may be of different origin. In support of the hypothesis that chorionepitheliomas are of different nature in men and in women, the following characteristics are cited. The teratomatous chorionepithelioma occurs only in men and always in the testicle; the entire tumor is of a malignant nature and free from benign elements, in contradistinction to the tumors in women, the metastases of the chorionepithelioma in men appear almost exclusively in the retroperitoneal lymph nodes, combinations of chorionepithelioma with other types of testicular tumors as well as a direct transition of chorionepithelioma-like structures into adenocarcinomatous proliferations are demonstrable only in men. The author arrives at the hypothesis that chorionepithelioma originates like all other testicular tumors in the testicular parenchyma. Its anatomic structure proves to a certain extent that its syncytial cells originate from Sertoli's cells.

Impairment of Blood Vessels by Pneumatic Tools—It is pointed out by Junghanns that the literature of recent years brings isolated reports of cases of vascular disturbances in the hands of workers who for years have handled pneumatic tools. He himself describes observations on a man, aged 38, who for eleven years had operated a pneumatic hammer. He concludes that workers whose hands are exposed to continuous concussions from the operation of pneumatic tools gradually develop a traumatic angioneurosis of the capillaries of the fingers. This angioneurosis manifests itself in pallor of the fingers, a feeling of deadness, impaired movement, and disturbances in the sense of touch and sensitivity to cold. In rare cases these vascular disturbances, which appear at first in the form of spasms, may become so exacerbated on the fingers, hands and lower part of the arms that local tissue death results (wounds heal poorly and the tips of the fingers or the fingers become gangrenous). Histologic studies on the blood vessels of the lower part of the arm of the patient whose history is reported revealed changes similar to those of Burger's endangitis obliterans (closure of the vessel by connective tissue plugs, separation of the layers of the vascular wall, tubercle-like accumulations of cells with giant cells, and so on). The author suggests that this form of vascular disease should be recognized as an occupational disease, just like the impairments of muscles, bones and joints that develop in workers who operate pneumatic tools. Workers in whom the beginnings of such disturbances are noticed should discontinue their work with pneumatic tools. At any rate, it is advisable that such work which involves continuous concussion should be done only for a few hours each day and, if possible, the workers should be relieved from it completely for several months out of the year.

Sacralization of Fifth Lumbar Vertebra—Wenzl admits that persons with sacralization may go through life without having the least difficulty from it and that some cases of sacralization are discovered only by accident. The fact that some persons with sacralization are entirely free from pains has induced some authors to reject completely all connection between sacralization and backache. Nevertheless, many recognize that sacralization is the cause of many otherwise unexplainable disorders. To clarify the symptoms that are caused by sacralization, the author analyzes a so-called sciatic complex and a skeletal complex. He describes several cases. He designates as the skeletal complex those static disturbances which develop as the result of the vertebral changes in sacralization. The neuralgiform pains, the sciatic complex, is often the result of the simultaneous increase in the thickness of the transverse process. To this group belong relapsing sciatic cases in which the roentgenoscopy fails to reveal sacralization. In most cases of sacralization the two complexes are combined. The author thinks that, whenever symptoms can be traced

with certainty to sacralization, surgical is preferable to symptomatic treatment. He shows that the operation, namely, the excision of the transverse process, is not difficult and can be performed without great risk for the nerve. After the operation the patients should be put in a suspended position, which makes possible a lordotic position in the region of the lumbar portion of the vertebral column. After three weeks the patients usually can get up again.

Vitamin C and Oil of Bergamot for Protection Against Ultraviolet Rays—Urbach and Kral describe experiments which prove that the oral, rectal or paracutaneous administration of vitamin C in combination with the external application of oil of bergamot has a definite photoprotective effect. However, in order to protect the skin against ultraviolet rays, it is necessary that vitamin C form a chemical compound with the entire complex of oil of bergamot. Vitamin C acts most rapidly after intravenous administration, for if so administered it becomes effective after one hour, as against three hours in oral administration. This indicates that not the vitamin as such but rather one of its products protects against light rays. Moreover, if vitamin is rubbed into the skin, it does not prevent the ray erythema. It is noteworthy that only natural but not rectified oil of bergamot protects against light. Even heating to more than 60°C cancels the effectiveness of the oil against ray erythema and none of its constituents exert the photoprotective action. Moreover, the combination of vitamin C and oil of bergamot protects only against short, not against long, light waves.

Fresh Air Treatment of Bronchopneumonia in Children—Degkwitz discusses the mortality rate in two groups of children who contracted bronchopneumonia. The first group comprised 334 cases which were treated during the time when the fresh air treatment was not yet used. In the second group of 424 children, the fresh air treatment was used. The ages of the children, the percentage of severe cases and the incidence of complications were about the same in the two groups. Identical also were certain indispensable nursing and medicinal measures. However, whereas the first group was treated in ordinary wards, the second group received fresh air treatment in open-air verandas or in open-air rooms (with open windows and unheated) or the children were changed back and forth between the open-air veranda and steam saturated warm air (steam bed, bronchitis box), and they were not constantly left in bed but were carried around much. Children who died within the first two days after hospitalization were not included in either of the two groups. In discussing general indispensable measures that are required in pneumonia, the author stresses the importance of correct bedding (horizontal position with a flat pillow or roll under the shoulders), so that the respiratory musculature can function properly. In the second group this position was alternated for brief periods with the lateral position. Moreover, the children were frequently car-

ried around in the open air (usually in the sitting position). The author further stresses the necessity of supplying the children with adequate amounts of fluid and of carefully watching the circulation. In discussing the mortality, he points out that nurslings and small children die more frequently of pneumonia than does any other age group. However, a comparison of the mortality rates in the two groups of children proved that in the group in which the open-air treatment and the more active measures (carrying around) were used the mortality was reduced to one third of the rate that occurred in the children receiving ordinary ward treatment.

Stuporous Conditions After Insulin Treatment in Schizophrenia—Salm describes stuporous conditions which developed in schizophrenic patients who underwent the insulin shock treatment. The symptoms were generally continuous stupor in spite of the administration of large amounts of sugar, lack of energy, somnolence, vomiting and occasionally fever (up to 104°F). In some instances the stupor was preceded by a number of attacks, which continued in spite of the administration of large amounts of sugar and could be controlled only by hypnotics. The stuporous conditions may appear even if the shock is not unusually deep and lasting, and the quantities of the injected insulin differed likewise in the cases in which stupor followed. One patient died after eleven days of stupor. The author cites similar cases from the literature and, in attempting an explanation, expresses the opinion that the hypoglycemia elicits lesions in the diencephalic regions, which in turn produce disturbances in the heat regulation and in the circulation and perhaps severe sweating. If the hypoglycemia causes severe damage, stupor and somnolence may result. These cases constitute a serious problem because, if they do not yield to the repeated administration of sugar it is useless to administer more carbohydrates, particularly if the blood sugar value is high. The circulation should be carefully watched, for if the pulse and the general condition remain favorable the patient usually wakes from the stupor.

Historical Sketch of Development of Short Wave Therapy J. W. Schereschewsky—p. 769
*Short Waves Mode of Action and Indications for Use E. Schliephake—p. 771

Short Wave Therapy in Articular Diseases—Maragliano employed short wave therapy in about 100 cases of articular disorders. The short waves were employed to obtain a thermic effect. The treatment was nearly always local. In applying the rays to the large joints, the body temperature was usually slightly raised. It was observed that the best results could be obtained when the patients were kept resting after the treatment. Accordingly, the treatment was most effective with hospital patients. In some instances acute exacerbations were observed after the first few treatments, but these subsided again and it appeared as if the incipient exacerbation indicated a favorable final result. The response to short wave treatment was most favorable in the traumatic articular processes, such as the sequelae of distortions, of luxations and of endo articular or periarticular fractures. In the articular disorders of metabolic origin such as gout, the short wave therapy produced varying results, for whereas some cases responded favorably, others were not improved or were even exacerbated. In the metabolic articular disorders as well as in the chronic polyarthritides it may be advisable to combine the local treatment with general treatment, the aim of the latter being a slight increase in the body temperature. Short wave treatment of arthritis deformans produced only a temporary reduction in pain. An analgesic effect was produced also in the gonorrheal arthritides. The author treated only one case of tuberculous arthritis with short waves and in this case the treatment failed. The combination of short wave and roentgen therapy proved helpful in counteracting the pains in arthritis deformans.

Short Waves Mode of Action and Indications for Use—Schliephake discusses the indications for short wave therapy and its technic. He deprecates the uncritical reports which represent the short wave therapy as a cure-all, thereby bringing it into disrepute. He regards as one of the chief indications for short wave therapy a group of suppurating inflammations, particularly furunculosis, carbuncles, panaritiums and some empyemas. The particular value of the short wave therapy lies in the fact that the infectious foci are localized. During the early stage, resorption is usually obtained, during the later stage, demarcation and spontaneous perforation. Regarding the use of ultrashort waves in chronic conditions, the author says that it is indicated in practically the same conditions as is diathermy. He also mentions the production of fever by means of the short wave field, pointing out that at his institute this treatment was used chiefly in rheumatic conditions. He stresses that excessive doses must be avoided. He thinks that the more acute the process, the smaller should be the dose and the shorter should be the time of exposure to the short waves. In giving his attention to the action mechanism, he points out that much confusion has been produced by the discussion about thermic effects versus specific effects. He says that if there are specific effects they can be produced only by physical processes, for instance, electrical powers may influence the structure of molecules or of colloidal particles, but in such processes there is always also a thermic effect.

*Synthetic Cevitamic Acid New Auxiliary Remedy in Arsphenamine Therapy S Landfisch —p 575

Synthetic Cevitamic Acid in Nearsphenamine Therapy—Landfisch states that, notwithstanding the great improvements in the preparation of nearsphenamine, it often happens that for various reasons the physician has to interrupt the treatment with nearsphenamine. Various auxiliary preparations have been tried with the view of creating greater tolerance to nearsphenamine in the patient but have failed to produce the desired result. He has treated twenty-five patients, to whom a nearsphenamine preparation could not be administered safely, with synthetic cevitamic acid in ampules in doses of 0.05 Gm dissolved in 10 cc of water and in tablet form for oral administration. The cevitamic acid injections have been given together with the nearsphenamine injections or half an hour before administration of the nearsphenamine. The tablets, three a day, were given one day before administration of nearsphenamine or on the same day. The following results were obtained. Among the twenty-five patients, twelve male and thirteen female, the evidence of intolerance disappeared in eleven male and nine female, or 80 per cent, slight and insignificant intolerance symptoms were observed in four female patients, or 16 per cent, and one male patient remained intolerant, or 4 per cent. On the basis of this experiment he concludes that the auxiliary remedy of synthetic cevitamic acid for intolerance in nearsphenamine therapy is worthy of further consideration.

*Treatment of Cryptorchidism with Gonadotropic Substance E Dahl Iversen and U Starup —p 657

*Intracranial Angioma Case C Johansen —p 671

Renal Rickets Case J Bichel —p 678

Treatment of Cryptorchidism with Gonadotropic Substance—Of 208 cases of cryptorchidism treated with endocrine preparations collected from the literature in which exact statements of the results were given complete descent with growth of the testicles was attained in 129 cases (62 per cent), growth of the testicles with partial descent in twenty-five (12 per cent) and in fifty-four (26 per cent) the location of the testicles was unchanged, although in some the size was increased. The last group included patients who were between 20 and 30 years of

age or who had previously undergone unsuccessful orchiopexy or inguinal herniotomy. Of the 155 cases known to be unilateral or bilateral, good results were achieved in forty-three (66 per cent) of the bilateral cases, improvement in eleven (17 per cent) and negative results in eleven (17 per cent), while forty-five (50 per cent) of the unilateral cases showed good results, nine (10 per cent) were improved and thirty-six (40 per cent) gave poor results. Dahl-Iversen and Starup's experience has also been that bilateral cases react better to endocrine treatment than do the unilateral. The hypothesis is thus supported that unilateral retention depends on a mechanical obstacle to descent, while the bilateral depends on hormone disturbances. Further, endocrine treatment gave good results in seventy-two (76 per cent) of the ninety-five patients with general physical underdevelopment or genital underdevelopment or with clinically established endocrine disturbance, fourteen (15 per cent) showed improvement and only nine (9 per cent) failed to respond to the treatment. The authors conclude that endocrine treatment is superior to operative treatment. The contraindications are true ectopies, retention complicated with hernia, cases with annulus subcutaneus complicated with hydrocele, possibly in combination with open vaginal process, cases in which examination reveals a fixation of the testicles or narrow annulus subcutaneus, or in which there is other demonstrable cause for the maldescent and, finally, in which malignant change of the testicles may be suspected. According to present experience, they would not begin endocrine treatment till the age of 12 or 14. A universal endocrine disorder may indicate an earlier beginning of treatment. A dosage of 400 mouse units of the luteinizing factor twice weekly is recommended, under close control of the patient's development, both general and genital, and in cases of unilateral retention, with attention to the possibility of atrophy of the normal testicle, a condition about which little, however, is known. They use the luteinizing factor from the urine of pregnancy because this principle is believed to act preeminently on the Leydig cells, assumed to play the most important part in descent of the testicles. In their material the duration of treatment has been from about six weeks to about nine and a half months.

Intracranial Angioma—Microscopic examination showed that Johansen's case of intracranial hemorrhage following a slight trauma was due to rupture of an intracranial angioma racemosum.

CONTROL OF COMMUNICABLE DISEASES IN SCHOOLS

JOHN A. FERRELL, M.D., DR. P.H.

Associate Director International Health Division of the Rockefeller Foundation
Chairman of the Executive Board of the American Public Health Association
NEW YORK

The control of communicable (contagious) diseases in schools is a subject that might be discussed from more than one angle. One approach would involve listing quite a number of the important communicable diseases to which school children are exposed and discussing each with respect to the present status of knowledge and to the consensus among health authorities as to the best procedures for its prevention, treatment and control. This would be tedious, time consuming and wearying. Besides, all that I could say is already conveniently available in reference books, in manuals for health officers and in rules and regulations of health departments. A particularly useful handbook of this character is the Report of the Committee on Communicable Disease Control, under section II of Public Health Service and Administration of the White House Conference on Child Health and Protection, published by the Century Company in 1931. It is a brief, clear-cut review covering present knowledge regarding the communicable diseases, and it reflects the prevailing opinion among public health authorities as to appropriate measures for combating each. I deem it inadvisable, therefore, to pursue this line of approach and prefer to present a discussion directed to placing administrative responsibility for the control of communicable diseases.

Sweeping and categorical statements regarding this responsibility for the country as a whole are not warranted. An extremely wide variety of communities is found. On the one hand there are great cities in which there is a concentration of population and wealth and in which conditions are extremely complex. On the other hand there is the rural community with its small population, which is widely scattered and has very limited economic resources. Also there is the school or college isolated to a large extent from community governmental services. Certain industrial organizations may be similarly situated. They find it necessary to organize and operate their own health and medical services and to assume almost complete responsibility for the health protection of their community.

Again, in communities that may be similar as to wealth, population and other features there may exist a great variety in ideas, customs and historical back-

ground, and tradition may influence practice. One finds in the New England states that the rather small township has become the unit of local government, whereas elsewhere the much larger county is the accepted unit of local government. Moreover, in certain states and cities the public schools were developed early and many of them had able and aggressive leadership, whereas the public health service in certain of these areas was backward and inadequate and had part time, untrained and indifferent direction. The school authorities were prompt to recognize the necessity for health protection of the students. They sometimes employed physicians and nurses—some on a full time basis, others on part time—to supply the schools with health services.

In communities in which for varying reasons a particular type of procedure has grown up, it is difficult to bring about logical changes designed to procure reasonably uniform practice. Fortunately, the school authorities in most states and cities have recognized that the community should have only one system of schools and only one health service. Moreover, they have been wise enough to advocate a health service designed to give protection against disease to residents of all ages and not to burden the taxpayers unduly with a second health service designed to serve the school age group, a service which at times has become competitive rather than complementary to the general health service. They have liberally supported the general health department to the extent of supplying money and personnel toward strengthening it. They realize that any soundly conceived and administered health service will concentrate activities to a large degree on persons of preschool and school age, because the largest returns in comparison with expenditures are to be obtained by this course. The schools then rarely have reason to fear lest the health department will neglect the health needs of the schools. There should exist, of course, a very intimate working relationship between the director of education and the director of health and among their associates. Where there has been able and cooperative leadership in both the educational and the health community services the results generally have been very satisfactory, and occasion has seldom arisen for having two health services in a single community.

Since, as already explained, there is such a wide variety in communities, the task of placing responsibility for the control of communicable diseases in schools will be simplified if consideration is limited to communities averaging high as to resources and citizenship and to civic jurisdictions—county or city—having a population ranging from 50,000 to 500,000. Such communities usually have a board of supervisors, a mayor or a manager as a public administrator. The schools may have separate boards or they may operate as do other branches under the general community

Read in the Symposium on Health Problems in Education under the sponsorship of the National Education Association and the American Medical Association Atlantic City N. J. June 8 1937

board or executive. There is usually a single branch or division of service for the levy and collection of all taxes. As to personnel, some may have a civil service system or operate otherwise on an approach to a merit system. Others unfortunately may be influenced by politics and enjoy only limited stability and efficiency.

Regardless of these variations, all the communities under consideration have their systems of public schools and all have their problems of controlling communicable diseases both inside and outside the public schools. Where should the responsibility be placed for properly combating these diseases?

One naturally thinks first of the responsibility that the parents or family should assume. Certainly the home should do all that is practicable toward protecting its children, regardless of age, from communicable diseases. If financially able to utilize the services of private physicians, the parents should have their children immunized at an early age—that is, during the infancy or preschool period—against diphtheria, small-pox, typhoid and other diseases against which it may be feasible with safety to secure immunity. The home should be supplied with safe water, the facilities for the disposal of night soil should be adequate, the heating, ventilation and lighting should be hygienically correct, and the house, particularly the kitchen and dining room, should be screened against insects that may convey disease. The food should contain the essential elements and be supplied in sufficient quantity. By example and teaching the parents should as far as possible protect their children against disease and disability and provide them with a healthful environment. The extent to which parents can meet this program will vary. Certainly it is impracticable for even the fairly well-to-do families to keep their children at home for more than a part of the time and they can do little to safeguard them against diseases for which immunizing or curative measures have not been developed. Again, many families are unable to provide themselves with the necessities of life, including medical care. Obviously, such families can do little to protect themselves or their community against communicable diseases. A number of families which could meet all or a part of the cost of immunizing their children are neglectful, careless or ignorant. It seems clear that the health of the community at best would be only partially safeguarded if complete reliance should be placed on parents. The economic factor is important with most families, but it is not the sole reason for failure of individuals and families to take appropriate protective measures against disease. It would seem then that there is some parental responsibility and that it should be developed as far as possible, but neither the community nor its schools can rely on it except to a limited degree.

The responsibility of the school for the control of communicable diseases is of particular interest. In the field of public services the schools usually have led. They began operating on an efficient basis with trained personnel that could meet reasonable qualification standards much earlier than have other community services. In general it may be said that in architecture, sanitation and hygienic conditions they have endeavored to set high standards in order that the pupils who enter them will enjoy health protection and not be subjected to needless health hazards. They have served as community demonstrations of correct health measures which the homes of the community would do well to emulate. The teachers in general have been required to

teach hygiene and health protection, and as a rule they have been taught to recognize promptly symptoms of communicable diseases, with the result that there is a minimum of delay in calling in the health officer and his aids at the first appearance of a contagious disease when the chances are best for preventing an epidemic. As already stated, some schools have employed their own physicians and nurses. The schools then, generally speaking, have been alert and have endeavored, as far as practicable, to protect the children and the schools from the serious consequences that may be caused by controllable diseases.

Notwithstanding the admirable health protection provided by the schools, the question is still: How far can the schools go and how far should they go in setting up machinery at public expense for the control of communicable diseases? Corrective measures with respect to tonsils, adenoids, teeth and the production of immunity as far as practicable should be completed before the child reaches school age and comes under the jurisdiction of the schools. To have these procedures completed before the child starts school is advantageous to parents, schools and taxpayers, makes for stronger and healthier children and minimizes the likelihood of epidemics interrupting the school work. After reaching school age the child will spend approximately 25 per cent of each school day under the jurisdiction of the school, but for the remaining 75 per cent of the school day and the 180 days, or about half the year, when the school is not in session, the school could not exercise jurisdiction over the child. Is not this period of school jurisdiction too limited to justify an attempt by the schools to assume responsibility for the control of disease among its pupils? Moreover, it is questionable whether the director of schools is qualified or should attempt to administer public service beyond the realm of education. Why should a school operate a medical or health service which at best can serve only that part of the community enrolled in the schools, and that group for only about 25 per cent or less of the school day and thus for less than half the days in the year? From the standpoint of the community government, the schools have an extremely important function, but to my way of thinking it does not include the operation of a health service, a police service or a social welfare service. But the relationship of the schools to these services should be quite intimate.

The private physician is an important factor in the control of communicable diseases inside and outside the school, provided he is qualified and his services are utilized. Every one, practically speaking, favors utilizing his services by all families that can pay him for his work in combating disease and for other services. He should not be expected to render services without compensation. Giving health protection of the kind the private physician might render to families who themselves cannot afford his services is a responsibility of the community as a whole. The question that has not been satisfactorily settled is: Shall the community hire the private physician to do such protective work and pay him on a fair basis or shall it require its full time employee, the health officer, to do the work? With respect to items such as immunization against diphtheria, the health officer's chief concern is that the child be immunized. He is not particularly interested in who produces the immunity. The financial problem in many communities has prevented the use of the private physician by the community in such situations. It has

been very difficult to secure enough public appropriation to pay salaries of a small full time staff for the health department. Only Detroit and possibly a few other cities so far have provided funds that could be used to compensate physicians for authorized protective services to families unable to pay. The private physician cannot be held responsible for controlling communicable diseases beyond the extent to which it is feasible to compensate him for his services. The same may be said of the local medical society. Both in and out of the school, physicians are actual and potential factors in disease control, but except when privately employed and compensated by families their work at public expense should be organized and supervised by the health department. This follows the procedure expected by taxpayers in the case of other public activities that they finance. As an influence in the education of the people in health protection measures, the physician likewise can and does play a useful role.

Since responsibility for protecting the health of the child can be assumed in part only by the family, in part only by the school and in part only by the private physician, we come finally to the public health department and a consideration of the extent to which it should be held responsible for the control of communicable diseases whenever and wherever they occur in the community, both inside and outside the schools. Divided responsibility is unsatisfactory. Since the community must have a general health service there seems no occasion for financing a second one just for the schools. It is important, however, that the families, the schools and the physicians should support the community health organization and cooperate with it in every way. Likewise the health service, if wisely guided, will recognize the value of these forces and utilize them and others that can contribute to the success of health measures.

It seems hardly necessary, after making the foregoing remarks, to discuss the community health organization and its responsibility for the control of communicable diseases, so far as may be possible, for persons of all ages and at all times and places. In its task it should utilize all the support it can secure from the family, the school and the physician. At times it may be necessary also to call on the courts and police for support. If the community is to center responsibility on its health department it must make provision for an adequate staff of competent persons, each trained for the task he or she is to perform. This involves ample appropriations and conditions of service that make for stability. Ideas as to adequacy of staff in terms of cost vary from 50 cents per capita to \$2 or more. The smaller the per capita expenditure the thinner in general will be the veneer of service. If the community services to fight fire, to enforce the laws or to combat disease are too weak to cope with situations as they arise, the consequences may be disastrous. Since the present object is merely to place responsibility specifically for the control of communicable disease in the community, there is no need to dwell on what the other functions of the health department should be or on the size and character of its personnel and budget beyond insisting that the organization should be adequate to make possible the discharging of its responsibilities.

In taking the position that the community should have a unified service for health, another for education and still another for social welfare (provision for the aged, the orphaned, the sick, the afflicted, the destitute and the underprivileged), I wish to state emphatically that such services should not be isolated compartments

working independently. Many community problems, such for example as tuberculosis, syphilis or nutrition, have ramifications in every phase of community life. Moreover, the economic base on which the community and its services rest may determine the scope on which operations of all kinds, including education and health, may be planned. This means, of course, that there should be planning and guidance for building up and maintaining family and community resources at a high level. All the major problems of the community should be appraised by competent but detached persons. Plans for balanced programs for the various fields of service should be formulated and they should be related to present and potential resources. Trained public employees should be used and they should be permitted to operate under a merit system. The taxpayer should get a proper return on his expenditures. The present competition among community services for jurisdiction and for public funds should be regulated and reconciled. By indirection I am asserting that many local community governments, such as I have under consideration, whether county or city, are not effective, efficient or economical. Were this not true, it would not be difficult to settle the question under consideration relative to placing responsibility for controlling diseases in schools. Community problems of much greater magnitude exist and efforts should be made to solve them. The members of boards of supervisors and town councils and the mayors or other executives in most cases undoubtedly mean well, but they are not trained for their official responsibilities and in general they are part time, and their thinking is largely about private matters. A few communities have replaced this antiquated inefficient system of administration by employing trained business managers, sometimes called public administrators, to run the public business. When they are successful in securing a qualified executive, he in turn can secure trained and competent associates in each essential branch of the community's business. Under this plan there is reasonable assurance of teamwork, coordination of effort and cooperation. The taxpayer's dollar under this plan will as a rule accomplish much and the director of schools and the director of health will have much in common and little, if any, disagreement, and they can expect the wholehearted and consistent backing of the manager. The results in health protection and in other directions desired by both will be obtained through harmonious cooperation. While some communities are awaiting the arrival of this hoped for era, which I believe is on the way, I would urge that the community have but one health service and that the directors of education and of health jointly plan the best program of health protection for the community, with emphasis on the schools, that can be supplied with the financial resources in sight.

49 West Forty-Ninth Street

Success Dwells in the Silences—With a background of family practitioners, I have, by the fall of the dice, come to lead a life different from theirs, not so sequestered as that of some, but sufficiently so to let me estimate the recompenses and weigh the satisfactions which come from an existence of the two kinds. Certainly the self-sacrificing career of the practicing physician, respected and beloved of his community, is no less, perhaps even more, character making and ennobling than the secluded life of a pure laboratory worker, whatever be the importance of his researches and discoveries. In either case "success dwells in the silences though fame be in the song"—Cushing Harvey. *Consecratio Medici and Other Papers* Boston Little Brown & Co, 1928

NUTRITION PROBLEMS IN EDUCATION

JAMES S McLESTER, M D

Medical Director of the Birmingham Public Schools

BIRMINGHAM, ALA

It is a principle of the school system in which I work that the health of the child comes first. This is an expression not merely of solicitude for the child's comfort and happiness but of the realization that it is the healthy child who can make best use of the education offered him. Indeed, it is a part of our creed that in childhood even the development of character proceeds more surely in the presence of health. It is recognized, too, in the Birmingham schools that good nutrition is a prerequisite to health, and every effort is made to see that the child is properly nourished. These efforts extend in many directions.

To evaluate properly the nutritional status of the child is no easy matter. It has been suggested that use be made of precise methods which measure the exact degree to which the pupil is lacking in certain specific food factors, but such precision is not possible. True, efforts are being made to devise methods of this type, an example of which is seen in the Jeans photometer, used for the detection of vitamin A deficiencies, but these methods will find the greatest usefulness in the study of limited groups of children rather than in a general survey. Even to measure the precise degree of anemia from which the pupil suffers, which is an excellent way of detecting nutritional failure, is not feasible, for red cell counts and hemoglobin estimates on large groups of children are for many reasons impracticable. Anemia can be searched for in the school only by looking at the child's skin and mucous membranes. In spite of its inherent fallacies, it seems to me that the best criterion of the child's nutritive state is to be found in a comparison of height and weight. There are today few short cuts to diagnosis in medicine and none to the recognition of the nutritive status of large groups of school children. In this field, as in so many others in medicine, dependence must be placed on careful general observation and the putting together of the information obtained from many sources.

Nutritional failure in America is seldom simple or complete. It is, as a rule, multiple and incomplete and correspondingly complex. True, scurvy, active or latent, rickets, beriberi, perhaps, and in my section pellagra are occasionally recognized in the school child, but such well developed clear cut forms of deficiency disease are extremely rare, so rare in fact as to be of little interest in this discussion. It is the vague borderline case of nutritive failure of mild degree that is most interesting, for such cases are frequent. I am thinking of the child who doesn't get quite enough to eat, who is permitted to govern his diet by bizarre likes and dislikes, who has nervous anorexia, who thinks he can't drink milk or who will not eat because he is in too much haste to return to his play and who, as a result, is underweight, easily exhausted or nervously unstable. To recognize disorders of this type and to correct them is a prime duty of the school physician.

To what extent does the state of the child's body interfere with his ability to utilize his food properly? Fortunately it is not necessary to consider here, as one

must in adult life, the "conditioning" of the gastrointestinal tract that comes from addiction to alcohol and other types of injury. Indeed, I know of no similar influence in childhood, but there are other disturbances, notably foci of infection, which are almost equally potent. Animal experiments and clinical experience both indicate that in the presence of a focus of infection certain food factors are poorly utilized. In the presence of diseased tonsils, an infected sinus or an abscessed tooth, for example, it is sometimes well nigh impossible to correct the child's secondary anemia, the iron administered is utilized poorly if at all. There is definite evidence too, that vitamin A is utilized poorly in the presence of an infection. Remove the offending focus and the difficulty disappears. This applies to other nutritive substances. For this as well as for other reasons the eradication of infection becomes an important part of the nutritional program.

Should the school content itself with merely the correction of recognized nutritional failure and ignore the opportunity for enhancing the development of the apparently normal child? Should it ask only that the diet be adequate? The answer is definitely No. I should like to emphasize the little known fact that adequate and optimum as related to diet are by no means synonymous. The aim should be to reach the optimum.

Experience with the albino rat has shown that by suitable additions to a diet that previously has been regarded as adequate an entirely new race of rats, of greater vigor and larger stature, can be produced. Likewise, studies of population have shown that something similar can be accomplished for the human race, in numerous instances improved environmental conditions, notably with regard to food, have resulted in a more vigorous, taller race of men and women. The time to improve the environment is in childhood. In the Birmingham public schools it is realized that the child should have the optimum diet and that to secure this for him will require not only supervision but also education of three groups, the pupil, the parent and the teacher.

How is this to be done? The greatest energy should be expended not on individual, selected children but rather on the student body as a whole. Only too often home visitors, nutrition workers and school nurses become keenly interested in the individual case of obvious nutritional failure and focus all attention on this one child. His nutritional history, his dietary habits and the habits of his family are all closely scrutinized, and with good result, but the scope of such work is too limited. I realize fully the importance of correcting individual instances of nutritional failure, but this shrinks into relative insignificance when compared with the good to be achieved through improvement of the nutritive status of all the pupils. Not only will numerous cases of minor, unrecognized nutritive deficiency be thus corrected but the development of a large group of pupils will be materially enhanced. This demands well planned educational efforts addressed to the group as a whole.

To what extent is it proper in the teaching of health to emphasize the essential nature of any one food factor or group of factors? This, I am afraid, when carried too far is a dangerous thing. It is apt to lead to one of the greatest causes of nutritional failure in America, food faddism, a fault which the teacher of nutrition must constantly combat. I hasten to add that an exception should be made in the case of milk. Because of

its importance to the child I think it proper to emphasize time and again the great value of milk, but, for example, to say too much about fruits and green vegetables, and their richness in vitamins and minerals, and too little about meat and eggs may result in the making of vegetarians. This would be a grievous mistake, for few forms of mental invalidism are more insidious than vegetarianism. The teaching should include instruction in the value of each of the foods and the place each should have in the diet, and emphasis should be placed always on the danger of the one-sided diet.

Experience taught us in the Birmingham schools many years ago the great educational value of the nutrition class. The underweight and otherwise undernourished children were placed in special classes and given intensive instruction in nutrition. In addition, each child was required to take specified amounts of milk, and graphic wall charts were kept of the gains in growth and weight. At intervals graduation exercises were held and pupils who had reached the requisite body weight and nutritional status were given an appropriate diploma. I emphasize the importance of the nutrition class not alone because of its help to the undernourished pupil but because of the manifold ramifications of its influence. The instruction given in these classes gradually percolated throughout the entire school and came in time to influence the dietary habits of an appreciable proportion of all the pupils. It was early noted, for example, that the milk sales in the lunch room were increased in each of the schools in which nutrition classes were established. Also, the influence of the class reached into the home and not infrequently influenced the dietary habits of the pupil's entire family. We encouraged ourselves to believe that we were improving the nutritive status of the entire community.

The responsibility for the teaching of health does not rest alone with the department of child health. In the school plan which has been developed in my city, this department examines the pupil, plans the work, offers advice, prepares bulletins for guidance and conducts a certain amount of supervision, but the greatest part of the instruction is given by the teacher. She is asked to correlate this instruction with her other work, for example, the writing of theses on nutrition may be used as a drill in English or the making of nutrition posters in the study of art. Of great importance are the auditorium exercises, of which the schools devote one each week to health. There are lectures on health and other exercises, and not infrequently a play about health is staged by the pupils. The teacher of the past generation did not prepare herself to teach nutrition or to give other forms of instruction on health, and it has not been an easy matter to demonstrate to her that this subject is just as important a part of the school work as the teaching of English. Gradually, however, she has come to recognize the part she is expected to play and is developing a genuine interest and enthusiasm for her work on health.

Of great help in this field of instruction is the example set by the lunch room. Although for various reasons the lunch room may best be conducted by an independent school agency, the maintenance of a relationship of cordial helpfulness between this agency and the department of child health is not difficult. We have not found it so. The department of child health of the Birmingham schools has no direct authority in the lunch room, but its advice is frequently sought on important matters, and its suggestions have always been adopted without question. In this way it has been possible to

provide menus that are both nourishing and wholesome, and the example of these has been of distinct educational value.

CONCLUSIONS

A nutritional program for the public schools should include not only measures for the detection of the individual case of nutritional failure but comprehensive efforts toward an improvement in the nutritional status of the entire student body. It should be broadly educational.

HEARING PROBLEMS IN EDUCATION

HORACE NEWHART, M.D.

MINNEAPOLIS

My purpose in this paper is to emphasize the responsibility of the educator and the physician in meeting the needs of the hard of hearing school child.

The possession of normal hearing acuity is necessary for a normal growth in intelligence, the acquisition of articulate speech, the development of a personality capable of winning success, and the attainment and preservation of one's economic and social security. These objectives should all be included among the aims of a modern education.

From the otologist's point of view the hearing problem of first importance in education is the prevention of hearing deficiencies and the conservation of hearing among school children.

A definite mandate to this effect was directed to educators and the medical profession alike when, at its meeting in 1926, the House of Delegates of the American Medical Association, on the recommendation of the Section on Laryngology, Otology and Rhinology, passed the following resolution:

Recognizing the fact that the most effective means for the prevention of deafness consists in the early detection of hearing impairment, thereby giving opportunity for the prompt removal of contributing causes and believing it to be one of the important functions of our public school authorities to safeguard the integrity of the special sense organs as well as the general health of the school child be it

Resolved, By the Section on Laryngology, Otology and Rhinology of the American Medical Association that it heartily favors the provision by our public school authorities for regular, periodic examinations of the hearing acuity of all public school children, such examinations to be adequate to detect even slight degrees of hearing loss.

The obvious purpose of this resolution was to encourage the general use of scientifically accurate methods for the routine testing of the hearing of all school children, such methods having been made available by the release of audiometers of various types, particularly the 4-A or phonograph audiometer designed for group testing of school children in a practical, economical way. The older methods—the watch-tick, whisper, conversation voice and acoumeter—as ordinarily applied had proved sadly inadequate for this purpose.

This resolution was promptly adopted by all the national organizations composed of otolaryngologists and by many other national, state and local groups, including the American Federation of Organizations for the Hard of Hearing, now the American Society for the Hard of Hearing, and the American Student Health Association. Practical endorsement of the principle of early detection and prompt corrective treat-

ment implied in the resolution has since been made by the boards of education of many widely distributed American communities in which the use of the audiometer has been incorporated in their respective school health programs.

The most outstanding and inspiring endorsements of the principle recently have been made by both the state and the city of New York. During the past two years the Board of Education of New York City, with the liberal support of federal and state funds, has put in successful operation as PWA Project 188-1177 a most comprehensive survey of the hearing of public and parochial school children, including the medical and educational follow up necessary to insure the child with defective hearing an equal educational opportunity with the normal hearing child.

This survey has included a screening test by the 4-A audiometer and a second test by the same means of all pupils found to have an apparent loss of 9 decibels or more. All who by the second test again showed a loss of 9 decibels were further checked with the 2-A audiometer, a pitch-range instrument used for determining hearing loss by pure tones over a range of from 64 to 8,192 cycles. This method has the endorsement of the state education department of New York and is already in use in many communities of the state. The program includes the reference of cases presenting discovered hearing impairment to the private otologist or, in indigent cases, to the otologist acting for the interested welfare organization.

During the past year the state of New York has enacted legislation making mandatory the testing of all public school children by the audiometer. This legislation was endorsed by and became effective through efforts of the Medical Society of the State of New York, the state education department and the state board of health, as well as by the New York League for the Hard of Hearing and other chapters of the American Society for the Hard of Hearing, and many civic-minded groups throughout the state. These two notably successful steps in the effort to conserve the hearing are a fine example for similar action in other states.

Surveys of the hearing already made by different observers have brought out many important facts pertinent to this educational problem.

The older methods of testing hearing acuity, because of their inaccuracy, disclose a definitely smaller number of children having a significant hearing loss than is revealed by the audiometer. Certain discrepancies noted in the results of the tests occur from failure to observe fundamental acoustic principles necessarily followed in testing hearing acuity by any method, the most important being that no test can be accurate when made in the presence of distracting or masking noises. Each ear must be tested separately, as is done with the audiometer, the other ear being excluded during the test.

The 4-A audiometer and its improved successor, the 4-B instrument, are used for expeditiously screening large groups of pupils who are old enough to write to dictation and for checking younger children by individual tests to disclose those having a significant hearing loss. The latter require a careful otolaryngologic examination including a check up by a pitch-range audiometer whenever possible.

The supervision of such tests, their standardization and the provision for the medical follow up and, in case of indigence, provision for the indicated medical or surgical corrective treatment, constitute a hearing prob-

lem the solution of which should be directed by the state medical service. The closest cooperation between the state board of education and the state board of health is here necessary.

It should be emphasized that the needed medical care, whenever possible, should be rendered by the private practitioner or the otolaryngologist. To counteract the possible apprehension that these state-directed activities may lead to an alienation of the private patient from his physician, it has been suggested by Dr. Burt R. Shurly, an otologist and a member of the Detroit Board of Education, that the name of the family physician be regularly placed on the health records of all public school pupils.

All indigent hard of hearing children should be provided with needed medical care equal in quality to that received by the private patient. The local physicians rendering this service should be adequately compensated in a manner not prejudicial to the interests of the medical profession.

The question of state-operated ear clinics, stationary or ambulatory, is one of local expediency. In certain rural areas they are especially needed.

Audiometric surveys of school children have revealed the important fact that a slight hearing defect, in some cases not recognized by the pupil himself, his parents or his teachers, often causes retardation, speech defects, an inferiority complex and unsocial behavior problems.

Retardation, the pest of the teacher and a burden to the taxpayer, which results from many causes, occurs at least twice as often among children with a hearing defect as among normal hearing children. Speech defects have been shown to occur eight times as frequently among hard of hearing children as among pupils who hear normally.

Statistics for the occurrence of an inferiority complex and behavior problems due to hearing defects are not available, but every experienced teacher and staff member of a child guidance clinic knows the damaging results from diffidence, discouragement and lowered morale in the child who has failed because of an overlooked, neglected or uncompensated hearing deficiency.

The periodic testing of school children with the audiometer in Minneapolis over a ten year period has proved the effectiveness of this procedure in definitely reducing the incidence of hearing impairment in the school population. While this in part has resulted from such factors as immunization, stricter isolation of cases of contagious diseases and better hygiene, the marked drop from 8 per cent in 1926 to 5.3 in 1936 is due chiefly to the production of a greater community ear consciousness, especially on the part of parents.

Defective hearing is definitely more prevalent in rural areas than in communities having an effective school health program. In the rural schools adjacent to Minneapolis, according to a survey made as a University of Minnesota WPA project, the incidence of a significant loss of hearing was found to be 13.6 per cent, while for the same age group, as tested by the same technic, pupils in the city schools showed an incidence of only 5.3 per cent. In this connection it is of interest to note that Minnesota public health nurses carefully testing rural school children by the old methods reported only 2.2 per cent as having a significant hearing loss, as compared with 8 per cent found among Minneapolis school children when the audiometer was first introduced.

Another important problem in education related to the hard of hearing pupil is that of providing instruction

in lip reading and speech correction in the regular schools for all pupils who need it in order to keep up with their classes. Those with a severe hearing loss and having marked speech difficulties who cannot advantageously continue in regular classes must be given this special help in residential and day schools, but they should not be segregated with the totally deaf, which practice, in the opinion of those best informed, is a gross pedagogic error. The determination of the degree of hearing loss requiring special instruction and admission to a special school should be made on the recommendation of a qualified otologist.

A further problem which demands the attention of the educator is the provision of suitable electrical hearing devices for such hard of hearing pupils as can be benefited by their use, in the form both of portable or semiportable individual hearing devices and of multiple aids for use in group instruction in grade subjects and for speech training and correction. Marked improvements recently made in the efficiency of electrical hearing aids has greatly broadened their field of application. Audiometer tests of pupils in schools for the hard of hearing and the deaf disclose the fact that some of the pupils have sufficient residual hearing to have enabled them to pursue their education in the home school, could they have been equipped with a modern hearing aid in early childhood. They had been placed in special schools because of their speech difficulties.

Another hearing problem confronting the educator is the conservation of residual hearing. Even a slight remnant of hearing power in the speech range, when supplemented by lip reading and, in suitable cases, by a hearing aid, is useful in acquiring speech and in preserving rhythm, flexibility, enunciation, accent and other qualities. Therefore it is important to guard all pupils, especially those in day and residential schools, against infections of the upper respiratory tract and contagious and other diseases that are likely to cause further hearing loss.

Two further hearing problems that are related to education are vocational guidance for older children and the provision of instruction in lip reading for adults. The latter is being satisfactorily met in many cities through cooperation between boards of education and local chapters of the American Society for the Hard of Hearing.

The problem of deafness prevention and the best care of the hard of hearing is a national educational and medical problem of large magnitude. The two chief obstacles that stand in the way of its early solution are, first, a general lack of knowledge concerning the fundamental principles involved and the large possibilities of attainment through intelligent, organized effort, and, second, the pathetic lack of needed funds.

The first obstacle can be overcome only by a well directed campaign of education among physicians, educators, parent-teacher organizations, teachers in training, social welfare workers and legislators.

The second obstacle, the urgent need of funds, can be met by well planned, national and state welfare and social security legislation. The necessary leadership to secure effective legislation of this kind can best come from those organizations which are here represented, namely, the American Education Association and the Section on Pediatrics and the Section on Preventive and Industrial Medicine and Public Health of the American Medical Association working in cooperation with parent-teacher groups.

78 South Ninth Street

LIGHT IN THE SCHOOLROOM

EDWARD JACKSON, M.D.

DENVER

The command "Let there be light" was the beginning of creation, and all created life has found it "was good." Plants and animals transform the force of the sun's rays into food and life. The human race, in all languages, has used light to interpret joy, hope, intelligence, information, truth. The contrast of light and darkness explains the contrast of good and evil.

Each day in the past winter I have watched the children running to school, shouting to one another, happy to greet one another, to get together for a few minutes outdoors on the playground. It seemed so different from Shakespeare's picture of "the schoolboy with shining morning face, creeping like a snail, unwillingly to school." There seemed no reason for this contrast except that the playground was out in the sunlight and the schoolroom was in comparative darkness. Perhaps the schoolrooms were even worse in Shakespeare's time than they are today.

The bright joy of childhood comes to the child in the sunlight. There is no reason why he should be deprived of it. Long ago the fear of enemies drove cave dwellers into darkness or into forts for protection or people have been driven into houses for rest. These have made the darkness of the shut in and have made us tolerant of poor lighting. Our churches for introspection and colleges for instruction have given to near-darkness a prestige and toleration that make them suggestive of learning. But the child has lived outdoors in all ages, drawing health, strength, stimulus and joy from the sunshine. It is a serious change from the free, self direction of childhood—the following of race instincts and the outlet in games that have been played for generations until they fit in with the natural development—to the performance of imposed tasks, justified only by their preparation to meet the needs of later life. This change is made more difficult by the requirement of giving up, with freedom of conduct, the stimulus of good light.

If school could begin with two years of supervised play, in outdoor playgrounds, with full light, it would help to get the full cooperation of the child. Loss of the child's hearty, interested cooperation is the first grave error of our educational system. It is a more serious error than we have known. It has set up an opposition between natural desire and suggested tasks, between normal activity and purposeful occupation, between what we want to do and what is expected of us. It sets up a conflict between study and health. Those who most need health sacrifice it for study. Those who most need opportunities of study throw them away to cultivate the natural desire for health and bodily vigor. Failure to recognize the child's inherited need and enjoyment of light outweighs in effect much of our labor on the curriculum and skill in pedagogy.

More than all else, it lowers the child's standards of health as a main objective. This is a loss which even a lifetime study of health and the health interests of patients fails to restore wholly. Let us understand this in preparing to deal with all the health problems in the schools. We, who have to consider the problems of

vision in the schools, are constantly being reminded, and are often baffled, by the low standards of lighting needs that are prevalent in the community

The light standards of the children are the light standards of the human race, the light standards of savage men who hunted and fought and worked under the open sky. They are the light standards of the higher animals that see their food and their enemies by the light of day, not that of the owl, the hyena or even the wolf, guided by the sense of smell and mainly hunting at night. The child's standards must also include those of macular vision, to recognize the minute differences in the forms of letters, textures and structures which require more light than the objects perceived in the peripheral field of vision. The only standards acceptable for the school are those of optimal vision—the highest visual acuity, the easiest and quickest vision, good light on a cloudy day and in the morning and evening.

If we wish to inculcate principles of justice, we must practice equal justice in the essentials of school life. A physician who became the health officer of his city and the president of his state medical society knew, as a boy, that he was near sighted. But his father did not "believe" that boys should wear glasses, and his teacher's ideas of justice did not include peculiarities or disabilities of particular boys. His teacher wrote something on the blackboard and told William to read it from his seat. William said "I cannot see it." "Yes, you can," said the teacher, and told the next boy to read it, who read it promptly and easily. "Now you can see it," said the teacher. "I can't see it," repeated William. Then, as William told it when he was president of the medical society, "he boxed my ears and gave me ten demerits."

With the light meters of the present day, the light that falls on each desk and book can be measured in every part of the schoolroom. Doing this in some of the best lighted schoolrooms of Denver, we found that the light at the bottom of the windows opening to the clear sky was from 100 to 200 foot-candles. On the tops of the row of desks nearest these windows it was from 40 to 50 foot-candles. On the desks farthest from the windows it was from 5 to 10 foot-candles, and on the blackboard smeared with chalk, on which were written things for all the children to read, it was always less than 10 foot-candles, in some parts of the room the eyes had also to contend with glare of the reflections of the windows.

In the School Clinic of the University of Colorado Medical School, we found two sisters who had reached the seventh and eighth grades in school and who kept up with their classes. This doubtless depended on their using very strong light and getting much help from other members of their family, for they each had 15 diopters of hyperopia—more than is commonly left after removing a cataract from an eye that has previously been hyperopic.

Justice requires something more than good light in the schoolroom. But it cannot be done without adequate light for all the children. And this cannot be attained until teachers and parents and pupils understand what is good light and its great importance at all times. When all of these have mastered this essential, school authorities, school architects and school financiers still have to be educated to know that good lighting and justice are worth having in any community.

HEALTH EDUCATION AND HEALTH SERVICES IN SCHOOLS

FROM THE POINT OF VIEW OF THE
"EDUCATOR"

JAMES FREDERICK ROGERS, M.D., DR.P.H.
Consultant in Hygiene U. S. Department of the Interior,
Office of Education
WASHINGTON, D. C.

The term "health education" has been used to cover all conditions and activities influencing the health of the school child. In this sense it includes the school health service but since, in the subject assigned, I have both "health education" and "health service," it must have been the intention of the program makers to limit the former expression to health instruction. The title might then be reworded to read "The Health Service from an Educational or Informational Point of View."

The teacher and the physician or, to be more exact, a few teachers and a few physicians, have always been mutually interested in the welfare of the school child. The first book on hygiene intended for the use of students was written 350 years ago by a physician who was also a teacher. A hundred years ago Horace Mann, an educator, was the leading agent in efforts to improve schoolroom conditions and to furnish instruction in hygiene to all children. But he was ably abetted in his endeavors by a physician, William Alcott, who was the author of an interesting textbook on physiology and hygiene for the use of schools. Alcott urged the adequate training of teachers in "a thorough and practical knowledge of the science of human life and health." Moreover, he expressed his "doubts whether our common schools will ever become what they ought to be as places for the promotion of health until they are brought under the care of judicious medical men. For, say what you will of the novelty of such a plan or proposal, our schools ought to have their regular physicians, as much as our houses of industry, our almshouses or our penitentiaries." He continued, "there will be daily or hourly recurring cases" which "the honest, faithful, enquiring teachers who have had their minds turned to the subject of health will want to present to the medical man at his semiweekly, weekly or monthly visits."

In this prophetic proposal of a school health service, it will be noted that the service was not to be carried on by physicians but by physicians with the assistance of the teachers.

When, a half century later, this dream of Alcott's became a reality, the duty of the fifty "medical visitors" appointed to the schools of Boston was to inspect the children previously selected and sent to them by the classroom teachers as showing signs or symptoms of disease. They made the diagnoses but the teachers did the examining. We sometimes become fretful over the seeming lack of results from our schemes of medical inspection and it is encouraging to remember that in four months 9,000 children were suspected by the Boston teachers as ailing, and the suspicion was confirmed in the case of 5,825 pupils, or nearly two out of three, and 1,033 were sent home. The great majority had skin diseases, but there were fifty-eight cases of diphtheria, nineteen of scarlet fever, forty-two of measles, 178 of whooping cough, thirty-five of mumps, twenty-two of chickenpox and seven of congenital

Read in the Symposium on Health Problems in Education under the sponsorship of the National Education Association and the American Medical Association Atlantic City N. J. June 8, 1937.

syphilis. Considering that the teachers were not at all trained for this function, they had done a good piece of work. The superintendent could well comment "I believe the importance of this work can hardly be overestimated."

This beginning in health services (in which the educator and physician joined forces for the reduction and prevention of disease) was brought to pass after much effort by a public health official who was himself a physician. It was chiefly a police and a protective, and not an educative, measure. In other words it was a service, but it was a service to education in that it reduced absenteeism on account of illness and improved the condition of those who had been plagued, while present, by itch mites, head lice and other signs of insanitation.

Educators had long been more or less concerned over the child with poor vision and the deafened pupil and had sometimes asked the parents to consider the need of seeing a physician. Five years after the systematic search for disease was instituted in Boston, the state of Connecticut passed a law requiring the examination, every three years, of the vision of school children. Here again the examining was to be done by teachers, and when vision was defective the parents were notified, in the hope that something would be done about it. This examination could have been used in connection with health instruction, but the teaching of hygiene was falling to a low ebb since its high water mark in the eighties and the examination proved largely a service, although it helped to impress some children and some parents that there was such a thing as poor vision, which could often be improved.

Beginning with this examination of the most important mechanism of the child having to do with his acquisition of knowledge, the interest of educators, or physicians employed by schools, extended to an appraisal, of various degrees of thoroughness, of other bodily conditions that might affect the child in his school progress. In seven states the responsibility of making these more extensive examinations is laid by law on the teacher and in eleven more the teacher is included among the examiners, although in only two states is any training for this function to be furnished.

Since this was a development from the search for scabies or for scarlet fever, the same afterfinding procedures were followed. While the child was not sent home, a note was sent to the parent telling of conditions that seemed to exist and concerning which a physician should be consulted.

Growing, as it did, out of the search for communicable disease, for which at this time there were, except for smallpox, no preventive measures other than isolation, it did not occur to the examiner that something more than a notification might be desirable. However, some educator, school physician or school hygienist suggested that the medical inspection should be made more of an educational event for both child and parent, and the only way to make this event truly educative is for the examiner to take the person most interested, the parent, into his confidence, first hand, and to ask him to be present at the examination.

Of course, when the process of examination consisted in the scanning of a dozen or so children per minute there was no possibility of having any one present besides the physician, child and possibly a recording angel in the person of a nurse. This speedy process was not the fault of the educator, and the educator in the person of the teacher as first examiner was left out

of account. There was a serious neglect of an important historical precedent.

Attempts have been made in certain grades at school to prepare the child for his physical examination by explaining how it will be done and that its purpose is not merely to find what is wrong with him but to help him to keep fit for work and play. The value of periodic examinations is emphasized. The examination has also been used by many teachers as a hook on which to hang lessons concerning health. Such teaching should produce good results, but it does not compensate for a lack of intimacy and understanding with parents and especially in connection with the examination of children in their earlier years.

The purpose of the health service is not merely to find defects or diseases but to get something done about them. Something had to be done about communicable diseases, but the matter of defects was not taken so seriously. Little attention was paid to the curt note sent by the principal in the earlier days of medical inspection. The parent was not present at the examination and did not know what it was all about. The laborious visits of the school nurse helped to enlighten the parent but, even so, as low as 15 per cent of defects treated or corrected are still reported, which means an enormous waste of time and public funds. Moreover, if at all educative, it would seem to be in the direction of developing a feeling of futility toward the efforts made by the school, for the parent sees that his child usually survives despite his refusal to follow the advice offered.

The child not only survives but gets along in school, for except in a very small proportion of children (those having very gross defects) there is little evident relationship between physical condition and school progress. There may be a relationship between even minor ailments and fitness for work and play sometime in afterschool life, but the medical service might confine itself to conditions which it is certain may prove a menace and are worth the cost and sometimes the risk of treatment.

Here again we need to take the parent and teacher into our confidence to make sure we are right before we go ahead. There is considerable evidence that if this were done not so many tonsils would be sent to the guillotine and the evidence of good results would be less dilute than when 90 per cent are recommended for this not altogether safe ordeal. The same is true for other conditions often labeled defects.

In one of our school systems, two thirds of the glasses prescribed and fitted were found to be residing in a drawer at home instead of on the noses of the children for whom they were intended. In England, of 1,000 children who had been supplied with glasses and who had been out of school six years or more, only 50 per cent were wearing them. Treatment was forthcoming in all these cases, but was the treatment needed or was it followed up to see whether there was need of further treatment?

Of seventy school physicians one, according to Newmayer, pronounced five children out of 1,000 anemic and another 250. Either the former was right and the rest were all wrong or the latter was correct and the others mistaken. Of the same seventy, one found nasal obstruction in 1 per cent, another in 22 per cent. If only five in 1,000 need treatment for anemia, we have no business trying to secure treatment for fifty times that number. Children cannot be standardized, and doctors will always disagree, but if we are not to waste public funds and if we are not to educate in the direction of considering the findings and recommendations of the

medical inspector of slight consequence, we should be conservative and should study the results of our efforts.

Every honest physician will confess that he knows none too much about any child whom he examines and he will be willing to learn all he can from both teacher and parent or from a colleague. The physician is always in need of education.

There is, in our school medical inspection records, a mine of information—a means of comparison of the treated with, for controls, the nontreated—a mine which, save in Philadelphia, Rochester and Minneapolis, has hardly been touched. Unfortunately we have as yet had only a handful of persons in our school health services who were interested in that service professionally and in reducing it to as nearly a science as the art of school medical examination can be made.

A most important reason for being conservative in our observations is the difficulty of securing treatment for those children whose parents cannot afford to pay. The educator and his agent, the medical inspector, have no wish to set up treatment clinics except as they are obliged to do so in order not to waste the efforts put forth in finding the conditions recommended for treatment. In the case of dental defects they are justified by the overwhelming problem of treatment that swamps the dental profession. There is also the matter of refraction. The cost of refraction by a private physician is often prohibitive for a large percentages of cases and some public means for this service and for the supply of glasses is often imperative. However, the school would gladly have this work of treatment done outside its walls. But it wants it done by somebody in order to achieve what it starts out to achieve—the physical betterment of the child.

In the beginnings of the search for conditions in the mechanisms of the child that might possibly be improved, there was no intention of taking this work out of the hands of the private physician. Although this was an innovation in medical procedure, parents were often asked to have the routine examination made at first hand and before the child was sent to school. In the medical inspection law of New York State passed twenty-four years ago, every pupil was required to furnish, annually, at the opening of school, a certificate signed by a duly licensed physician stating whether the pupil "is in fit condition of bodily health to permit his or her attendance at the public schools." If the certificate is not presented, a notice is to be served the parent and if a certificate of physical fitness is not forthcoming within fifteen days the penalty is an examination by a physician employed by the school. Ninety-five out of a hundred parents prefer to pay this money-saving penalty, so that this effort at securing examination by private physicians is a conspicuous failure. It is evident that other than a legal method of approach is necessary if periodic examinations, out of school, are to be secured, even by those who can well afford to pay for such examinations. Dr Smiley¹ has had something interesting to say on this subject, and recently an account was given by Dr Shurly² of progress in the linking of the educator and the family physician in Detroit. It is to be noted, however, from this article, that in some schools only 22 per cent of families have such a medical relationship.

The educator or the school health service has no desire to minimize the work of the private physician,

although it has not always done what it might to emphasize his importance. Nor has the physician any desire to have any child go untreated, or without adequate treatment. There is usually need for more sympathetic and systematic junction of forces to determine in each community where the lines are to be drawn between families that can and those that cannot pay and to see that all children are treated.

As useful as it is, the educator would like to see the health service reduced to a minimum and finally eliminated. It has helped to eliminate itself so far, for defects and chronic ailments are to a considerable extent the result of communicable disease, and the incidence of communicable disease has certainly been reduced. Defects are also a consequence of malnutrition, and while it is late to do anything about nutrition at school age, the educator and his health service hope that their teaching will have some effect on the nutrition of the next generation.

SUMMARY

From this historical review it will be noted that, as suggested a century ago, the teacher is an important agent in the school health service and, as Alcott mentioned, she should be better trained for this service. As a prominent school health officer remarked recently, "the teacher is the keystone of medical inspection." The teacher is the daily examiner, who is as important as the periodic examiner.

In the rapid shift from the isolation of communicable disease to attempts to improve bodily mechanisms, we have only begun to be educational. To be educational we shall need to take the parent into our confidence, and in so doing the medical examiner himself may learn something. He may also educate himself by study of the results of his own work.

It is not educational and it is a waste of time to attempt to do too much, and we need to be conservative in our conclusions and persistent in getting something done about them.

It is a part of education to see that the family physician is given the place he deserves in the social scheme. He should be the periodic examiner if possible. On the other hand, the physician should reciprocate by doing his utmost to provide treatment of the indigent.

The director of the school health service needs to be educated for making the most of his opportunities both for service and for study, in order that his service may be more economical, more effective and more educational.

The educator would, I am sure, be glad if the need for a medical service were a thing of the past, but at present he is in need of a better health service, a service better manned and better managed—one which cooperates fully with the medical profession and which receives the full cooperation of that profession.

U. S. Department of the Interior, Office of Education

ABSTRACT OF DISCUSSION

ON PAPERS OF DRS. FERRELL, MCLESTER, NEWHART, JACKSON AND ROGERS

DR. ALLAN G. IRELAND, Trenton, N. J. In facing this problem, it is essential that it be known what is meant by education. Great changes have taken place since our school days. Then it was a three R proposition. Today it is guidance toward human living and all that the term implies. Whatever aims are accepted for education there is one underlying theme: that education seeks first to perpetuate society; that is, the state. The best instrument or institution to date is the public

¹ Smiley, D. F. An Approach to the Problem of School Medical and Dental Service. J. A. M. A. 108: 435 (Feb. 6) 1937.
² Shurly, B. R. The Family Doctor. J. A. M. A. 108: 169B (May 22) 1937.

school Into it each year are placed the raw human material of every community in the nation It is this material we fashion and train to take our places as we pass on It becomes the state of succeeding generations and we hope a better state on increasingly higher levels of human living For this purpose the three R's and allied subjects alone will not suffice We are now in the process of weighing the accumulated knowledge of man We discard some and we save some Where we do this wisely we save those bits which go to give our young successors greater health, security and happiness To this end the core program is basically health—physical, mental, emotional and social The school staff is made up of specialists There are teachers of English, French, mathematics, music, home economics and others We approve of this Why not then such specialists as physicians, dentists, nurses, social case workers, visiting teachers, psychologists, psychiatrists and nutritionists? It is logical in view of the changing concept of education The superintendent of schools is the executive His job is integration, in which he holds the reins to these specialists He has one goal—education of the child in an all-round preparation for socialized human living To attain his goal, he can't drive half a team, leaving the other half to another agency, another executive The physician and the nurse are allies of the teacher They contribute their talents to the whole teaching process To do this with the whole-hearted cooperation that is essential, the specialists must be on the same team with the teacher and under the same captain

DR JOSEPH H KLER, New Brunswick, N J That there is need of a school health program every one will admit However, the scope of this program presents technical problems and problems of integration The processes of education are designed to complement the broad educational program of the home Our form of government did not endow the school with complete control over the bringing up of our children The home is still the unit of our civilization and as such must be the center of all our social processes Since education is dependent on health, a school health program is necessary As such we accept it The controversial points are its scope Why must we commit ourselves to a fixed program that all schools must adopt? We know that practically every community presents health problems peculiar to it Every school will present its individual problems Does it not seem reasonable to ask the cooperation of the medical profession with the school health authorities as well as the cooperation of the school physicians with the medical profession, as represented by the American Medical Association, in the development of an effective and mutually advantageous school health program? School physicians as a group need a helping hand With cooperation alone can we safeguard the health of our children and discharge our social and professional responsibility This cooperation can best be developed through meetings such as this one, where we may discuss our problems I therefore move that we extend our thanks to the committee in charge of this symposium and at the same time request the American Medical Association to arrange for a similar meeting to be held at subsequent annual sessions

DR THURMAN B RICE, Indianapolis I have been much interested in the papers concerning good hearing and vision There is one point which I should like to add to the discussion It has to do with the matter of character formation in relation to underlying physical defects Moderately short sighted children tend strongly to become bookworms and to develop without outdoor life or sports Such persons are likely to develop postural defects, owing to the fact that they do not get sufficient exercise They are inclined to have poor digestions and to be choice about their food, and then such persons become finicky This is due to the fact probably that they do not get a very broad conception of the surrounding world Moderately far sighted children are on the other hand, likely to be considered dull at school though they are bright enough outside Such children often come to be known as motor minded They love outdoor sports and activities but do not sufficiently appreciate the finer details of life, for example Glasses on these persons would tend to correct the underlying physical defect and tend strongly to improve their general reactions to normal living conditions Persons who are deaf are frequently inatten-

tive and strongly inclined to withdraw into themselves Not appreciating the annoyance that noise is to the normal individual, they frequently allow themselves to become unnecessarily noisy With reference to Dr McLester's paper there is one point which I should like to emphasize It is agreed that the modern generation is better fed than any previous generation and, as evidence of this, college students are now from 1 to 2 inches taller than were students of fifty or sixty years ago This seems at first thought to be definitely a good thing but one may wonder a little whether it really is or not If we have assurance that these boys and girls who are 1 or 2 inches taller and have heavier bones and muscles are really better off by being so, so far as I know there is no evidence that their hearts are correspondingly larger or that their kidneys have more tubules or better tubules Much as we admire a fine looking, upstanding young woman or young man, scientific caution compels us to wonder whether the parenchymatous organs are correspondingly developed If it should finally be shown that the heart, kidneys and other related organs are those of a person weighing 150 pounds it would certainly be no advantage for him to weigh 175 It might even be a handicap Nutrition is an extremely complicated phenomenon and cannot be measured in terms of height, weight or even red cell count or percentage of hemoglobin This being the case, it is still impossible to make sure just when nutrition may be said to have been the best

DR D F SMILEY, Ithaca, N Y If the present were the relatively simple civilization of the early Greeks, our schooling might well consist of philosophy to teach us how to think, and physical training Modern civilization has, however, long since outmoded this simple system of education We still try to teach children how to think but we have also added numerous factual and vocational courses We still too often continue to use the 'physical training approach,' forgetting (1) that in modern life physical development per se is not nearly as important as sound health habits, sound health knowledge, sound health attitudes and sound methods of health maintenance, (2) that physical training is only a small part of what school physicians, dentists, nurses, physical educators and specially trained health teachers can provide to protect and promote the health of school children What is most needed in our public schools is a preventive medical program built along lines of the six-point public health program of our city health departments, i e, communicable disease control measures, sanitation, child hygiene measures, vital statistics, public health laboratory services, health education Assuming that this goal was adopted, what would be the essential steps in approaching it? I would suggest five steps 1 Develop short training courses, which will prepare school physicians to attack the health problems intelligently and on the preventive medical basis 2 Develop a standard contract to be used by all physicians in their contractual relations with the public schools, this contract to set certain minimum standards as to the program of activities and the staff to carry it on It would not permit of a half time physician being asked to examine 4,500 children each year 3 Develop among the medical profession the following conceptions of school medical service (a) It is not a treatment service, (b) it is not expected to provide each child with a meticulous medical examination annually (that is the parents' responsibility and family physician's function), (c) it is expected to provide a continuous health supervisory service based on the continuous screening by the classroom teachers, (d) it is expected to provide certain group tests, and (e) if properly organized it can be made a high grade preventive medical service to which any doctor can be proud to contribute through a lifetime of service 4 Train all elementary teachers in the observation of the child's physical condition and in the elements of health instruction suitable to his age 5 Develop at our universities special training courses for health teachers who will superimpose on a foundation of science courses and professional education courses a course in health education which will prepare them (a) to present adequately to high school pupils the facts of modern preventive medicine and (b) to keep their health knowledge abreast of the many changes and additions that are being made to health knowledge from month to month

WOOD TICK PARALYSIS IN CHILDREN

E. J. BARNETT, M.D.

SPOKANE, WASH.

Wood tick paralysis in children¹ is acute and progressive but usually afebrile. The child awakens in the morning feeling entirely well. However, as soon as he attempts to stand alone he collapses. In an effort to walk with support the gait proves ataxic. In a few hours, walking and even standing with support become impossible because of the progressive and increasing muscular weakness. At the beginning of the illness it is generally difficult for the child to feed himself on account of the ataxic movements of the upper extremities, and after a few hours self feeding will probably be impossible.

The tick which has caused the paralysis has usually been feeding and engorging for six days. It may be attached anywhere on the body. Ticks have been recovered in cases of paralyzed children under my care from the axilla, the groin, over the mastoid region and over the lower part of the spine. However, I have most often discovered the ticks in the occipital region of the scalp. Prompt removal of the tick, which is easily accomplished by gentle steady pull, is always followed by rapid improvement, with complete recovery in about forty-eight hours. Delayed removal is, in most cases, without avail, because fatal respiratory paralysis develops. In adults and in larger animals the paralysis is far less likely to be fatal, it may be localized to an extremity and followed by complete recovery even though the tick is not removed promptly. Ticks that I have taken from paralyzed children have been reported to be impregnated female wood ticks. Attempts to reproduce the paralysis in animals, the same ticks being used, have been uniformly unsuccessful. After detachment the engorged female usually refuses to refeed.

Knowledge of tick paralysis has not reached the majority of older physicians or, it seems, even the majority of pediatricians. Recent medical graduates are often without any information on the subject, though they may establish practices in the affected area, where damaging criticism follows missed diagnosis. Physicians frequently confuse tick paralysis with the ascending type of acute poliomyelitis. Tick paralysis in man has been reported from Australia, British Columbia and the five states of Montana, Oregon, Wyoming, Idaho and Washington. Attention has also been directed to the occurrence of the paralysis in animals, usually sheep and cattle, in the same districts, in Crete and in Cape Colony. The range of the wood tick extends outward beyond the Rocky Mountain region and adjacent areas to include a total of thirteen states. It is not unreasonable, therefore, to anticipate the occurrence of tick paralysis in hitherto unreported localities. It is fortunate that the annual wood tick season is about completed by the time of early summer travel. Consequently, cases of tick paralysis are usually limited to permanent residents.

It is interesting to learn that in some countries tick paralysis is transmitted by species of ticks other than the wood tick. In Australia it is due to the common

scrub tick, *Ixodes holocyclus* Newmann, in Cape Colony a still different species, *Ixodes pilosus* Koch, is the offender. Experimental tick paralysis has been produced by laboratory workers² in Germany from the eggs of the brown, or tropical, dog tick, *Rhipicephalus sanguineus* Latreille, although in nature this tick has never been reported to have caused paralysis. This brown dog tick is common in the United States, where, however, it rarely bites man, though in certain other countries it is reported to bite man frequently. In the United States thirteen species of ticks³ are found, of which five species are agents of disease, five potential agents of disease and three only indirectly connected with disease in man. Paralytic effects are limited to the wood tick. It should be noted that in the United States tick paralysis, like other tick-transmitted diseases, such as Rocky Mountain spotted fever, may not always be produced by the Rocky Mountain wood tick alone.

THE WOOD TICK

The Rocky Mountain wood tick is scientifically known as *Dermacentor andersoni* Stiles. This tick is an agent in the transmission or causation of three and probably four distinct disease entities in man, namely, Rocky Mountain spotted fever, tularemia, tick paralysis and Colorado tick fever.

The wood tick lives not only in the Rocky Mountain regions and adjacent areas but to the West in Washington, Oregon and California and to the East in the southwest corner of North Dakota and probably in the Black Hills country of western South Dakota, as well as occasionally in western Nebraska. In Colorado the tick probably does not live far beyond the eastern limit of the Rocky Mountain system. In the extreme south it has been found in at least the northern portion of New Mexico and Arizona. To the extreme north it has been discovered a considerable distance into British Columbia and is present in at least the southern portions of the provinces of Alberta and Saskatchewan.

THE BIOLOGY OF THE WOOD TICK⁴

Like all ticks, *Dermacentor andersoni* Stiles sucks blood and lays eggs. The eggs are normally deposited on the ground during the late spring and early summer. Six-legged larvae soon hatch from the pile of tick eggs, disperse to some extent, climb up grass and other vegetation and attach to passing small mammals, on which they feed. Being fully fed in about six days, the larvae drop to the ground, crawl away for protection, become inactive and soon change to eight-legged nymphs. These nymphs usually crawl into hiding and appear again the following spring, ready to feed on the blood of the same small rodents. After feeding for about a week they drop off, hide away and, after approximately three weeks of quiescence, appear as adults, either male or female. The adult tick seeks to conceal itself under waste, at or near the surface of the soil, until the following spring, when it comes out and begins its search for a new host, and the host it now seeks is one of the larger animals. Ticks are not primarily a parasite of man, and when man is bitten it is merely an accident of nature. The normal feeding season of adult ticks begins usually in March or early April and terminates with the coming of hot, dry

weather, generally in June or early July. Copulation takes place on the host. The female, when fully fed, in about nine days, drops to the ground and crawls away to find a suitable place to lay her eggs. The egg laying begins about a week afterward and consumes about three weeks. Approximately 300 eggs are laid each day. Thus the total deposited by one female averages some 6,000. The eggs require approximately thirty-five days for incubation and are hatched during the summer in which they are laid, in time for the larvae to feed on their chosen host. The normal cycle of the tick is two years. It has, however, the remarkable ability to go for as long as from two to four years without food while waiting for an opportunity to attach itself to a suitable host.

THE TICK VENOM

Experimental tick paralysis by attachment of female ticks has been produced in animals in from six to thirteen days, according to the size of the animal or the rapidity of engorgement of the tick. Similar paralysis has never been transmitted by the blood of affected animals or by the injection of the intestinal contents of ticks taken from paralyzed animals. Postmortem observations have been reported negative. Demonstration of specific parasites has not been successful. It has been suggested that poison in the salivary glands is the exciting agent. In this country efforts to transmit paralysis by the injection of eggs of wood ticks have not been attempted.

Brown dog ticks reveal many peculiarities. Regenzanz and Reichenow² in their experiments on this variety found that the eggs contain a venom whose effect is evidently identical with that of tick paralysis. Large amounts of eggs, usually the layings of about fifty ticks, or 150,000 eggs, when thoroughly ground in a small porcelain mortar with physiologic solution of sodium chloride and injected subcutaneously or intraperitoneally, were found to produce weakness in large dogs and paralysis and death in small dogs. Subsequently, the larger dogs, after further injection of tremendous numbers of eggs, acquired paralysis and died. This would seem to indicate a strong resistance to, but a lack of immunity against, tick paralysis. Necropsy disclosed extensive degeneration in all parts of the spinal cord (Marchi staining). Smaller amounts of tick eggs were found to produce paralysis and death in smaller animals, such as rabbits and guinea-pigs. After even smaller injections of eggs, rats and mice were found dead in from one to two days, usually without preliminary paralysis.

Initial symptoms in animals may occur without any incubation immediately after the injection of tick eggs. It seems improbable that any virus or micro-organism is the cause of the paralysis. Introduction of emulsion of eggs into the stomach of animals was tried, but no effect was observed, nor could death in animals be produced by injection of emulsion of larvae. Brown dog tick venom, which is resistant to drying, is not destroyed by alcohol and does not become inactive from high temperatures until heated to 85 C for fifteen minutes or to 100 C for one minute. Attenuation of the poison follows Berkefeld N filtration. The venom has only a weak hemolytic action. Its production in the adult female tick takes place simultaneously with the termination of blood sucking and the maturation of the eggs. Neither the salivary nor the head glands contain individually the poison in demonstrable quantities, although the poison is traceable in these glands as well as in the ovaries.

The venom of the brown dog tick, or *Rhipicephalus sanguineus*, is like the venom of the black widow spider in that it is poisonous and a motor-paralyzing agent for all animals by parenteral administration while it is inactive when given orally. However, the spider venom varies in that it is destroyed by alcohol and by a lower temperature. Spider venom is strongly hemolytic, and immunization is easily obtained.

REPORT OF CASE

The following case history indicates that the onset of tick paralysis may be an irritative lesion of the posterior sensory roots, followed by involvement of the anterior horn cells. Paresthesia, the first complaint, had not disappeared with the onset of the motor paralysis. The paralysis, as was observed in a motion picture taken one-half hour after removal of the tick, is quadriplegia rather than the usually described paraplegia. Another motion picture taken twenty-four hours after removal of the tick showed complete recovery from the paralysis. In this case, as in most all others in children, death from respiratory paralysis would probably have resulted in another two or three days if the engorged tick had not been found and removed.

J. C., a girl, aged 6 years, of Kingston, Idaho, was seen at noon on June 8, 1936. The previous day she had complained of itching and burning fingers and toes but ran around and played as usual. She slept well that night. On the morning of the examination she cried in pain on putting on slippers and 'wilted' when attempting to stand. She was carried around the house in the parent's arms because she was unable to walk. She had become afraid even to attempt to take a step lest she might fall. The history was so typical of wood tick paralysis that the scalp was examined first, an engorged tick 1 cm wide and 1.5 cm long was found and removed. The child complained of pain on passive movements of the legs. She rubbed the feet together to obtain relief from itching and burning. The patellar reflexes were absent. There was ataxia of all the extremities, more marked in the lower extremities, and the muscular power was so weak that, although the child sat up well, when she stood the body swayed and she required support. She could stand or walk only with the feet widespread.

The child returned for examination the following day. The mother reported that by bedtime the preceding evening she had begun to walk fairly well without support. Now she could again kick accurately and firmly. The reflexes were normal. The grip was strong, the movements of the upper extremities were accurate. She could walk and even run normally.

A complete neurologic examination by Dr. Joseph Lynch one and a half hours after removal of the tick revealed a robust child who walked with an extremely ataxic gait, with the trunk swaying laterally and anteroposteriorly, with a broad base. Examination of her head revealed slow nystagmus with the quick component to the right when she looked to the right and to the left when she looked to the left. The pupils were round and equal and reacted normally to light and in accommodation. Examination of the ocular fundi revealed normal optic disk, the outline of the disks being clear and well defined and not edematous. The retinal vessels were normal. The external ocular muscles were normally innervated. There was no diplopia, gross tests of the visual fields revealed no abnormalities. There was no disturbance of the sensation of smell. The sensation of the face was normal to stimulation by pin prick, cotton wool, heat and cold. There was normal contraction of all the muscles of mastication. The muscles of facial expression were normal and bilaterally equal. The platysma was normally innervated on each side. The tongue protruded in midline. There were no fibrillary twitchings. The uvula was retracted in midline, and there was no disturbance in motor power of the soft palate. The voice was normal, high and low tones being pronounced with equal facility. There was no disturbance of hearing. The tick of a watch was detected at normal and equal distances on each side. The sternocleidomastoid and trapezius muscles reacted normally. Examination of the neck revealed no change in sensation and no disturbance in muscular power of any cervical muscles.

Examination of the upper extremities disclosed an absence of both the biceps and the triceps reflex and a marked reduction of the supinator reflex more noticeable on the right than on the left. Hoffman's sign was absent on each side. There was no change in the upper extremities to stimulation of the skin with pin prick, hot or cold, cotton wool or vibration. Muscle and joint sensations in hands, wrists and elbows were likewise normal. However, the grip was reduced about 50 per cent in both the right and the left hand. The finger to nose test revealed marked ataxia in both hands. There was a lack of between 35 and 50 per cent in resistance to passive motion at the wrists and elbows but no lack of resistance at the shoulders. Examination of the chest revealed normal innervation of the intercostal and the pectoral muscles and normal excursion of the diaphragm. There was no impairment in the muscles of respiration or any sensory changes in the chest.

Examination of the abdomen revealed no sensory changes to any of the previously mentioned stimuli. However, the abdominal reflexes, upper and lower on each side, were absent, as was the epigastric reflex. Test of the lower extremities revealed normal sensation with all modalities, but the knee jerk and the achilles jerk were absent on each side. No pathologic reflexes were present in either extremity. There was marked weakness in the two lower extremities and a reduction of nearly 75 per cent in resistance to passive motion in ankles and knees. Muscle and joint and vibratory sensations were normal in both lower extremities. The Romberg sign was strongly positive. The patient was unable to stand alone even with a broad base and the eyes open. Examination of the muscles of the back and pelvis revealed marked weakening of all muscles of the trunk. When the patient attempted to stand or walk, her trunk swayed as if she was ataxic. The heel to knee test was very poorly performed because of marked ataxia of both lower extremities.

Summary.—Neurologic examination revealed that all the cranial nerves were normal. There were marked motor paralysis, characterized by severe weakness of the muscles, and absence of abdominal reflexes and of tendon reflexes in all the extremities. The lesion was of the lower motor neuron type but not of the peripheral nerve and was probably a lesion attacking the lower motor neuron in the region of the anterior horn cells of the spinal cord.

COMMENT

A rich field of research awaits the full investigation of the possibility of venom in wood tick eggs as the cause of tick paralysis in this country. The ticks taken from paralyzed children under my care have been engorged female ticks. In nature the paralysis develops after days of tick attachment, the time of early formation of the eggs. Human experiments in paralysis with tick attachment are unwise. There are two clinical reports of fatal spotted fever and associated paralysis.

The reason children are more often affected by tick paralysis may be not only that they fail to find and brush off ticks as readily as do exposed adults but that, because of their smaller size, less poison is required to produce the paralysis. In adults it is possible that ticks may attach in hairy regions, feed fully and drop off without producing symptoms. Ticks are often not found during attachment and feeding, as they apparently pour into the bite a local anesthetic and coagulant secretion of the salivary glands.

It is peculiar that the occurrence of wood tick paralysis does not yet correspond to the total geographic distribution of the tick. As has been mentioned, the paralysis has been reported in only five of the thirteen states in which the tick ranges.

Although a large number of eggs from many brown or tropical dog ticks produce a paralyzing venom in laboratory animals, it is notable that no case of tick paralysis in nature following the bite of this species has been reported. The egg venom may be so weak that paralysis in nature cannot result from the bite of a single tick. Is it possible that in wood tick paralysis

a single tick produces excessive egg venom early in the formation of eggs and excretes it promptly by the enlarged overactive salivary glands?

It would not be surprising if species other than wood ticks should be found to contribute to tick paralysis in nature in this country. Intriguing it would be to speculate whether tick venom from eggs could be a hormone, neurotoxic to human beings and to animals. We may venture the suggestion that patients with complete tick paralysis with respiratory involvement might be placed in respirators. This has not yet been done.

In spite of the wide range of the different species of ticks in the United States, there is no reason for great alarm, for, although many persons are bitten, relatively few are really afflicted.

SUMMARY

In cases in children clinical evidence indicates that the disease is a mild irritative lesion of the posterior sensory roots and a severe irritative lesion of the anterior horn cells of the cord. The resulting muscular involvement of the extremities is progressive and extensive, with death from respiratory paralysis in cases not properly recognized and treated by removal of the tick. Experimental evidence from another species of tick suggests that the disease is a poison liberated in the tick eggs. With the range of the wood tick extending, and with the possibility that eventually other ticks in this country may produce the paralysis, the subject occasions more pronounced concern. It is recommended that textbooks contain more information on all tick-borne diseases and that pediatric instruction in medical schools include information on tick paralysis.

END RESULTS IN FRACTURES OF THE SHAFT OF THE FEMUR

ELDRIDGE L. ELIASON, MD

AND

JOHN PAUL NORTH, MD

PHILADELPHIA

This review deals with a consecutive series of seventy-four cases of fracture of the shaft of the femur, of which 81 per cent have been followed, so that the ultimate anatomic and functional results are known. It presents the results of treatment by numerous surgeons, since, in addition to two chiefs, fifteen assistant surgeons were concerned with the management of these patients. Moreover it is not a series selected to illustrate the results of any one method of treatment for, as will be shown, a variety of methods were employed. The cases were all fractures of the shaft proper, subtrochanteric and supracondylar fractures are not included, as they present distinct problems. Consideration is given only to cases admitted to the hospital within one week of the injury and to those in which the fracture occurred through normal bone. The report of six patients who died in the hospital from associated injuries is omitted, since we are concerned here chiefly with end results. Of the seventy-four patients, twenty-four were over 16 years of age, and in certain respects it is appropriate to separate the adult and juvenile groups.

Read before the Section on Orthopedic Surgery at the Eighty Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 9, 1937.

The cases here reported are from the services of the senior author at the Hospital of the University of Pennsylvania 1922-1936 and the Presbyterian Hospital 1934-1936 and by courtesy the service of Dr. George I. Muller at the University Hospital 1922-1933.

No single method of treatment has been adhered to, for each case requires treatment according to its individual indications. We have, nevertheless, acquired certain impressions regarding the range of usefulness and also the limitations of the several methods, and these impressions will be briefly discussed. It will be apparent that certain technics now in vogue have not been used. For example, neither the Anderson two pin method nor the Braun frame has been included. While excellent results are being secured by these and other mechanical methods, like results can be obtained by simpler means when fundamental principles are strictly followed. This point should be strongly emphasized in teaching students and interns. The men going out into small communities to handle fractures should be impressed with the ideas, first, that good function is the goal to be achieved and, secondly, that patients can be satisfactorily treated by simple and conservative methods.

THE CRITERIA OF SATISFACTORY REDUCTION

It is apparent in the records of these cases that at the time of admission to the hospital there was often no certainty of opinion as to what method of treatment would be effective. The method instituted at the outset was satisfactory in only 36 per cent of the cases. In the remaining 64 per cent changes were made to improve the position of the fractured fragments. Not uncommonly three or four methods were thus tried. These alterations were time consuming, distressing to the patient and disturbing to the healing process. Probably some of them were unnecessary and certainly many were not beneficial. Correlation of the final position of the fracture fragments with the end results should help to determine the essential criteria of reduction satisfactory for good function, which is our prime aim. Perfect anatomic reposition obviously is an ideal to be sought, but in fractures of the femoral shaft it is often difficult to attain. As a matter of fact, good position—namely, alignment with no more than 15 degrees angulation, apposition of at least one third of the diameter of the bone ends and normal bone length—was obtained in no more than half of the cases. Since the proportion of entirely satisfactory functional results in our series was much higher than this, something short of perfection in anatomic restoration may still be compatible with a good functional result. The practical problem to decide is how much deviation from the ideal is permissible. As might be anticipated, no patients with good reduction, as defined, had residual disability, except the few impaired by stiffness of the knee, which stiffness was due to late treatment and not related to the accuracy of reduction. Displacement without overlap, even though sometimes there was no end to end apposition whatever, likewise was followed by favorable union and function in ten followed cases. Imperfect alignment with angulation up to 30 degrees generally did not interfere with the ultimate outcome. Greater amounts than this may result in actual shortening of the limb and especially if there is a lateral bowing will produce disturbance in gait. Alignment accordingly should be favorable for an assured good result. Abnormality in the length of the bone was the deformity responsible for most of our unsatisfactory results. In seven out of fifteen patients who had shortening at the time of union, a permanent functional disability exists. The essentials of satisfactory reduction appear therefore to be the restoration of accurate length and approximate alignment.

The Prognosis With Shortening—In this series fifteen cases presenting shortening of the femur at the time of union have been followed for a sufficient period (from one to twelve years) to determine the ultimate results. It is common belief that, whereas any shortening in adults will be permanent, children may be expected to compensate with growth and thus regain equality in the length of the two limbs. Our experience shows that this statement is only partly true. In the adult group two patients with one-half inch overlap in the x-ray films showed no disparity when measured respectively six months and three years after their injuries. Three others, however, had constant and permanent shortening of from one-half to 2 inches. Among the children seven with an overlap of from one-half to 1¼ inches showed complete restitution of length, usually within a year after uniting. One with an original inequality of a full inch has now only a half inch of shortening. The three remaining children have shown no improvement whatever following union with respectively one-half, 1 and 1½ inches of overlap. It is apparent from this that any prediction with respect to the outcome in these cases must be made with reservation.

Osseous Union—The securing of firm union in fractures of the femoral shaft is not a great problem. The time required is variable and it may be prolonged, but eventual bony union is the rule. Premature removal of apparatus or too early weight bearing must be guarded against. There were five instances of refracture in this series occurring one at four, one at six, two at eight and one as late as eighteen weeks after the original injury. Union will occur, however, even with such marked displacement of the fragments that there is no end to end apposition whatever. This emphasizes the fact that the important points in reduction are length and alignment without too great concern about other displacements. Indeed, the formation of callus may be retarded by repeated attempts to secure accurate replacement.

COMPARISON OF METHODS OF TREATMENT

Traction Methods in General—Certain fundamental principles must be strictly adhered to with any method of traction, whether skin or skeletal. Any deviation from these fundamentals should be regarded as a failure on the part of the surgeon in charge rather than as a failure of the method itself. 1 The mechanics of the application of the traction must be sound. 2 Traction must be uninterrupted. 3 Sufficient force must be applied to meet the needs of the individual case. In a femur this may be 4 pounds or 40. 4 Constant supervision must insure that the original intentions of the apparatus are being maintained. 5 Traction must be continued until firm union ensues.

Bryant Traction—The Bryant or Schede method of traction with both legs suspended from an overhead frame is the method that we prefer in children under 7 years of age. It greatly facilitates the nursing and hygiene of these patients, is easily applied and requires little attention. Our results have been good in fourteen cases with three exceptions in which union with shortening occurred. Perhaps in this group of young patients almost any method would give equally good results, but overhead traction is recommended mainly on the basis of the facility of its application and management. It is important that the traction weight be sufficient to elevate the pelvis off the bed and that proportionately greater weight be applied to the injured limb. Care must also be taken to prevent rotation.

deformity, and this may be done by affixing a slotted rider to the spreader of the injured side in such a way that any tendency toward rotation is checked by the traction rope affixed to the well leg

Russell Traction—We favor this method of traction because of its simplicity. It requires little in the way of special equipment, save for an overhead frame, and may be used in the home as well as in the hospital. There is no interference with nursing care and no danger of sepsis. Moreover, and this one should not overlook in fracture therapy, the patient is very comfortable.

Nonetheless our experience with it has not been as satisfactory as that reported from other clinics. In half of the twenty-two instances in which we used it in children, and in five out of eight adult cases, satisfactory reduction by the Russell method has not been obtained and we turned to other means. In one of these instances, muscle interposition was found to account for the difficulties. Proponents of Russell traction have acknowledged difficulties in dealing with fractures of the lower third of the femoral shaft. Most of our disappointments have been with the involvement of the middle of the bone and only once with the lower portion. In muscular adults with a considerable amount of shortening, no method employing skin traction with adhesive tape can be depended on. In simpler cases presenting moderate displacement, the Russell method can be used with satisfaction. Wherever a brief trial of the Russell method showed satisfactory reduction of the fragments, we have been able to predict good ultimate results. In those cases in which trial is unsuccessful, other methods should be attempted without delay.

Skin Traction with Suspension on Thomas-Pearson Splint—Simple traction applied to the thigh alone by adhesive tape is seldom adequate for the entire period of treatment. In about one third of our cases it was employed at some time, but largely as an adjunct to other methods. It was used often during the period of shock and was sometimes continued for several days as a temporary dressing. In a few instances a reduction successfully obtained under anesthesia with fluoroscopic control was maintained by skin traction. The only adult case that was satisfactorily managed by skin traction alone was one of a fracture in an amputation stump in which little traction was required.

Skeletal Traction—For efficiency in securing and maintaining good apposition, skeletal traction is surpassed only by operative reduction and is without the risk of infection at the fracture site entailed by open operation. It does necessitate a certain amount of apparatus, strict asepsis and close supervision. Skeletal traction need not be employed as a routine, for many cases do not require it. On the other hand, if repeated measurement of the limb and roentgenologic checks reveal that the desired reduction is not being obtained, skeletal traction should be employed without further delay.

Skeletal traction was tried in fourteen cases and gave satisfactory results in all except three. In two of these, muscle was found interposed between fragments at operation. The third patient was not operated on but there were clinical and x-ray evidences of separation of the fragments suggestive of soft tissue interposition. Under such circumstances no closed method could produce results. In each of these methods ice tongs, a means we no longer employ, were used. There were no instances of frank osteomyelitis, although in one

instance chronic necrosis of bone resulted from a Steinmann nail, and the opening in the skin remained two years after discharge. Necrosis of soft tissue has occurred, generally from improper introduction of the nail or wire, in that undue tension was placed on the skin, but this has not been serious or unduly slow in healing.

Several means of securing skeletal traction are available. While ice tongs were used in some of our earlier cases, they were apt to slip, with injury to soft parts as well as loss of traction. Recently we have used only the Steinmann nail or the Kirschner wire, and the choice between the two is a matter of personal preference and available equipment. The wire needs special apparatus to introduce and to keep taut, but if this is available it affords a very simple and effective means of applying skeletal traction.

Plaster Spica Casts—These have a very limited field of usefulness in fractures of the femoral shaft. Any fracture that requires continuous traction to overcome shortening or angulation is ill suited for treatment in plaster. On the other hand, fractures without serious displacement, those which remain in good position after manipulation and those in which early callus formation has served to fix the fragments may, under certain circumstances, be satisfactorily treated in a plaster spica which fixes the hip and knee on the affected side. In uncooperative patients this means of fixation may be the only one possible. Fragments may slip even in a cast, and one of the best means of insurance against this is to apply the cast with the limb in a position of muscle equilibrium, namely, with the hip and knee flexed. In our series casts were employed frequently as an adjunct to operative reduction with internal fixation, as well as in the other types of case mentioned. By encasement in plaster the period of hospitalization may be shortened, but continued observation is required. There is a finality about plaster encasement which makes the method dangerous unless adequate supervision is provided. Particular attention must always be paid to securing mobility of the knee at an appropriate time. We have discharged patients in casts only to find that the immobilization was continued far too long, with resulting functional impairment. All six of the cases showing permanent disabling restriction of knee motion were treated by plaster casts. One of these cases occurred in a child, although many claim that prolonged immobilization is not crippling to young patients.

Operative Reduction—This was performed on eighteen patients in this series. In four of these debridement was done for compound fracture. Excluding these, the incidence of operative intervention in simple fractures was 14 per cent in children and 33 per cent in adults. This we believe to be unnecessarily high. The indication for operation in seven cases was the failure of Russell traction to secure or maintain satisfactory reduction. We now feel that a trial of skeletal traction might well have given equally good results without the risks attendant on operation. Two patients were operated on because of delay in union and the operations did nothing to hasten its development. Once refracture occurred at five weeks and again closed methods might well have been used. In the remaining four cases, open reduction was the only course possible, once because the slipping of tongs had injured the soft tissues and three times because evidence of muscle interposition foretold failure for any closed method.

The mechanical difficulties of access to a bone surrounded by muscle, as is the shaft of the femur, and the

securing of reduction and adequate internal fixation are always great, and the risk of infection is not negligible. In the experience of this series of cases the results have not justified the procedure. The cases chosen for operation were not necessarily the worst fractures, but the results have been inferior to those with closed methods and complications have been multiplied. Five children are known to have a good result but one child has a stiff knee. Among the adults, three out of seven patients with simple fractures have a good functional result. One had osteomyelitis with a short limb, another developed persistent lymphedema of the leg and now has an inch of shortening and a stiff knee. Two others have disability from impaired knee motion. Surely the seriousness of these complications outweighs the advantages of operation.

This discussion is a survey of the experience of several years and not an attempt to draw final conclusions, yet, were this experience to be repeated, we should probably operate in four cases instead of fourteen and we would employ skeletal traction much more extensively than in the past.

RESULTS AND CONCLUSIONS

1 The emphasis in fracture therapy should be on restitution of function.

2 In fractures of the femoral shaft, perfect anatomic reduction is not necessary for normal function of the limb.

3 Simple closed methods of treatment will give good results in this fracture, provided fundamental principles are respected.

4 Of the several methods of traction employed, that of adhesive tape on the thigh was least effective in producing satisfactory reduction of the fragments. It had to be displaced by other means in all but 13 per cent of children and 11 per cent of adults. Skeletal traction, on the other hand, proved satisfactory in 67 and 62 per cent respectively. Russell and Bryant traction were each effective in 41 per cent of cases in children, although in adults the Russell traction fulfilled the surgeon's requirements in only 25 per cent of patients.

5 Length and alignment should be obtained to assure an ultimately good result. Shortening of the limb is apt to be permanent even in children.

6 Whereas in this series there were 92 per cent of perfect function results in children, only 64 per cent of adults escaped disability. The disappointing results in the latter are largely due to the permanence of shortening, stiffness of the knee from prolonged immobilization and the unsatisfactory results of operative reduction.

326 South Nineteenth Street—1907 Spruce Street

ABSTRACT OF DISCUSSION

DR. FREDERICK C. KIDNER, Detroit. There are so many reports of fancy surgical methods of reduction of fractures that I think we sometimes lose our sanity. Such a paper as this recalls one to sanity by stating that satisfactory results in a considerable number of fractures of the shaft of the femur can be obtained by simple means. During the war, in England, it was my privilege to be the consultant in orthopedics. On one occasion the American hospital unit installed in a hospital just outside London received a trainload of freshly wounded men from France. I had taught the unit the use of adhesive plaster traction with the Thomas splint and Balkan frame. In the trainload of wounded there were ninety-four compound fractures of the femur. When I visited the hospital after forty-eight hours, the whole ninety-four fractures were satisfactorily reduced and the greatest shortening was a half inch. This was accomplished with adhesive plaster traction only. On the

other hand, in the last bed in this fracture ward was a boy of 16 who had been run over by the ambulance in the hospital yard the night before and received a fracture of the left femur. He had no Balkan frame or Thomas splint but was lying in an old fashioned long DeSault splint. His fracture was sharply angulated and there was 2 inches of shortening. When I asked why he had not been put up as had been the ninety-four battle fractures I was told that one did not treat civilian fractures according to war methods. I think that 95 per cent of the fractures of the shaft of the femur can be treated satisfactorily throughout their whole course by adhesive plaster traction on a Thomas splint, by a man who has not the skill or equipment to use skeletal traction properly. As to operative treatment, it seems to me that the authors had rather hard luck in the number of accidents. It is occasionally necessary to reduce a fracture of the shaft of the femur by an open incision. In a modern, well organized hospital, this procedure should be free from accidents.

DR. P. H. SCARDINO, Houston, Texas. Since a great number of fractures are being treated by the general surgeon and the practitioner, it is the master surgeons who have tried to simplify the methods used to obtain the best functional results and make them as fool proof as possible. Every effort should be made in the reduction of fractures of the long bones, especially in the shaft of the femur, to use some of the so-called closed methods, the operator using the method with which he is the most capable. I am inclined to use the method that seems to be best adapted to the individual case. With either open or closed reduction, traction is the prime requisite, of which we have the choice of (1) manual, (2) adhesive and (3) skeletal. In the hands of a master the manual method can sometimes be used in an irregular transverse fracture, but it is difficult to hold the reduction in a plaster spica. Adhesive traction is no longer tenable because of its cumbersome overhead apparatus, ropes, pulleys and weights together with its daily checking and reraying. Skeletal traction is by far the most acceptable. The methods of obtaining skeletal traction are numerous: the Roger Anderson or one of its many modifications is the most satisfactory. The two Steinman pins or Kirschner wire (claimed by Putt, Foster et al.), the Bryant or Schede method of traction for children, and the Russell traction may be used. In my hands the Roger Anderson anatomic splint method has proved most satisfactory. Failure to obtain a proper and sufficient reduction should not permit the surgeon to wait too long before using some method of open reduction. Here the procedure may be admirably facilitated, in the absence of a fracture table, by the preliminary application of the Roger Anderson well leg traction splint, by which shortening is easily overcome and alignment is facilitated with use of pins through fragments or any of the well known methods. All internal fixation must be preceded by careful reduction, and correct alignment maintained by sufficient and adequate external splinting. The Anderson well leg apparatus is excellent when used in place of the Hawley table in open reduction and may be left in situ and the body cast added. The splint helps to keep the alignment, and constant traction prevents breakage of the internal fixation. It should lend itself admirably in bone graft for cases of nonunion. First aid in fractures is usually rendered by the general practitioner and often followed by bad end results unless he has made a special study and has had wide experience in fracture work. Too much stress is placed on the x-ray examination and too little on the physical examination in suspected fractures. The x-rays should be used as a check up on a diagnosis, and the end results sought should be good functional ones rather than x-ray perfection. The master surgeons should strive to give us simplification and not standardization of treatment of fractures.

DR. WILLIS C. CAMPBELL, Memphis, Tenn. In treatment of fractures of the shaft of the femur I see no reason why the same principles should not be employed as in fractures of other long bones. In 1924 I reported a method of treatment particularly for transverse fractures of the shaft of the femur by this method at least 75 per cent of transverse fractures of the shaft can be manually reduced and maintained by a plaster cast. Instead of obtaining reduction entirely by traction the fragments are angulated under slight traction until the ends of the bone impinge and can be locked after which the thigh is gradually

straightened until normal anteroposterior and lateral alignment is obtained. A double spica cast is applied with the knee and hip partially flexed. Roentgenograms should be made at the end of one week and three weeks to assure maintenance of position in the cast. If there is some doubt of maintaining end to end engagement, a Kirschner wire is inserted through the condyles of the femur and incorporated in the cast. Then, if displacement occurs, the anterior half of the cast is removed and skeletal traction applied. This method of treatment enables a patient to conserve his finances, as prolonged hospitalization is unnecessary. After ten days the patient is dismissed, to return at variable intervals of from three to four weeks and from six to eight weeks respectively for x-ray check up and removal of the cast. No untoward complications have been noted, as stiffness of the knee, and as a whole the results have been most satisfactory. In children there is practically no shortening. Of 153 cases treated by this method up to 1924, only 5 per cent in adults and 18 per cent in children had poor results (shortening over 1 inch or excessive deformity).

AIR EMBOLISM VERSUS PLEURAL REFLEX AS THE CAUSE OF PLEURAL SHOCK

THE FRANK BILLINGS LECTURE

JOSEPH A. CAPPS, M.D.

CHICAGO

In accepting the invitation to deliver the Frank Billings lecture, I do so with humility and deep appreciation. The honor is the more highly valued because, in an association of over thirty years with Dr. Billings, I owe so much to the influence of his teaching, his example and his inspiring personality.

In all operative procedures involving the pleural cavity, whether pneumothorax therapy, draining an empyema, the withdrawal of fluid by means of an aspirating needle or merely an exploratory thoracentesis, there lurks the danger of so-called pleural shock. This may take the form of faintness, or at times loss of consciousness with a pulse that becomes weaker and weaker until it can no longer be detected by the finger. Rarely convulsions occur and death. When the patient recovers, there may be a transitory hemiplegia or weakness on one side.

It is my purpose in this paper to consider the explanation of this syncope and perhaps to clarify the physiologic mechanism responsible for its occurrence.

INCIDENCE

For many decades clinicians have described these cases of syncope, often fatal, which occur during thoracentesis. When postmortem examinations were made, rarely emboli or thrombi were found in the pulmonary or coronary arteries and even more rarely in the cerebral arteries. Air embolism was sometimes considered to be a causal factor, as in Janeway's¹ report of syncope following irrigation of the pleural cavity with hydrogen peroxide. However, as one reviews the literature one is impressed with the failure of the pathologist to discover (in the great majority of casualties) any anatomic lesions that would explain the cause of death.

Leichtenstern² collected twenty-four fatal accidents; four patients died suddenly during thoracentesis.

fifteen died a few minutes after operation, five died during irrigation of the pleural cavity. Some of these patients had convulsions.

Weill³ also described convulsions during irrigation of the chest.

Russell⁴ observed three deaths during exploratory puncture.

Sears⁵ relates a number of casualties that occurred during thoracentesis, and he emphasizes the danger of lung puncture pneumothorax.

Prendergast⁶ reports two cases in which death occurred while exploratory puncture following pneumonia was being performed.

The older writers thought that if cerebral embolism could be excluded the chief factors in producing death in these cases were anemia of the heart or brain, sudden heart failure or some unexplained reflex action of the circulatory centers excited by irritation of the lung or pleura.

Fresh interest in the subject has been stimulated by the general use of pneumothorax therapy. Forlanini⁷ has seen twelve cases of syncope in 10,000 punctures on 134 patients treated by pneumothorax—all serious, but all with final recovery. Sachs⁸ encountered twenty-two instances in 1,122 patients thus treated, Sangmann⁹ only two instances in 5,500 injections. Matz¹⁰ encountered pleural shock eighteen times in 588 treatments, Bruns¹¹ sixteen times in giving 12,700 injections, with seven deaths. Cocke¹² describes four such accidents in his experience of more than 4,000 air injections. Andrews¹³ reports six instances of shock in 8,528 needle punctures of the chest, in 8,085 of these air was injected. One patient died.

MECHANISM OF SHOCK

Two hypotheses have been presented to explain this phenomenon of syncope, air embolism, and shock from a pleural reflex. In recent years the theory of air embolism has gained adherents, especially among the surgeons.

CLINICAL EVIDENCE OF AIR EMBOLISM

Let us consider the evidence that supports the theory of air embolism—clinical and experimental.

Clinical—A number of observations have been recorded in which the aspiration of air into the pulmonary vessels has been accompanied by symptoms of shock. Thus Wever¹⁴ while cauterizing a bronchus, noted a hissing sound of air with the collapse of the patient. Other observers have described the presence of air bubbles in the retinal arteries, simultaneously with syncope, in the course of surgical operation on the lungs. Again, air bubbles have been discovered post mortem in the coronary arteries in a patient who died suddenly during surgical drainage of a pulmonary abscess. It should be stated that most of this evidence of air in the arteries has been found in association with operations on the lungs.

Experimental—By injecting air directly into the left side of the heart or aorta, convulsions, paralysis and death have been produced.

Rukstina and LeCount forced air into the lungs under high pressures and caused death in guinea-pigs. Postmortem examination under water revealed some pneumothorax, air in the aorta, carotid, bronchial and iliac arteries, and frothy blood in all the heart chambers. Always they found air in the coronary arteries, and to this tamponade the authors attributed the fatal outcome.

It is well known that considerable quantities of air can be introduced into the systemic veins without causing any circulatory disturbance. Air thus introduced travels to the lungs, which to a great degree prevent the further passage to the left side of the heart. However, if air is injected into the pulmonic veins, it is logical to assume that it may enter the coronary or cerebral arteries. It is argued that in pneumothorax therapy the needle may pierce the lung and that air may be forced into the pulmonary veins. Likewise, it is reasoned that in surgical manipulation of the lungs air may be sucked into the pulmonary veins.

OBJECTIONS TO AIR EMBOLISM THEORY

Without denying that air embolism does occur and that it may produce syncope or even death, certain facts do not support this explanation of the ordinary accidents.

1 The syncope phenomenon is not encountered sufficiently often in procedures that involve the injection of air, viz., pneumothorax therapy. Considering the enormous number of such injections, the incidence of syncope is small.

2 Syncope occurs most often in simple exploratory puncture where no air is introduced. Chabaud,¹⁵ in a review of 114 cases of pleural shock, states that two thirds of the accidents were observed during exploratory or aspiratory puncture, less than one third during lavage and only a small number during pneumothorax therapy.

3 Numerous individuals who have succumbed to pleural shock have shown (post mortem) no evidence whatever of air embolism in the brain or coronary arteries.

THE PLEURAL REFLEX

Let us now consider the evidence relative to a pleural reflex as the cause of syncope. In 1907 Dr. Dean Lewis and I had an experience that aroused our interest in this subject. A clinic patient with an acute pleural effusion was prepared for drainage. As the needle entered the pleural cavity and only a few cubic centimeters of serum had been withdrawn, the patient went into collapse. Pallor, weak pulse, unconsciousness and death ensued. At the necropsy no penetration of the lung could be found and no air was present in the heart or brain. Dr. Lewis and I¹⁶ then undertook some experiments on animals and obtained the following results:

1 Irritation of the visceral pleura of healthy dogs by mechanical, thermal and electrical means and by certain chemicals produces little or no effect on the blood pressure, except over the roots of the lungs, where mechanical and electrical excitations produce long strokes of vagal type.

2 In dogs with pleurisy induced by injections of turpentine or of oil contaminated with bacteria excitation of the inflamed visceral pleura by mechanical and chemical irritants gives varying results. In some cases there is no marked change in blood pressure, in others there is a considerable fall in pressure which may even be fatal.

3 These reflexes conform to two types which, as a rule, occur singly but which may be combined. (a) The cardio-inhibitory type, in which the heart is slowed and the pulse tracings make violent excursions with a great range between systolic and diastolic pressure. Respirations also are usually slowed and may be inhibited. This type of reflex when it occurs alone is seldom fatal. (b) The vasomotor type, in which the pulse tracings show a steady rapid decline of pressure without a great difference in systolic and diastolic pressure, frequently this type terminates in death. Respirations as a rule are shallow and may be rapid. In fatal cases the blood vessels of the abdominal viscera are much engorged from acute vasodilatation. The brain shows no evidence of embolism or hemorrhage.

4 The cardio-inhibitory reflex is central, because it is prevented or stopped by cutting both vagus nerves in the neck. Atropine paralyzes the cardio-inhibitory fibers and destroys the reflex.

5 The vasomotor (dilator) reflex may be central or peripheral. If central, the afferent impulses reach the medulla by way of the thoracic sympathetic, the white ram and the cord, and not by the vagosympathetic cord. This is proved by the failure of section of the vagosympathetic cord to alter or abolish the reflex. If peripheral, the reflex goes from the pulmonary fibers to the pulmonary plexus, and thence to the thoracic sympathetic nerves and downward through the splanchnics to the celiac and other plexuses in the abdomen. This reflex is more direct than the central form but seems to me inconsistent with the views generally accepted as to the course and direction of impulses in the sympathetic nerves. Epinephrine is the physiologic antagonist to the vasodilator reflex and is often life saving.

6 These types of reflexes occur also in man during operative procedures on the inflamed pleura. The cardio-inhibitory type is manifested by a slow intermittent pulse, with a great difference between systolic and diastolic pressures, the vasomotor type, by a steady fall in blood pressure, with no marked difference in systolic and diastolic pressures, and by a pulse that grows steadily weaker until it cannot be felt.

OTHER EXPERIMENTS

Schlaepfer¹⁷ failed to obtain any circulatory reflexes by applying various forms of irritants to the pleura of normal animals and concluded that the shock observed in human beings could not originate in the pleura. His results were similar to those in our own experiments related in the previous paragraphs, but his conclusions were quite different. We also found that the normal pleura gives no such circulatory response to irritation. To make the animal experiment resemble the clinical picture, however, we repeated the experiments after producing an acute pleurisy. We found that the inflamed pleura often gives such a circulatory response, similar to that observed in man. Several times during an aspiration of pleural effusion in human beings I have purposely irritated the visceral pleura with the end of the trocar and have observed a significant fall in blood pressure.

COMMENT

We are now in a better position to determine the mechanism of pleural shock. Granted that the injection of air under pressure in the pulmonic veins may cause symptoms of syncope and convulsions, we find confirmation of this hypothesis in very few necropsies.

Furthermore, we should expect air embolism to be relatively common in pneumothorax therapy, in which air is forced into the pleural cavity under pressure. Such is not the fact, as witness Cocke's experience of only four such accidents in more than 4,000 air injections. On the contrary, we find that pleural shock is most commonly encountered in simple thoracentesis for exploration or aspiration, when little or no air is introduced into the cavity. No doubt this is explained by the fact that exploratory thoracentesis is usually performed in the presence of an active pleuritis, which is sensitive to vascular reflexes. In the chronic tuberculous patients treated by pneumothorax, the pleura is not often acutely inflamed and, therefore, is less subject to reflex symptoms.

Formerly there was much skepticism concerning the physiologic basis for a pleural reflex with dangerous manifestations. The understanding of this phenomenon is illuminated by the analogous vasovagal reflex induced by pressure on the carotid sinus in certain sensitive individuals.¹⁸ The symptoms arising from these two locations, carotid sinus and pleura, are almost identical, viz, fainting, slow pulse, fall in blood pressure, often unconsciousness and convulsions. The mechanism involved apparently is the same, viz, vagal, slowing the pulse, sympathetic, lowering the blood pressure.

Another analogy between pleural shock and carotid sinus syncope is that both are decidedly exaggerated by the upright position.

SUMMARY

1 The experimental evidence supporting the theory of air embolism is based on the effects of direct introduction of air under pressure into the lungs, heart or carotid arteries.

2 The clinical observations in favor of air embolism are chiefly concerned with operations on the lung with exposure of large veins.

3 Necropsy reports of fatal cases occurring after thoracentesis have rarely, if ever, revealed any signs of air embolism.

4 If we accept the hypothesis of air embolism, we would expect syncope to take place most frequently in procedures requiring the injection of air, whereas, actually, the incidence of syncope is relatively infrequent in pneumotherapy.

5 Clinically the majority of instances of pleural shock are encountered in simple thoracentesis in which no air is introduced.

6 In experimental animals we have succeeded in producing by irritation of the inflamed pleura the syndrome of syncope and a slow pulse, a pulse of low pressure or both. In man, identical results have been obtained by intentional irritation of the inflamed pleura.

7 Attention is called to the parallelism of the pulse changes seen with pressure on the carotid sinus of sensitive individuals and the pulse changes observed with irritation of the inflamed pleura in sensitive individuals.

8 Considering the sound physiologic basis for a depressor circulatory reflex from irritation of the inflamed pleura, it seems to me that a true pleural reflex is the logical explanation for the great majority of such accidents, viz, syncope and collapse. In exceptional cases in which air is forced directly into the lung or the lung is subjected to surgical operations, the possibility of air embolism must be recognized.

ANAPHYLAXIS DURING ETHER ANESTHESIA

L. M. QUILL, M.D.

CINCINNATI

For a number of years it has been a regular procedure in the surgical department of the Cincinnati General Hospital in accident cases to administer prophylactic antitoxic serum while emergency operative procedures are being carried out with the patient under ether anesthesia. This has been done without previous skin testing for sensitization to foreign serums and without fear of anaphylactic reaction in accordance with the belief that anaphylactic reaction cannot occur in a patient under ether anesthesia. Recently, this procedure was carried out on a patient whose case history is herewith presented.

On Nov. 29, 1936, at 3 a. m., a colored man, aged 26, was brought to the receiving ward with a gunshot wound in the abdomen incurred one-half hour prior to admission. His general condition was considered good; the temperature was 98 F. and the blood pressure 100 systolic and 60 diastolic. In the right lower quadrant of the abdomen a bullet wound was noted with the point of exit over the right trochanter. It was believed that the abdominal cavity had been penetrated.

Nitrous oxide-oxygen anesthesia was begun at 4:55 a. m., and open drop ether anesthesia was substituted shortly thereafter. An exploratory laparotomy was started at 5:05. Four penetrating wounds of the ileum were found. A blood transfusion was begun, although the condition of the patient was good. It was decided immediately to do an end to end anastomosis of the intestine, and about 6 inches of the ileum, which included all perforations, was resected. This operation was completed at 6:15 a. m. The general condition of the patient following the procedure was pronounced good by the anesthetist. The blood pressure was recorded at 100 systolic and 80 diastolic. Approximately 350 cc. of whole citrated blood had been given, with no evidence of reaction. Fifteen hundred units of anti-tetanus serum was now administered subcutaneously. A reaction took place immediately. The pulse became imperceptible and the respirations ceased. The patient became cyanotic, and despite emergency stimulative therapy he died on the operating table within three minutes after the administration of the serum. Complete exploration of the abdomen was done, and except for a moderately sized retroperitoneal hematoma no further evidence of injury could be discovered.

Postmortem examination confirmed the abdominal condition recorded at operation. Examination of the thorax revealed marked edema and congestion of the lungs. The heart and other viscera, however, presented no remarkable changes.

Since it was considered that the patient had died of an anaphylactic reaction taking place while he was under ether anesthesia, an attempt was made to determine the basis of the belief that anesthesia inhibits such reactions. In addition, a questionnaire was forwarded to the larger clinics in the country asking for an opinion on this subject and information as to the practices followed. The questionnaire was completely filled out and returned to us by eight surgical clinics. Briefly analyzed, the answers given were as follows: Fifty per cent of the writers maintained definitely that anaphylactic reaction cannot occur during ether anesthesia. Consequently, in their clinics (Johns Hopkins, Duke, Tulane, Louisiana) serum is regularly administered to patients under anesthesia without fear of anaphylactic response. Twenty-five per cent maintained the opposite view (the Massachusetts General Hospital, and the Barnes Hospital, St. Louis) and one of these reported the occurrence of anaphylactic reaction in 1.

From the Department of Surgery, University of Cincinnati College of Medicine and the Cincinnati General Hospital.

patient under ether anesthesia. The remaining 25 per cent (the New York Hospital, and the Strong Memorial Hospital, Rochester, N. Y.) replied that they had had no experience on the subject and were therefore undecided whether anaphylaxis could take place under ether anesthesia.

The concept that anesthesia inhibits or suppresses anaphylaxis apparently originated with Besredka.¹ As early as 1907 he reported that the symptoms of anaphylactic reaction could be suppressed by the administration of ether to the sensitized guinea-pig. He has maintained even in his most recent publications that anaphylactic reaction is suppressed by various anesthetics (ether, chloroform, alcohol, ethyl chloride).

Bronfenbrenner² developed the theory that the action of anesthetics which protect the animal from anaphylaxis is the setting free of antitryptic ferment by the anesthetic agent. This enzyme retards or neutralizes proteolytic ferments liberated on the introduction of antigen into the sensitized animal. Anaphylactic reaction, thus, cannot take place except to a limited degree and perhaps over a greater period of time.

In the meantime numerous workers in the field of anaphylaxis, which was rapidly developing, were producing and recording anaphylactic reactions in sensitized animals under anesthesia. Voegtlin and Bernheim³ studied the anaphylactic reaction of sensitized and dehepatized dogs anesthetized with ether. Auer⁴ reported the occurrence of fatal anaphylactic shock in sensitized rabbits under ether anesthesia. Schultz⁵ described the anaphylactic response of various organs of rabbits, dogs and guinea-pigs under ether anesthesia. Simonds⁶ produced anaphylactic reactions in dogs anesthetized with ether and made kymographic records of the induced shock. Weil,⁷ aware of the previous view on the subject, declared that anaphylactic reaction in dogs is not in the least degree inhibited by ether anesthesia. This open declaration stands in direct opposition to Besredka's contention, whereas the previous experimenters had produced anaphylaxis in anesthetized animals apparently without commenting on the fact that anesthesia might possibly inhibit or suppress the phenomenon they were laboring to produce.

Kopazewski and the Roffos⁸ stated that they were able to protect guinea-pigs sensitized with horse serum from anaphylactic reaction by the intravenous administration of ether or chloroform. They advanced the theory that anaphylaxis is suppressed by the alteration in surface tension of the blood serum produced by the anesthetic and the resultant nonflocculation of the anaphylatoxin.

However, contributors to the field of anaphylaxis continued to report the occurrence of anaphylactic shock in anesthetized animals. Prominent among this group, and the animals used by them, were Manwaring and his associates,⁹ Webb,¹⁰ and Dragstedt and his associates,¹¹

dogs, Hanzlik and Stockton,¹² pigeons, Bally,¹³ rabbits, and Krafka, McCrae and Vogt,¹⁴ cats.

In 1934 Scimone¹⁵ reported a series of observations made on rabbits. He concluded that ether anesthesia exercises a protective action against the occurrence of anaphylactic shock in these animals. Ether anesthesia was administered during both the sensitizing and the shocking procedures.

Dragstedt,¹⁶ a vigorous opponent of the theory of desensitization by anesthesia, in a communication to THE JOURNAL in July 1935 concluded with the following statement: "However, the experiments on laboratory animals together with the evidence that anaphylactic shock is largely a histamine intoxication (Gebauer-Fuelnegg and Dragstedt, *Am J Physiol* 102:520 [Nov.] 1932) and that ether anesthesia (Dale, *Brit J Exper Path* 1:103 [April] 1920) increases the susceptibility to histamine not only lend no support to the idea that anesthesia would diminish anaphylactic shock but actually indicates the reverse."

Most recently, Re,¹⁷ following the work of his fellow Italian Scimone, but working with a different species of animal (guinea-pig), has reaffirmed Scimone's conclusion that ether anesthesia exercises a protective action against anaphylaxis whether administered during the sensitization or the shocking procedure. He referred the antianaphylactic action of narcosis "to the inhibition of certain functional relationships of the nervous system with the biologic and immunitary structure of the blood."

EXPERIMENTAL WORK

The purpose of the experimental procedures undertaken was to produce anaphylactic reaction in sensitized animals under ether anesthesia. Three species of animals, viz., dogs, rabbits and guinea-pigs, were included in the experiment because of the known variation in the anaphylactic response of these animals. Series of the animals were sensitized to foreign serum (sheep's) according to the procedures outlined by Gay and his associates.¹⁸ Five-tenths cubic centimeter of antigen per kilogram of body weight was administered to the dogs both subcutaneously and intravenously for three doses at daily intervals. Skin tests done prior to the sensitization procedure gave negative results. After the sensitization period (from three to four weeks), intradermal skin tests showed definite positive reactions, as evidenced by erythema and edema about the site of the injection. Sensitization of the rabbits was produced by the administration of 3 cc of the antigen subcutaneously for eight injections at daily intervals. Skin tests of these animals proved unsatisfactory. An incubation period of fourteen days was found adequate. The guinea-pigs were given 0.5 cc subcutaneously and intracardially each for only one dose. An incubation period of twenty days was allowed. Skin tests of the animals of this series likewise proved unsatisfactory.

After the sensitization or incubation period the sensitized animals were anesthetized by the open drop ether method (no previous medication being given), and

anesthesia was maintained for a minimum period of fifteen minutes at moderate depth prior to injection of the antigen. A cannula was placed in the femoral artery of the dogs with aseptic technic and the blood pressure recorded on a kymograph. With the animal under careful observation, the shocking dose of the antigen as recommended by Gay and his associates was administered intravenously. The reaction of each animal was closely studied. Anesthesia was maintained for at least fifteen minutes after the administration of the antigen in the animals in which the signs of reaction subsided quickly. In the remaining surviving animals anesthesia was maintained for one-half hour. On reaction from etherization, all the animals exhibited signs and symptoms of having undergone some degree of anaphylactic shock. During this period of recovery the manifestations noted were great weakness and marked hypotonia of the skeletal musculature, vomiting, marked loss of control of the sphincters, and convulsions.

The animals recovering from the anaphylactic reaction were permitted to rest for a short period (minimum, six days) to regain their sensitivity. The shocking procedure was then repeated and the animals observed as indicated. The intravenous dose of antigen was now increased, and this factor was probably responsible for the occurrence of fatal anaphylactic reactions on this occasion.

The normal anaphylactic response was demonstrated by the intravenous administration of the antigen to animals of each series without ether anesthesia. An essentially identical syndrome was observed (fall of blood pressure with marked rapidity and irregularity of the pulse and respiratory difficulties with dyspnea and cyanosis). Fatal reactions during ether anesthesia occurred in 50 per cent of the dogs (three of six dogs),

the heart was noted in the rabbits, while in the dogs interstitial hemorrhage and marked congestion were observed throughout the gastro-enteric tract.

The nontoxicity of the serum antigen was proved by the intravenous administration of the material to non-sensitized animals. The quantity given was generally at least twice the maximum shocking dose given the sensitized animals. In addition, this procedure was carried out with animals under ether anesthesia and without anesthesia. No reaction was noted. The procedure is indicated in the accompanying table.

CONCLUSIONS

A review of the literature of anaphylaxis amply provides one with records of anaphylactic reactions occurring during ether anesthesia. This is particularly true in the case of the experimental animal. However,

Typical kymographic tracing of the blood pressure of a dog under ether anesthesia during anaphylactic reaction. The figure 1 indicates the point at which the antigen (30 cc) was given intravenously. 2 an intentional break in the tracing for administration of artificial respiration. 3 a second break for artificial respiration and 4 the death of the animal. Two hours elapsed between administration of the antigen and death. Administration of the anesthetic was discontinued after one half hour.

probable instances of anaphylaxis in man during ether anesthesia have been observed at the Cincinnati General Hospital and at one other clinic.

Laboratory experimental evidence as supplied by three species of animals, is in favor of the conclusion that anaphylaxis does take place during ether anesthesia. I do not believe that anaphylaxis with the subjects under ether anesthesia is inhibited to any degree, although this question is debatable. Since at the present time sensitivity cannot be quantitatively measured, the yard stick by which this question might be answered is not available. Until the degree of sensitivity is measurable, the absolute value, if any, of ether anesthesia as a desensitizing agent cannot be determined.

However, since the precept as originally laid down by Besredka that ether anesthesia protects against anaphylactic reaction is maintained by many clinics and since a case in which a fatal anaphylactic reaction is believed to have taken place can be cited, it is reasonable to state that ether anesthesia is valueless as a desensitizing agent. Certainly the practice of administering antitoxic serum to patients under ether anesthesia with the expectation that the anesthetic will protect the patient (if he is sensitive to the foreign serum) from anaphylactic reaction should be discontinued.

Procedures Used to Prove Nontoxicity of the Serum Antigen

Animal	Anesthetic	Sheep s Serum	How Given	Reaction
Dog 543	Ether	60 cc	Intravenously	None

in 100 per cent of the guinea-pigs (five of five guinea-pigs) and in 100 per cent of the rabbits (five of five rabbits). A less violent but nevertheless definite anaphylactic reaction was noted in the surviving dogs.

Postmortem examination of the animals that died of anaphylactic reaction revealed the characteristic changes of anaphylaxis in the individual animals. The guinea-pigs exhibited marked emphysema of the lungs, which constituted the only remarkable change in this species. There was no evidence of trauma to the heart in any of the animals as a result of the intracardiac administration of the antigen. Engorgement of the right side of

What Havoc We Make of Our Chances —In the wards, where quiet and order reign, he has further opportunities for insight, and for more deliberate observation. He learns, with higher exactness, to trust and to distrust himself to be slow to find fault with other men and quick to help them. He becomes acquainted with heavy responsibility, with the full bitterness of a bad mistake, the full delight of pulling people out of death's way. He begins to be able to read characters, and to see, by the scars on the lives allotted to his care what havoc we make of our chances —Paget, Stephen. *Confessio Medici*, New York, Macmillan Company, 1931.

THE OCCURRENCE OF RENAL CALCULI AND THEIR POSSIBLE RELATION TO DIET

AS ILLUSTRATED IN THE SOUTH AFRICAN NEGRO

VINCENT VERMOOTEN, M.D.
JOHANNESBURG, SOUTH AFRICA

For many years calculous disease of the urinary tract has been looked on as a surgical problem. Since the advent of aseptic surgery and the invention of the modern cystoscope, other methods of relief have hardly been considered.

The many failures to correct the disease surgically and the frequency of recurrence after surgical removal of the stone have demanded a more thorough investigation into cause and effect. From time to time many theories have naturally been advanced regarding the formation of urinary calculi. In the light of recent observations on this matter I will interpret my observations on the huge biologic experiment that is being enacted at present in the Union of South Africa.

STASIS

As early as 1914 Fowler¹ described ureteral stricture and the subsequent urinary stasis as an etiologic factor in the formation of kidney stones. In 1924 Hunner² emphasized this with tremendous force in the description of a patient with recurrent renal calculi.

A woman, aged 36, seen in April 1917, had a calculus in her lower right ureter, which was passed after several ureteral dilations. She was seen again in January 1922 with a normal uninfected left kidney and extensive calculous pyonephrosis on the right side, for which a right nephrectomy was done. In August 1922 she was readmitted, this time with calculous anuria. The calculi were removed, and the patient went home well, only to return three months later (November 22) with another attack of calculous anuria. The new calculus was removed, and a nephrostomy was done. She was discharged a month after the operation with a nephrostomy tube but no calculus. When she arrived home the tube was removed with the result that she had to return to the hospital three weeks after her discharge (Jan 13, 1923), two more calculi having developed in her only remaining kidney. One was causing a partial obstruction. These were removed January 15. After this operation she was not allowed out of the hospital before her ureter had been thoroughly dilated.

Recently I spoke to Dr. Hunner about this patient, only to find that she still comes in for periodic ureteral dilation and, after fourteen years, is still free from further recurrence of the calculi. A case report such as this must convince even the most skeptical of the importance of ureteral stricture and stasis in the occurrence and recurrence of renal calculi.

INFECTION

Infection has always played a leading role. That it actually has been an important part was demonstrated in 1922 by Rosenow and Meisser.³ By embedding streptococci isolated from a stone-forming patient into the socket of a recently extracted dog's tooth, they were able in a high percentage of instances to cause stones to be formed in the kidneys of these animals. This, then, definitely established for the first time a very positive

cause and effect. The only objection to this work from the clinical standpoint is that frequently patients with stones are seen with no renal infection or, if infection is present, there may be no evidence of the specific streptococcus of Rosenow.

PRECIPITATION FROM SUPERSATURATED SOLUTIONS

Taking for granted that stasis or the presence of a urea-splitting streptococcus or *Proteus ammoniae*⁴ or both may be responsible for the formation or at least for the growth of a calculus, one is still at a loss to explain the existence of a large number of calculi which obviously do not depend on these two factors. On account of this, organic and physical chemists suggested the precipitation of crystalloids and colloids from supersaturated solutions as a basis for the formation of renal calculi. Proof of the existence of the nidus necessary to start the precipitation was, however, lacking. This has recently been furnished by Randall⁵ and by Hellstrom.⁶ Not much more than ten years ago this was apparently the most popular and acceptable theory, for it is the chief topic of discussion on the subject of urinary calculi in the 1926 edition of Young's "Practice of Urology."⁷ It has been supported experimentally by Keyser,⁸ among others, has published researches from 1920 to the present on the experimental production of renal calculi. He has been able to produce calculi (1) by feeding of oxamide, (2) by producing an artificial excessive excretion of calcium oxalate, (3) by excessive doses of parathyroid extract and of viosterol and (4) by formation of uric acid calculi in dogs with Eck's fistulas. He divided calculi into two groups, the hyperexcretory and the infectious.

CALCIUM METABOLISM

One must not neglect to consider the part played by disturbance of the calcium metabolism, especially in cases of hyperparathyroidism. Attention was directed to this first by Barr, Bulger and Dixon⁹ and more recently by Albright, Aub and Bauer.¹⁰ These authors emphasized that the inability of the bones to retain calcium is the outstanding clinical manifestation of hyperparathyroidism, together, not infrequently, with progressive calcification of the renal cortex accompanied by the formation of renal calculi.

DIET

It was not until 1933 that Higgins¹¹ drew attention to the work of Osborne, Mendel and Ferry,¹² who in their experiments on vitamin A deficiency found a large incidence of renal and vesical calculi and also to the work of Fujimaki,¹³ who confirmed the work of Osborne, Mendel and Ferry and further noted that in all rats in which calculi developed the urine was alkaline and that the calculi were invariably dissolved when these rats were fed vitamin A. Higgins in 1933 was able not only to confirm these observations but to make the further observations that, as a rule, urinary infection was present and that keratinization of the urinary

epithelium coexisted. In 1935 he¹⁴ presented evidence that the same experiments could be repeated on dogs with chronic vitamin A deficiency.

Higgins has been able to translate his dietary experiments to human beings and claims not only that with the aid of vitamin A and an acid ash diet he has been able to reduce the recurrence of calculi in his patients from 16.4 per cent to 4.7 per cent but that he actually has complete reports of twenty-three cases¹⁵ in which stones in the kidney have entirely disappeared under medical (dietary) management.

In contradistinction to this, one may read such articles as that from Dr Edwin Beer's service at the Mount Sinai Hospital, New York, by Oppenheimer and Pollack,¹⁶ who found that in five of twenty-seven patients observed from six to sixteen months the stones increased and that in none did they disintegrate or even diminish in size.

EMBRYONIC RENAL CALCULI

Randall,⁵ of Philadelphia, and, independently of him, Hellstrom⁶ made the interesting observation that plaques of pure calcium are frequently deposited under the epithelium of the renal papillae. Presumably, stones develop on these plaques when the surface epithelium has been eroded. This exceedingly important observation may give an entirely new concept, not alone of the origin of renal calculi but also of their subsequent development.

GEOGRAPHIC DISTRIBUTION

Apart from all these most fascinating studies, it is known that the incidence of urinary calculi varies from one country to another and even within different parts of the same country. It is also known that there are marked racial differences. According to Hoffman,¹⁷ statistician for the Prudential Life Insurance Company, for persons over 30 years of age the incidence of deaths due to calculous disease of the urinary tract is 23.9 per million of population in Utah and only 2.4 in Vermont. In England and Wales (1914-1918) the death rate from urinary calculi (all ages) was 7.5 per million of population, while in Uruguay and Chile (1914-1918) it was only 1.3. Similarly, in Victoria, B. C. (1916-1920), the mortality rate from this cause per million of population was 26.2, in London (1915-1920) 7.9, in Amsterdam (1914-1918) 3.2 and in Mexico City (1916-1919) only 1.8.

Hoffman's most interesting figures, however, are those having to do with racial differences. Mortality statistics for the United States registration area show, per million of population, white males 9 and colored males 7, white females 4.1 and colored females 2.7. This is of the utmost importance in the light of my data regarding the South African Negro, for it indicates only a slightly lower incidence in the Negro than in the white race.

Hinman,¹⁸ in discussing the geographic distribution of urinary calculi, says "The most notable stone districts (India, Mesopotamia and South China) lack proper sanitation and suitable food, but the African Negro, similarly deficient, is almost immune to stone," and "in general the higher the standard of living the

lower the incidence." Except so far as the African Negro is concerned these statements are not necessarily correct, as the aforementioned statistics prove.

INCIDENCE OF URINARY CALCULI IN THE SOUTH AFRICAN NEGRO

Living in the Union of South Africa, I soon noticed that statements similar to the foregoing regarding the lack of urinary calculi in the African Negro seemed to be correct despite the fact that I could find no accurate statistics on the matter. With this in mind I consulted A. J. Orenstein, chief medical officer for the Chamber of Mines. At my request he had the records of the admissions to the various mine hospitals analyzed. The patients admitted to the mine hospitals are all Negroes who when recruited for work on the mines were apparently physically well. In this analysis he found that in a series of one million admissions, in only one case was the diagnosis made of renal calculus. This discovery was so striking that with the permission of the superintendent of the Johannesburg General Hospital I examined their records covering the fourteen years from 1922 to 1935 inclusive. During this time 126,000 white and 91,000 colored patients were admitted to the wards. Of these, 273 white and only four colored patients were proved to have had renal or ureteral calculi. Of the four colored (non-European) patients, one was an Indian, two were half-caste and only one was a full-blooded Negro. She was a Masuto, a domestic servant, aged 30, who was admitted to the hospital in 1927, having been ill for four months with pain in the lower part of the abdomen. She had missed her previous menstrual period. Her urine contained a few pus cells and a trace of albumin. X-ray examination, however, showed a small shadow in the course of the right ureter, presumably a ureteral calculus. A calculus was not passed, and as cystoscopic examination was refused I am unable to say definitely whether the shadow represented a calculus. These figures indicate that about one white patient in 460 admitted to the Johannesburg General Hospital has a renal or ureteral calculus. In contradiction to this, in over 90,000 admissions to the non-European section of the hospital there was only one Negro who may possibly have had a renal or ureteral calculus.

DIFFERENCES IN THE NEGRO AND THE CAUCASIAN KIDNEY

Is the Negro kidney different from the Caucasian in its anatomy or its physiology? Does the calcium metabolism differ markedly in the two races or does diet play a part?

From the aforementioned statistics one is almost led to believe that the difference in incidence of renal calculus is not due to an anatomic or a physiologic difference in the Negro kidney, for in the United States the mortality from calculous disease is apparently only slightly lower in the Negro than in the white population. If one were to collect data on only the pure-blooded American Negro, one might of course get a different picture.

HEALTH AND DIET OF THE SOUTH AFRICAN NEGRO

Between 1920 and 1933 Burton¹⁹ examined some 30,000 Xosa and Fingo natives in the Kingwillamstown area. From this study he came to the conclusion that the men of those tribes must be regarded as very healthy, the majority were of good physique, and among them he found a standard of muscular develop-

ment equal to or surpassing that seen among Europeans. He estimated that only 10 per cent could be classed as physically unfit. Their bony structure is as a rule densely calcified, and their teeth rarely if ever show any caries.

According to the 1932 report of the medical officer of health for the Bechuanaland Protectorate, one finds malnutrition not so widespread among the Negroes as among the poor white population.

According to Fox,²⁰ the Negro on the whole finds no difficulty in satisfying his simple requirements, which consist of various combinations of maize (chiefly eaten cooked as a cereal in the form of corn meal, with sugar and with some milk when available), meat, yellow pumpkin and various edible plants which are to be found growing as weeds on the veld. A similar diet has been worked out for the Negroes who work in the Rand Gold Mines. It consists of corn (maize) meal, meat and/or milk, beans or peanuts, and green vegetables. Dr. Fox, the biologist for the South African Institute for Medical Research, told me that his chief difficulty in computing this diet was to arrange one which the Negro would be willing to eat and which would also satisfy (apart from the necessary organic constituents) at least the minimum maintenance requirement of 0.45 Gm of calcium per day. This he has not been able to do, and outside of the mine compounds the Negro, he feels sure, exists on less than one tenth of this minimal daily requirement. In analyzing this simple standard diet, on which three and one-half million Negroes living in the Negro reserves, two and one-half million Negroes living on farms belonging to their white employers, and the half million town dwellers all exist and remain healthy, one finds several striking characteristics: (1) an extremely low calcium content, (2) an acid ash base and (3) a high vitamin A content. What more ideal diet could one find to comply with Higgins's experimental work?

SIGNIFICANCE OF DIET AND VITAMIN A

In view of these facts, when one summarizes all the data that have been accumulating so rapidly the past few years, one feels that diet must and does have an important part in the formation of renal calculi, as is also well illustrated by the frequent formation of renal calculi in patients on a Sippy diet. It cannot be a matter of the standard of living or of proper sanitation, as intimated by Hinman¹⁸ in his recent textbook, nor can it be, one is inclined to feel, merely a matter of a high vitamin A and an acid ash diet, as is so well shown by the recent article by Oppenheimer and Pollack.¹⁶

Jeans, Blanchard and Zentmire,²¹ in describing a new photometer for detecting the vitamin A deficiency of their patients, again bring to one's attention the fact that a large percentage (from 19 to 35) of apparently healthy children, chiefly in the higher social classes, suffer from vitamin A deficiency. They also point out that the administration of vitamin A does not necessarily cure all these patients. This indicates that vitamin A, although taken in sufficient quantity, is not always assimilated by the body. It makes one feel that certain foods may inhibit and others aid in the assimilation of vitamin A. This might well account for the difference between the results obtained by Higgins and those of the Mount Sinai Hospital. If the Jeans and Zentmire photometer were used on patients with urinary

calculi before and after the administration of vitamin A, one might obtain the answer to some of the marked differences that are being observed clinically.

CONCLUSIONS

1 The South African Negro (Bantu) does not form renal calculi, as illustrated by examination of the hospital admission records of 1,091,000 Negro patients.

2 Members of the white population of South Africa, as illustrated by the examination of hospital records of 126,000 admissions, form renal calculi in the ratio of one in 460 admissions.

3 The South African Negro lives on a simple, stable and uniform diet. This diet is rich in vitamin A, has an acid ash base and is extremely low in calcium.

4 Urinary stasis and infection have an important part in the formation of renal calculi.

5 The efficacy of the administration of vitamin A should regularly be checked by studying the regeneration of the visual purple, so that one can be certain that it is available for assimilation.

THE DIAGNOSIS AND TREATMENT OF THE COMMONER FORMS OF CEREBRAL TRAUMA

CHALMERS H. MOORE, M.D.

BIRMINGHAM, ALA.

The diagnosis, prognosis and treatment of cranial injury after head trauma are in an unsettled state. The more modern devices of treatment, such as the use of intravenous hypertonic solutions, repeated lumbar puncture, and even subtemporal decompression of the brain are all methods not as yet proved to be either essential or even valuable in the treatment of this condition.

These words are quoted from an editorial in the *New England Journal of Medicine* for April 1933.¹

In the same year Dandy² stated that 20 per cent of the total number of patients with severe head injury must be regarded as beyond redemption by any rational means available and that another 10 per cent can be saved only by a subtemporal decompression.

Coleman,³ in a recent contribution on the management of acute head injuries, said:

In my own experience with dehydration it was found that if the dehydration were carried to the extent where fluid was removed from the brain in sufficient amount to cause marked reduction of intracranial pressure the condition of the patient was made worse rather than better.

On the other hand, Munro⁴ in 1934 stated:

The diagnosis of craniocerebral trauma is firmly established on a pathological basis. One treatment for the usual forms of brain injury has been standardized. It consists of the preliminary treatment of surgical shock, when present, followed by therapeutic dehydration [by means of a hypertonic solution of dextrose administered intravenously] and repeated lumbar puncture for decompression.

These divergent views all from sources whose authority demands respectful attention, justify critical

possibility I have not as yet had the opportunity to confirm this in a sufficiently large number of cases to warrant an opinion. Unless used with the greatest caution and checked by frequent pressure readings, dehydration may prove a dangerous boomerang.

On the other hand, repeated spinal drainage will reduce brain volume because the intracranial pressure is lowered, thus tending to restore the cerebral circulation to normal. This mechanical decompression promotes the absorption of excess intracellular and perivascular fluids and permits the brain tissue once again to begin to receive its required amount of oxygen. In addition to the removal of excess fluids, much of the extravasated blood incident to the contusion and laceration of the brain is removed, creating in this manner more space in the overcrowded cranial cavity.

For these reasons, in all cases in which the pressure is increased as indicated by manometric observation, and in which the fluid is found to contain blood, one performs drainage as often as in one's judgment the particular situation demands. In the presence of bloody fluid, drainage is repeated at intervals of eight, twelve or twenty-four hours, depending on the richness of the mixture, until it is clear. The condition is never the same in any two cases, and I feel very strongly that one should not attempt to establish a routine.

If, after sufficient time has elapsed, signs of progressive improvement in the patient's condition do not appear, one is quite justified in presuming that, in addition to one or more of the conditions in this fundamental group, more serious damage is present, such as subdural or extradural bleeding. In this event one is justified in making subtemporal burr openings to ascertain whether such is the case. In experienced hands this is easily done with local anesthesia and does not jeopardize the patient's welfare in any way.

It is not in the province of this paper to discuss the treatment of the more unusual conditions, but I would emphasize the fact that unless one is equipped with an efficient suction apparatus, as well as an electric coagulation apparatus, one is courting disappointment and a high mortality rate in attempting any operative procedures, however simple, on the brain.

The principles of treatment herein outlined have succeeded in reducing the total mortality rate in 1,056 cases, seen during less than a three year period, from the former very high percentage of 46 to 14.6. If only the fundamental group is considered, the percentage drops to less than 8.4.

1023 South Twentieth Street

ABSTRACT OF DISCUSSION

DR. WALTER E. DANDY, Baltimore. In cerebral injury in the acute stage, the first consideration is the preservation of life. When life is safe, preservation of cerebral function engages the attention. If a patient is in shock, he should be at absolute rest, nothing is done except to clean and close a compound wound, this should practically always be done immediately. Depressions are left to a period when life is no longer at stake. The estimation of a patient's condition is dependent on a careful bedside study, study of the pulse, respiration and temperature, as Dr. Moore said, one should know these at fifteen minute intervals. In fact there isn't any condition in intracranial surgery that requires such close and accurate study as injuries of the head. Most patients get along better if they are left absolutely alone, i. e., if they are not dehydrated and if they do not get lumbar punctures and x-ray examinations. Roentgenograms mean nothing and should not be taken until the patient is well out of danger, and even then there is no point in x-ray examinations except for medicolegal reasons.

I do not think there is any medical treatment that adds to the patient's welfare during the acute stages of intracranial pressure. There is a great rebound in the use of intravenous dextrose and intravenous hypertonic salt. One thinks one is getting results, but the patient is paying for it by the rebound. The same holds true with lumbar punctures. Nature removes the fluid by passing it into the blood, and in much better fashion. There is only a small percentage of cases in which an operation is indicated, and that operation is usually a simple, subtemporal decompression. When intracranial pressure becomes so high that one can be certain that nature unaided can no longer save the life, the only hope lies in a direct relief of pressure by surgical means. My own method is to make a small perforator opening over the right parietal region, and if that shows no blood or extracerebral fluid the left side is similarly punctured. The effects of trauma will usually be disclosed by blood or fluid over one or the other cerebral hemisphere. A rapid subtemporal decompression under local anesthesia produces permanent relief, not relief over a period of a few hours, but permanent relief during the period of intracranial pressure. It sounds well to expect relief in other ways, but there just isn't any other way. In safe hands, this is a perfectly safe procedure. My firm belief is that the patient must be left absolutely at rest. Fluids should not be restricted. These patients need and should be given fluids if they are able to swallow. One should watch the pulse, temperature and respiration and, above all, the state of consciousness and the state of restlessness, which is the borderline between coma and consciousness. These bedside studies tell when one is in the danger zone. When life hangs in the balance, a decompression is the only safe method of relief.

DR. R. GLEN SPURLING, Louisville, Ky. Dr. Moore has expressed a safe, conservative point of view on this subject. Certainly the results of this treatment have been as satisfactory as in any large series of cases with which I am acquainted. There are several minor points in his arguments, however, with which I find myself in disagreement. The first of these is the incidence of traumatic shock seen after head injury. I have been impressed by the frequency of this state except when there are other associated injuries. Second, the effect of spinal puncture for the reduction of intracranial pressure impresses me as being so transient that its therapeutic value from this point of view is almost negligible. I agree, however, that spinal puncture when done for the purpose of diagnosis, for measurement of intracranial pressure or for the removal of blood when there are signs of meningeal irritation is a valuable procedure. Third, dehydration by hypertonic dextrose is, I believe, of questionable merit. That the absorption of dextrose by the brain tissue causes a secondary wave of edema has been amply demonstrated both clinically and experimentally. When vigorous dehydration is indicated, and I believe this is of relatively infrequent occurrence, sucrose is a far better drug because it is not associated with the undesirable pressure effects of dextrose. Severe dehydration by a greatly reduced fluid intake over a period of days is to my mind harmful rather than beneficial, for if one actually restricts the fluid sufficiently to reduce the size of the brain, one must likewise dehydrate every other soft tissue of the body to a like degree. I do not believe that this state is a desirable one. I am glad to hear Dr. Moore stress strongly the subject of Coleman's postural drainage. This is one of the most important contributions to the subject of head trauma in recent years. Having experimented for a good many years with most of the advocated methods of treatment of head trauma, I have about concluded that the most essential features are as follows: 1. Good nursing care. 2. Careful repair of scalp lacerations and compound skull fractures with or without underlying brain damage. 3. Postural drainage to prevent pulmonary complications in the unconscious patient. 4. Constant alert observations by the physician to recognize focal complications such as extradural and subdural clots and increased intracranial pressure. 5. Prompt operative intervention when neurologic examination indicates the presence of a surgical lesion. 6. Careful examination of the patient for associated injuries. 7. Withdrawal of bloody spinal fluid when signs of meningeal irritation appear. 8. Most important of all perhaps when one is in doubt as to indications for treatment, confining one's efforts to general nursing care and close observation.

Clinical Notes, Suggestions and New Instruments

MYOCARDIAL INFARCTION COMPLICATING PREGNANCY IN A YOUNG WOMAN

PAUL D WHITE MD R EARLE GLENDY MD
AND
PAUL GUSTAFSON MD
BOSTON

A Jewish woman, aged 22, consulted us May 4 1936 because of some uncertainty about the significance of chest pain occurring eight days before. She had always been in excellent health except for scarlet fever at the age of 10 years and tonsillitis followed by tonsillectomy at 12. She had worked hard and played tennis without any symptoms. At the time of the occurrence of the pain she was at the end of the second month of her first pregnancy. There had been no evidence of infection or of an attempt to interrupt the pregnancy.

Her father, mother, four sisters and one brother were alive and well.

April 26, on getting out of bed she had been seized by a moderate paroxysm of coughing which was at once followed by a rather severe oppressive pain across the front of the upper part of the chest, radiating equally down the two arms to the wrists. She coughed no more and there was no sputum, but nausea developed and she vomited three times that day. There was no blood in the vomitus. Because of the persistence of the disagreeable chest pain she went to see her physician in the afternoon and he found nothing apparently wrong. However, he gave her some medicine (capsules) for the pain and advised rest in bed for four days. This she carried out and then got up and about feeling somewhat weak and having a poor appetite. No note was made of any fever. While in bed she was seen by a consultant, who took an electrocardiogram the day following the occurrence of the pain, which showed late inversion of the T waves in lead 1, of this we learned only several weeks later.

rate and rhythm. There were no murmurs. The pulse rate was 76 and the blood pressure measured 115 mm of mercury systolic and 70 diastolic.

Fluoroscopic examination showed no abnormalities of the heart, great vessels or lungs. By orthodiagram the transverse diameter of the heart measured 91 cm and the internal diameter of the thorax 22.8 cm.

A tentative diagnosis of chest muscle strain and acute respiratory infection was made until the electrocardiogram was seen at the end of the examination. This occasioned considerable surprise and was repeated for certainty. It showed normal rhythm, with a rate of 90, with late inversion of the T waves in lead 1, high T waves in lead 3 and upright T waves in lead 4, indicative of infarction of the myocardium in the region

Fig 2—Tracing taken at the time of delivery, December 13, 1937, at 12:25 a.m. during the second stage, fully dilated, pulse rate from 127 to 146. B at 1:40 a.m. one hour post partum, pulse rate 90. Note the normal T waves in all leads in both records.

Fig 1—Tracings (four leads) following the attack of chest pain. A, May 4, 1936, eight days after the attack of pain. B, June 4, one month later. C, July 3, two months later. D, September 3, four months later. E, November 6, six months later. Note the late inversion of the T waves in lead 1, the high T waves in lead 3 and the upright T waves with persistence of the Q waves in lead 4. May 4 and June 4. There is a slight decrease in these abnormalities in the second tracing, July 3. The T waves in lead 1 are lightly diphasic, almost flat, while the T waves in lead 4 have become very slightly inverted with a level ST segment. September 3, the record is more normal, and November 6, the record is completely normal, with a return of the T waves in lead 1 to an upright position, a decrease in the height of the T waves in lead 3 and normal T waves in lead 4.

At the time of examination in our office, May 4, she felt a bit weak and nervous but otherwise well. Physical examination was entirely negative, save for slight pallor and an oral temperature of 99°F. The heart was normal in size, sounds

From the Cardiac and Obstetrical Clinics of the Massachusetts General Hospital. Presented in part before the meeting of the New England Heart Association, Massachusetts General Hospital, Nov. 9, 1936.

of the apex of the left ventricle (fig 1). The abnormal electrocardiogram which had been taken several days earlier, was not then known to us.

A convalescent period of several weeks in bed was prescribed and the patient rapidly regained a state of perfect health, with but one unpleasant episode, consisting of a paroxysm of tachycardia for half an hour, May 10, six days later, at the time of some nervous excitement. She continued in excellent health after that, with normal manifestations on physical examination at intervals of every few weeks. The electrocardiogram gradually returned to normal in the course of six months.

The pregnancy progressed uneventfully and on December 12, seven and one-half months after the attack of chest pain, labor began after spontaneous rupture of the membranes. The patient was kept asleep and quiet with the aid of hydrochlorides of the alkaloids of opium, principally morphine and pentobarbital sodium throughout the first stage of labor, which lasted seven hours during which time there were no symptoms or signs of cardiac embarrassment. As soon as the os was fully dilated she was delivered with central episiotomy and low forceps, and the placenta and membranes were expressed a few minutes later. The puerperium was uneventful. The mother and child were in excellent health Feb. 17, 1937, two months after childbirth. The electrocardiogram was then normal, as shown in figures 1E and 2B.

Electrocardiograms taken during labor (fig 2A) and post partum (fig 2B) showed no abnormalities of the T wave; the QRS waves in lead 2 decreased sharply in voltage for a few beats at the time of the actual delivery.

The persistence of the Q wave in lead 4 indicates the probability that the infarct in this case was not on the septal and anterior wall of the left ventricular apex but rather on the lateral wall.

There has been no evidence of coronary embolism, myocardial infection or trauma or pericardial disease.

SUMMARY AND CONCLUSIONS

A woman, aged 22 has been observed with clinical and electrocardiographic evidence of acute myocardial infarction, undoubtedly the result of coronary thrombosis (coronary embolism is a very remote possibility). So far as we know she is the youngest woman who has ever been reported as having this lesion.¹ We have encountered one man of the same age (22 years) with excellent recovery after coronary thrombosis, and four other patients, all men under the age of 30 (23, 26, 26 and 29 years). The youngest person on record was a youth aged 18 years.²

In the case reported here the coronary thrombosis complicated pregnancy in the second month with no harmful effect on the normal course of the pregnancy, childbirth and puerperium. There is one other published case of coronary thrombosis complicating pregnancy, this was in a woman, aged 45, with marked hypertension and congestive failure.³

Our case strongly suggests that coronary thrombosis and myocardial scarring may easily escape notice in a young person and this, with our other experience, indicates that myocardial infarction may after all not be very rare in young adults. Electrocardiographic evidence is essential for diagnosis in view of the fact that recovery even after extensive infarcts is the rule in youth.

PRIMARY SUPPURATIVE CHOLANGEITIS

REPORT OF A CASE AND THE VALUE OF LIVER
REHABILITATION IN THERAPY

ANTHONY BASSLER, M.D. NEW YORK

Suppurative cholangitis is considered to be secondary to conditions allowing of infections, such as gallstones, obstructions of the bile ducts from various causes, parasitic worms and carcinoma and from wasting conditions, such as typhoid, cholera and pneumonia. The bacteria isolated have been streptococci, staphylococci, *Escherichia coli*, *Bacillus typhosus*, pneumococci and *Clostridium Welchii*, the latter sometimes occurring as a primary infection. The onset is usually vague and the condition not suspected until septic symptoms appear. It may begin with attacks of jaundice simulating catarrhal jaundice in which it is insidious or begins acutely as a septic process without jaundice. As a rule pain is absent until late in the disorder. In most instances the condition resembles malignant disease, from which it differs in the diffuse and regular enlargement of the liver, septic symptoms including a marked leukocytosis and polynuclear cytolysis, and rapidly developing serious illness. Even in the presence of jaundice from involvement of the periradicular tissue in the liver, the diagnosis of the primary form is especially difficult. In the presence of gallstones or recent severe infectious disease, when pyrexia, chills, jaundice, leukocytosis with high polymorphonuclears and enlargement and tenderness of the liver occur, the diagnosis may be assumed with considerable degree of accuracy. I have seen thirty-one cases in the last five years and in all but two the suppurative process in the liver was judged as accompanying or secondary to other pathologic conditions. One of these two was multiple small abscesses of the liver due to *Clostridium Welchii* infection in a prominent New York internist who died recently and the second, the case reported here strongly suggests that it may occur as an ascending infection and without other pathologic change or cause.

REPORT OF CASE

Dr. de R., aged 42 was born in Colombia, South America but lived most of his life in the United States. About ten years before admission he had a cough that lasted for several months it was diagnosed as due to pulmonary tuberculosis but cleared up without special attention in about ten weeks. He was operated on for rectal fistula in 1934. Four years before, when living in New York, he became jaundiced. Other than a slight

degree of anorexia, this ran a course similar to acute catarrhal jaundice. In February 1936 he became jaundiced again and the course was again characteristic of acute catarrhal jaundice. This cleared in four weeks under bland diet, bismuth and medical bile aspirations. One of the features of the latter was the constant presence of blood in the A fraction. The present illness began six weeks afterward and followed the shock of a fire and considerable worry over financial affairs. The illness lasted uninterruptedly up to the time of the operation. For the first three weeks the jaundice kept deepening with characteristic gray stools and deep bile-stained urine, intense itching, anorexia, loss of weight and physical weakness. The icterus index during this time varied between 18 and 37, dropping rapidly and the jaundice cleared during the week before operation. During the three weeks before the operation there was

Fig. 1.—Section of liver tissue. A small necrotic foci. B small bile ducts compressed by cuboidal cells. C periphery of lobules and normal liver tissue.

associated with the illness for the first time a rise in temperature. For the first week this was nominal, then rising and diphasic in character between 100 and 105. In the ten days before operation there were distinct chills followed by an abrupt rise in temperature and a drop to 100 in a few hours. During the time of the pyrexia the liver enlarged noticeably, was tender on pressure but remained smooth, the edge never being palpable. The white blood cell count began at about 10,000 with the polymorphonuclears about 80 per cent and gradually rose to 22,000 with polymorphonuclears of 92 per cent. The hippuric acid and blood phosphatase tests were normal before the onset of the septic symptoms and during all the time of septic state three estimations of hippuric acid, two blood phosphatase, one galactose and two urobilinogen estimations were done, all of them being but slightly positive. The comparison of the blood phosphatase and the urobilinogen tests, however, somewhat suggested an involvement of liver tissue. Two days before

1 Since this paper was written we have read a report published a few months ago by W. J. May on *Coronary Infarction in Young Adults* (South African M. J. 10: 763 [Nov. 28] 1936). Four patients under the age of 40 years are described in this paper with clinical and electrocardiographic pictures of coronary thrombosis. The youngest was a youth aged 19 years and the next youngest a woman aged 20. The latter had electrocardiographic evidence of a basal infarct. The other two cases were men aged 38 and 39 years respectively.

3 Reis, R. A. and Frankenthal, L. E., Jr. *Labor in the Cardiac Patient with a Report of the Occurrence of Coronary Occlusion in Pregnancy and Labor*. Am. J. Obst. & Gynec. 29: 44 (Jan.) 1935.

operation the blood examination was erythrocytes 2,700,000 hemoglobin 9.3 Gm (54 per cent), color index 1.0, leukocytes 18,800, polymorphonuclears 90 per cent, lymphocytes 5 per cent, mononuclears 4 per cent and basophils 1 per cent, sugar 89 mg, urea nitrogen 14 mg, chlorides 789 mg, and icteric index 20. The urine showed a trace of albumin and was bile negative. The fall of the icteric index and the urine negative for bile are probably explained in the distinct clearing of the jaundice in the week before operation.

Operation was done October 22 by Dr. John F. Erdmann at the Doctors Hospital. Abdominal exposure revealed liver spotted with multitudinous gray to pronounced yellow spots from pinpoint size to the size of two or three bank pinheads. Both lobes of the liver were greatly enlarged. No tumors were found. Courvoisier's gallbladder was found. The cystic duct was partially flexed. The terminal cystic duct was markedly distended. The common duct was distended to three-eighths inch in diameter. Search for stones revealed none in the common duct except a very small piece of soft material the size of a pinhead. The gallbladder was palpated with the finger, and instrument and no stones were found. Choledochostomy was accomplished with a T tube. Cholecystogastrostomy was performed. A densely adherent appendix was found and removed. One cigaret drain was left down to the choledochostomy with four retention sutures. A preliminary transfusion of 500 cc of blood was given.

A pathologic report was made by Dr. Henry R. Muller, October 26. Grossly, a piece of liver tissue 2 cm by 0.5 cm in the fixed condition and after cultures were made from it did not show the spots seen in the fresh state. A dome shaped specimen from the fundus of the gallbladder showed the walls thickened and the mucosa granular. The appendix was 6 cm long, its lumen packed with feces and the wall was thinned out.

Microscopically, sections of the liver showed small foci of necrosis with polymorphonuclear infiltration. In addition there was a marked inflammatory reaction around the portal canals consisting of fibrosis and polymorphonuclear and round cell infiltration. The wall of the gallbladder showed an active inflammatory process in the mucosa and in the wall itself. This was a chronic inflammation consisting chiefly of plasma cells and a deposit of fibroblasts. The appendix showed a mild chronic inflammation in the wall. The diagnosis was chronic cholecystitis, acute periportal hepatitis, miliary abscesses of the liver and chronic appendicitis.

Bacteriologically, liver culture yielded no growth, bile culture yielded *Escherichia coli* and *B. subtilis*. Subsequent examinations of bile drainage specimens all contained *Escherichia coli* and occasionally *Pseudomonas*.

After operation the temperature and pulse rate gradually subsided for seven days, becoming 99 and about 100 respectively. On the eighth day the pulse rate shot to 140, the temperature rose a degree or two, emesis came on and a postoperative dilatation existed, which was controlled by continued gastric drainage and lavage. After this the temperature and pulse remained for days slightly higher than before the gastric dilatation; the temperature gradually subsiding to normal and the pulse to about 105. For the first two or three days the bile drainage was practically clear and normal looking. It then suddenly became muddy with pus, this lasting for a day or two and then clearing. This continued in repeated ways for three weeks the bile then being quite clear and remaining so. After numerous items of treatment, mostly dextrose injections and liver injection therapy, his manhood deepened and he lost weight rapidly and became vitally weakened and markedly anemic. About three and a half weeks after the operation the blood protease and hippuric tests for the first time showed a marked hepatic deficiency, and the possibility of a liver death was imminent. At that time he had been hiccupping for seven days, a distinct diarrhea was present and the stomach was intolerant to fluid and food. At this time a conjoint program of liver rehabilitation was inaugurated which in twenty-four hours changed the whole serious aspect of the case. The fluids were forced by subcutaneous and rectal drip to dilute the excessive toxins in their passage through the liver, adrenals and kidneys; when the stomach became more tolerant the proteins were reduced to meet the lowered detoxicating ability of the liver, the carbohydrates were increased both in diet and by dextrose injections intravenously to build up the liver glycogen reserve; calcium

gluconate was given intravenously to build up liver function, in the fluids introduced there was liberal use of sodium chloride and dilute hydrochloric acid given by mouth to replenish blood and tissue chloride depletion and maintain normal water balance and adrenal cortex extract intramuscularly to aid in supporting the adrenal cortex. This program was modified as recovery was definite. In about two weeks after this the patient was well enough to leave his bed and improved slowly but definitely day by day. Bile drainage was kept up steadily for about ten days, and after this the tube was clamped off alternate hours, one hour on and one hour off, this being modified to one hour on and four hours off as time went on. From the time of the operation to November 27 when the T tube was removed, there was always a frank flow of bile. At the time of its removal the liver had markedly reduced in size and the patient had

Fig 2.—Section of liver tissue. A normal liver tissue. B edge of the area of necrosis which comprises all that is left of this showing degeneration of liver cells and infiltration with polymorphonuclears monocytes and fibroblasts.

gained strength to walk a little and was definitely on the way to recovery. During the convalescence and about three weeks after the operation diarrhea of acholic stools developed and he ceased to gain. The diarrhea mounted up to from ten to twenty stools a day with considerable urgency. At that time the liver rehabilitation program had been discontinued for about two weeks. A modified plan was then inaugurated consisting of considerable amounts of dextrose, calcium hydrochloric acid and increase of fluids by mouth. Within twenty-four hours of its institution the diarrhea was controlled far more effectively than it had been by bismuth and opium. The patient was seen December 18 in the office and was gaining weight and feeling quite well. Dextrose by mouth was being continued. A biliary fistula persisted it being too soon to expect closure. March 16, 1937, the patient was perfectly well following no treatment during the last month. He has gained 42 pounds (19 Kg) since he has been out of bed; the liver is not palpable and he is back at work putting in full days.

An interesting speculation now comes forward as to the possibility of a cirrhosis of the liver from the amount of fibrous tissue repair from the necrotic areas in the liver tissue and the periradicular inflammation as well as how much of a metabolic problem will be present in the months to come

FRACTURE OF THE ANTERIOR SUPERIOR SPINE
OF THE ILIUM

VOIGT MOONEY M.D. PITTSBURGH

Fracture of the anterior superior spine because of muscular violence is not frequent. With reports in the literature by Carp, Conwell, Christopher and several foreign writers, the number of cases had been brought up to fifty-eight

Fracture of anterior superior spine of right ilium

Searching the literature since Conwell and Alldredges report,¹ I found no other reference in the literature, so I am reporting the fifty-ninth case

W. H., a healthy Negro youth, aged 16, who was carried into the Allegheny General Hospital, May 25, 1936, complained of pain in the right side and inability to walk. He stated that while running down a hill he had experienced a sudden very sharp pain in the right side, which caused him to drop to the ground.

The patient was muscular and was in evident pain. The right thigh was held in the everted position. There was tenderness and crepitus over the anterior portion of the right ilium. Movements of the right hip and pelvis caused discomfort. X-ray examination revealed a fracture of the anterior superior spine of the right ilium.

I cut down on the fracture and replaced the loose fragment. A plaster-of-paris hip spica was applied with the thigh and knee flexed. Recovery was uneventful, the cast being removed at the end of six weeks.

A second case was that of a colored girl, aged 13 years, who participated in a track meet May 25, 1937. About five minutes after running she arose and found that she could not bear weight on the right leg. She was removed to the Allegheny General Hospital, Pittsburgh, Pa., where the examination showed that the right ilium and hip were tender to touch. All the hip movements, both active and passive, caused pain. X-ray examination of the right ilium revealed a fracture of the anterior superior spine.

PENETRATION OF TISSUE BY FUEL OIL UNDER
HIGH PRESSURE FROM DIESEL ENGINE

C. E. REES, M.D., SAN DIEGO, CALIF.

A recent query¹ in *THE JOURNAL* concerns injury resulting from the penetration of tissue by fuel oil from a Diesel engine. Since the reply indicates that no such cases have been reported in the medical literature, the present case report and discussion may be of interest.

A motor mechanic, aged 47, was testing the jet of a Diesel engine. He was holding the jet which he had removed from a cylinder head, about 1 inch from the tip of his right middle finger when he tripped the valve. Oil was forced from the jet into the finger at a pressure which he estimated to be about 4,000 pounds. There was immediate slight bleeding from several points in the finger-tip and pain, which gradually became intense. When I first saw the patient twenty-four hours later opiates were necessary to relieve the pain. At this time the finger and hand were edematous, swollen and tense, and the epitrochlear and axillary lymph nodes were enlarged and tender. A round area of epidermis about 1 cm. in diameter at the end of the finger was loose and was removed. The tissue beneath the skin was a dusky red.

The patient was sent to the hospital, where the hand was elevated and hot compresses were applied. A blood count at this time revealed a hemoglobin concentration of 95 per cent, 4,500,000 erythrocytes and 11,500 leukocytes, of which 80 per cent were polymorphonuclears and 20 per cent small lymphocytes, and many poikilocytes. The urine was acid in reaction and contained many amorphous urates, from 4 to 8 leukocytes and an occasional red blood cell per high power field. There was no albumin and no sugar.

Fig. 1.—Epidermis of third finger denuded to first interphalangeal joint showing dry gangrene. Area of destruction extends to darkened area in midpalmar space. Maceration of remainder of hand due to wet packs.

The pain in the finger and in a triangular area in the palm and dorsum of the hand at the base of the middle finger persisted, but the pain and swelling in the remainder of the hand subsided somewhat. Within the next twenty-four hours the epidermis on the distal half of the finger loosened and was removed, and again a deep red color in the underlying tissue

From the Rees Stealy Clinic.
1. Penetration of Tissue by Fuel Oil from Diesel Engine queries and minor notes. *J. A. M. A.* 108: 225-226 (Jan. 16) 1937.

was revealed. Dehydration of this area resulted in dry gangrene, which began at the tip of the finger and extended down to the first interphalangeal joint. The epidermal skin over the first phalanx and the base of the finger then loosened and the same dusky red that was seen at the tip of the finger before the onset of the gangrene was disclosed in the sub-jacent tissue.

Involvement of the bone was not demonstrable on the x-ray plate taken seven days after the injury. Exploratory incision

Fig 2—Dorsal view. Discoloration of nail of fourth finger due to former injury.

over the first phalanx at this time showed that all the tissue in this area had undergone liquefaction necrosis with secondary infection. A thick creamy pus was present in which an occasional gram-positive coccus was found. The tissue of the palm and dorsum of the hand at the base of the finger was of the same dusky red previously noted in the finger. Bleeding was very slight. The pain was still severe. During this time he had a gradually subsiding temperature range between 101.2 and 97 F.

It was decided to amputate the finger and remove if possible all the involved tissue. Amputation was performed through a palmar and dorsal wedge-shaped incision over the metacarpal bone. Dusky and edematous tissue with small pockets of pus extended into the midpalmar region. The metacarpal bone was sectioned in its middle third. Only the lateral digital artery required ligation. The wound was left open on the dorsal side and was closed by loose silk worm sutures on the palmar side. The swelling and pain in the remainder of the hand subsided immediately. There was considerable suppuration in the area of amputation following operation and it was not until eight weeks later that healing was complete. When the patient was seen again, two years after his accident, the function of the remaining fingers was good.

COMMENT

The introduction of the use of high pressures in industry has led to a number of injuries which are unique to accidents caused by such pressures. The normal operation of certain types of Diesel engines adds a new agent which is capable of producing injury when misapplied. These engines differ in principle from the well known gasoline engines in that the fuel in the explosion chamber is ignited not by an electrical spark but by heat generated from compression of the mixture of fuel and air. The fuel is supplied directly into the cylinder of the engine where it becomes mixed with air, compressed and fired. In one type of Diesel engine which uses the heavier fuels

the oil is forced into the cylinder through a jet where it is fragmented by air under very heavy pressure—from 1200 to 5000 pounds per square inch. Such pressure is capable of forcing fuel oil into tissue.

There are two types of oil used in Diesel engines. One is a light oil which is used in automotive engines such as tractors, and the other is a heavy, less refined oil which is used largely in marine engines. The light oil is composed of a multitude of hydrocarbons but has been considerably refined. The heavy oil contains a small amount of phenol, which is probably largely extracted from the light oil.

I have been informed that crude oil has been implanted in tissues through accident with apparently no more irritating effect than that of any other simple foreign body. It is quite conceivable however, that the forcing of such material into tissue under pressure might cause a gangrenous condition even though the constituents are not particularly toxic.

A similar accident has been reported to me which occurred to a Japanese fisherman while at sea. My informant states that the finger was incised after the accident by a member of the crew and that it healed shortly thereafter without loss of finger or function.

From the little information I have been able to gather it would seem that the severity of these accidents is dependent on the character and quantity of the oil and on the pressure under which it is introduced into the tissues. Conclusions cannot be drawn from experience with one case, but it is my impression that in an accident similar to the one reported in which the local reaction is marked, early and liberal incisions over and into the area should be considered. Such incisions would allow the escape of the irritant which apparently remains localized, and would relieve the edema, which is intense and may be destructive in itself if allowed to persist.

AN INSTRUMENT FOR THE CONTINUOUS READING OF RECTAL TEMPERATURE

WILLIAM BIERMAN, M.D., NEW YORK

During the period of fever produced by physical means, it is essential that the systemic temperature be known at all times. This is best determined by observation of the temperature in the rectum. The most commonly used technique is the insertion of a clinical thermometer at short intervals. This procedure disturbs the patient and is tiresome to the attendant.

The use of a continuous recording device such as a resistance thermometer is of great value. It allows of continuous observation—which is very important in that it permits the careful modulation of the thermal energies applied so as to maintain

Continuous indicating rectal thermometer

the desired temperature. Resistance thermometers have a time lag, require careful adjustment, are expensive and occasionally get out of order. Thermocouple devices have similar objections.

A continuous indicating mercury thermometer permits visualization of the rectal temperature at all times. I employ a specially designed instrument $13\frac{1}{2}$ inches in length and three-eighths inch in diameter. The last 4 inches of the thermometer is flattened so that the width of this part is about five eighths inch. Etched lines on the flattened portion indicate temperature values in fifths of one degree F, subdivisions extending from 98 to 112 F. Prisms on each side of the mercury column in the flattened portion of the instrument magnify this column so that it can be read readily at a distance of several feet.

The thermometer has been placed in a special housing to protect it from breakage and yet permit of its easy reading. The first 3 inches of this housing is made of thin shell

aluminum designed so that the thermometer fits snugly into the metal casing. Metal is used so that the temperature of the tissue may be readily transmitted to the thermometer bulb. The remainder of the housing is made of hard rubber or of bakelite surrounding the thermometer except for a window to permit visualization of the figures in the flattened portion of the thermometer. This type of material interferes with the transmission of the heat of the fever cabinet to the more thermal receptive portion of the thermometer. About 2 inches from the tip, the metal portion is expanded into a small bulb which facilitates retention of the instrument in the rectum.

The device is kept in place by resting the portion that protrudes on a small pillow. If the patient turns, a simple adjustment is all that is required to keep the mercury in the line of vision.

Special Clinical Article

THE COMPLICATIONS OF PEPTIC ULCER AND THEIR TREATMENT

CLINICAL LECTURE AT ATLANTIC CITY SESSION

FRED H. KRUSE, M.D.
SAN FRANCISCO

As the usual complications of gastric and duodenal ulcer are not simple but are intimately interrelated, a brief consideration of their nature and treatment as a single problem is of value. Some of the complications that occur are not always preventable, such as hemorrhage in an arterio-sclerotic subject, alkalosis in a subject with damaged kidneys, or sudden perforation in a subject with acute ulcer of infectious origin. However, most of the complications that arise represent a breakdown of medical control and management, partly the fault of the physician in not sufficiently educating his patient in the nature and dangers of his ulcer but primarily that of the patient in failing to follow his instructions rigidly.

Fig. 1—Organic and permanent obstruction.

Most of the complications considered here occurred in patients who were previously under some form of medical treatment that had not been sufficiently heeded.

The person with peptic ulcer must be educated as to the nature and permanence of his diathesis, just as the tuberculous and diabetic patient is taught to understand and care for himself. His instruction must include not

only dietary requirements and certain specific medical procedures but self management and environmental control.

As to specific medical procedures, it is becoming more and more apparent that the newer therapeutic agents being used, such as histidine, foreign proteins (with or without lipoids and emetine), mucin, mercurials

Fig. 2—Organic obstruction with active peristalsis which yielded later to treatment of edema and congestion.

(as metaphen) and other corrosives and disinfectants have only a limited and occasional value in the treatment of peptic ulcer. On the other hand, the recent work in the development and treatment of experimentally produced peptic ulcers (Stalker, Bollman and Mann) demonstrating the efficacy of alkaline therapy encourages the attempts to control acidity as well as motor spasm and a generally hypertensive nervous system.

During the last ten years, from April 1927 to April 1937, 575 persons with peptic ulcer were admitted to the University of California Hospital. Of these 399 had duodenal ulcer and 146 gastric ulcer, a ratio of about 3 to 1. Males numbered 441 and females 134, a proportion of 3.3 to 1. A slightly higher proportion of males had duodenal ulcer and a slightly higher proportion of females had gastric ulcer than is indicated by this ratio. Thirty patients, or 5 per cent, had gastrojejunal ulcer. The mortality in the hospital, as expressed by twenty-nine deaths to 575 entries, was 5 per cent. The main features of the 575 cases are summarized in table 1.

It has been estimated that from 20 to 25 per cent of patients who enter hospitals with peptic ulcer require surgical intervention. Over the ten year period 33 per cent of these patients were sent to operation, many more in the first five years than in the last five years, there being a distinct swing of late toward more prolonged and rigid medical treatment and a much more conservative selection of patients by surgeons for operation.

The most common complications, which I shall consider briefly, are given in table 2.

INTRACTABILITY

In considering intractability, I shall be brief, for the subject is involved and exhaustive consideration would necessarily include a review of the various methods of treatment.

The intractable ulcer should be studied in detail. The type of ulcer, as to location and mechanical aspects, and any possible gain by further medical treatment should be considered. In some cases surgical aid alone offers hope. Systemic causes, such as focal infections, a diseased gallbladder, metabolic disturbances and allergic or deficiency states should be investigated. Nervous factors, the wear and tear of life and the patient's mental outlook and psychologic make up should be taken into consideration. Most important by far is a careful analysis of the interval history and of the

Fig 3—Retention

procedures the patient is following. This analysis will frequently reveal that failure of medical treatment has been due chiefly to a lack of intelligent and whole-hearted cooperation on the part of the patient in the management and control of his condition. Only painstaking education, specific indication of errors in diet and in living habits and more frequent supervision by the physician can insure success.

HEMORRHAGE

In the University of California Hospital series of 575 cases of peptic ulcer recently reviewed, hemorrhages occurred in 28 per cent of the cases of duodenal ulcer and in 28 per cent of the cases of gastric ulcer, average, 28 per cent. Brown reported the incidence of hemorrhage as 25 per cent in 1,225 cases of peptic ulcer in which the Sippy treatment was used. Probably a true incidence of hemorrhage to all ulcers would be nearer 10 per cent.

The mortality of gross hemorrhage has usually been estimated as 5 per cent in the statistics of this country, but Leon Goldman found a mortality of 10 per cent

for 1,025 patients with peptic ulcer in the San Francisco Hospital while Tage Christiansen of Denmark reported a mortality in most countries of 10 per cent or more. There seems to be a general agreement that persons over 40 with peptic hemorrhage are more likely to die than younger persons (a ratio of 8 to 1) and that twice as many males as females die.

Fig 4—Obstruction that has yielded to lavage and medical management

The hemoglobin level is an important factor in prognosis. When it is below 60 per cent the death rate is almost four times that when it is above 60 per cent. Arteriosclerosis is an important factor affecting the incidence and mortality of this condition. Two or more gross hemorrhages indicate the likelihood of recurrences and show an abrupt rise in mortality after the second hemorrhage.

Symptoms and Diagnosis—When a chronic peptic ulcer bleeds, the source of the blood is generally a small blood vessel, most frequently an artery that has become eroded. In cases of massive hemorrhage, a ruptured vessel on the lesser curvature or posterior wall of the stomach or on the posterior wall of the duodenum is usually the cause.

The tendency to bleed is frequently a characteristic of the individual patient due to early scurvy or a so-called bleeding diathesis not directly related to any demonstrable blood dyscrasia.

Fig 5—Air bubble under diaphragm in case of acute perforation

The diagnosis is apparent when one notes either hematemesis or melena or both, pallor, rapid pulse, faintness, sweating and falling blood pressure. Hematemesis occurs only if the distention of the stomach caused by the hemorrhage is comparatively sudden. Owing to relief of local congestion any pain present usually disappears as the bleeding becomes more profuse.

The initial result of hemorrhage is diminution of blood volume, which causes a sudden fall in blood pressure. As the hemorrhage ceases the blood pressure rises, and the blood plasma increases as a result of

absorption of water from the tissues, thus causing a fall in the hemoglobin content. The total loss of blood can, of course, be judged only by the percentage of hemoglobin when at length it reaches its lowest level. The cessation of bleeding and any recurrence can be determined by frequent reading of the blood pressure. A single severe hemorrhage may cause the hemoglobin content to drop to 60 or even 40 per cent, and if it is repeated the hemoglobin may drop to 20 per cent.

If the vomited blood is bright red and alkaline, it is a clear indication that the hemorrhage has been profuse and rapid, if it is dark brown, coffee ground material and acid, the bleeding has been less abundant and comparatively slow.

Faintness, thirst, vertigo, tinnitus, palpitation, tremor, coldness of the extremities, nausea and profuse sweating, with rapid pulse and pallor, complete the clinical picture. Temporary blindness in one or both eyes is a rare sequel of severe hemorrhage.

Only after very severe hemorrhage from rupture of a large vessel is death likely to occur as an immediate result and this is indeed rare. In Goldman's series of

it ought to be performed at once. Except under these circumstances, the advisability of transfusion must depend on the indications in the particular case involved.

The management of severe hemorrhage complicating peptic ulcer is a subject commanding a great deal of attention and exciting a lot of controversy. The essential features of treatment, such as diet, starvation, intravenous and parenteral injection of fluids to combat dehydration, nitrogen retention and alkalosis and the use of transfusions as well as the indications for surgical intervention, have been productive of a wide and positive difference of opinion among the leading authorities.

So confusing are the statements of proper procedure and management that it is well not to pin one's faith on any stereotyped method but with certain principles in mind to individualize the treatment according to the needs of the patient and the individual problem presented.

For instance there has been considerable controversy about the dangers and advantages of blood transfusions in cases of peptic hemorrhage. Sippy taught that the

Fig. 6—Chronic perforation with the perforating sac seen as A a canal B a bud and C a pouch

patients who died of exsanguination, approximately twice as many had duodenal ulcer as had gastric ulcer.

Essential Considerations in Treatment—Experience teaches that the treatment of moderate or even of extensive hemorrhage should be medical. The mortality from surgical intervention is high. Too frequently the surgeon cannot locate the bleeding vessel. An arteriosclerotic vessel can sometimes be found and closed successfully in the case of an old chronic ulcer, or by cautery, excision or resection when possible, the site of hemorrhage may be eradicated, although this is often impossible and recurrence of hemorrhage later ensues. With few exceptions indication for surgery exists chiefly in the arteriosclerotic patient with recurring or persistent hemorrhage and in the person with a deeply penetrating ulcer on the posterior wall of the duodenum, eroding through a large arterial branch. Repeated recurrence and persistent oozing are indications for surgery if they continue in spite of proper medical treatment. In almost all cases bleeding will cease spontaneously without any treatment by drugs and will not be fatal. One must however, consider the patient over 40 with more than two hemorrhages in the danger zone and decide whether or not he can stand another hemorrhage. The favorable time for surgical intervention is after the hemorrhage has ceased. A hemoglobin percentage below 60 indicates that a transfusion may be required; a percentage below 40 signifies that

intravenous administration of fluids might start hemorrhage anew and that it was even dangerous to take the blood pressure for fear of raising the systolic pressure. Most physicians have feared that transfusions, especially large ones, of 500 cc or more, might increase the systolic pressure to such an extent, even up to normal or above that further bleeding would be encouraged since tarry stools are sometimes seen even after a blood transfusion of 500 cc. MacGuire, Unger and others expressed the opinion that such an occurrence is only a temporary condition and that blood added in large amounts is very beneficial to the patient. They questioned the benefit of small transfusions and discounted the dangers of the larger ones, claiming that the systolic pressure declines after repeated transfusions of whole blood, never coming up to normal, and is usually from 10 to 20 degrees below it. Such transfusions, they claimed, promote better clotting of the blood.

On the other hand, Christiansen (Scandinavia) said that in the past five years the mortality was almost twice that of the previous five years, despite the much wider use of blood transfusions. Eight of thirteen patients who had recently been given transfusions died. He expressed the belief that transfusions have not reduced the number of deaths from massive hemorrhage and have even contributed to its increase.

Usually no fluids are given and the patients are starved after peptic hemorrhage. The dangers of such a procedure have been clearly shown by the work of L. Meyler (Holland), which demonstrated that enormous toxic destruction of protein takes place after massive hemorrhage, with an accumulation of nitrogenous end products, thus elevating greatly the blood urea and nonprotein nitrogen content without lowering the blood chlorides or elevating the carbon dioxide con-

TABLE 1—Complications of Peptic Ulcer Cases Observed at the University of California Hospital from 1927 to 1937

Peptic Ulcer	Number	Hemorrhage	Obstruction	Vomiting	Night Pain and Hypersecretion	Acute Perforation	Subacute and Chronic Perforation	Previous Surgery	Surgery	Alkalosis

tent of the plasma, thereby indicating a condition of uremia and not of alkalosis. Unless the condition of dehydration is speedily corrected and balanced feeding instituted, death by uremia may follow.

Aside from severe gross hemorrhage, one often has the problem of continuous small loss of blood or oozing. With the aid of a standard capillary fragility test used in investigating scurvy, it has been found that preclinical and even severe scurvy is frequently present but unrecognized in adults. This condition is often induced by food restrictions imposed in cases of peptic ulcer and colon disorder and is probably due to diets deficient in vitamin C. At first there is no gross evidence of scurvy, but later frank hemorrhage may occur from the gums and intestine and under the skin. Oozing of blood may occur, associated with changes in the smaller vessels and due to increased fragility of their walls. Crystalline vitamin C (cevitamic acid) and liver extract may be injected repeatedly in cases of peptic hemorrhage under such conditions.

Finally, much evidence is accumulating that the liver suffers severely in many cases of prolonged peptic ulceration and hemorrhage, so that the intravenous injection of small amounts of dextrose solution of from 25 per cent to 50 per cent concentration, for its protection must be considered.

Medical Treatment—In the light of the aforementioned known conditions and reasons apparently favoring certain procedures, a rational treatment for hemorrhage might be stated as follows:

1 Complete rest, quiet and immobility of the patient should be secured, enough morphine to keep him drowsy and to control restlessness being used.

2 Fluids should be given as soon as it is necessary to combat dehydration to get rid of toxic nitrogenous products. These may be given as physiologic solution of sodium chloride by hypodermoclysis or as this solution alternated with 4 per cent dextrose in 300 cc rectal retention enemas, every four or six hours. Fluids by mouth as well as intravenously should be avoided at first unless a transfusion is indicated. Ice given by mouth is of no advantage. By the second

day, intravenous injections of 50 cc of from 20 per cent to 25 per cent dextrose solution may be given to maintain the liver glycogen.

3 Starvation for forty-eight hours at least, according to indications of control of the hemorrhage, would seem the safer course, particularly if the first two procedures are carried out. During this period the mouth should receive great care and the flow of saliva be kept free by having the patient chew a substance such as paraffin gum to avoid parotitis. The membranes of the mouth and throat should be kept moist.

4 Contraction of the stomach is desirable. If evidence of hemorrhage continues and it is suspected that food remnants or clotted blood are distending the stomach, a small tube may be put down from 16 to 20 inches (from 40 to 50 cm) with the terminal end just inside the cardia, and repeated lavage with 120 cc of ice water or with a 1:1,000 solution of ferric chloride, iced, may be carried out as indicated. From 4 to 12 cc of a 1:1,000 solution of epinephrine may be left in the stomach.

5 The blood pressure, the hemoglobin content and the red blood cell count should be observed. A further fall in the blood pressure may indicate need for washing out the stomach.

6 Transfusion is usually unnecessary in the average case of hemorrhage. If the hemoglobin content reaches 60 per cent or below it must be considered, and it is imperative if there is doubt that the patient can survive another hemorrhage or if the hemoglobin reaches 40 per cent or below. To administer from 300 to 500 cc of whole blood seems the most safe and conservative procedure unless there is very severe exsanguination, in which case 1,000 cc should be given and a second transfusion in a day or two may be necessary.

7 The value of neutralizing the increasing acidity of the gastric contents to prevent irritation is apparent. Along with Sippy and Huist, I myself like to use a powder composed of the tribasic calcium phosphates and magnesium phosphate. Beginning about the fourth or fifth hour from the start of the hemorrhage, 4 Gm of this powder is given every hour when the patient is awake, until regular ulcer management can be instituted. A thick mucin solution given frequently by Levine tube has also been used with considerable success.

TABLE 2—Common Complications of Peptic Ulcer

1 Intractability due to type of ulcer systemic causes nervous factors failure of cooperation in treatment	
2 Hemorrhage	25%
3 Retention and obstruction	51%
(a) Functional achalasia—spasm	
(b) Edema and congestion	
(c) Fibrosis and pyloric hypertrophy	
4 Hypersecretion and night pain	41%
5 Alkalosis	10% (?)
6 Acute perforation	4%
7 Subacute and chronic perforation	16%

8 For the immediate purpose of arresting hemorrhage, surgical intervention should be recommended but rarely. If it is indicated, the optimal time is after the patient has recovered from the immediate effects of the bleeding.

9 Feeding by mouth—when it should be begun, and how liberal the diet should be—creates much difference of opinion. The usual procedure has been to starve the patient for from three to five days and then cautiously to begin feedings with milk and cream, enlarging the diet with cereals, eggs, and purées slowly for several weeks.

The observation that dehydration and starvation may lead to serious kidney, liver and constitutional complications and the report of Meulengracht of Copenhagen of the treatment of 251 patients with hemorrhage by use of rest in bed and liberal diets from the first day, with only a 1 per cent mortality, as against the usual 5 or 10 per cent, should lead to a critical test of the wisdom of starvation, with its concomitants of exhaustion and anemia as its least serious aspects. Furthermore, Kellogg and Mettier have shown that anemia may persist after hemorrhage, owing to the alkalinization of the gastro-intestinal tract, with a modified Sippy regimen (interfering with utilization of dietary iron), unless large doses of inorganic iron are administered.

Certainly one must be alert to supply sufficient vitamins and the proper nutritional value to the diet as soon as safe. I still favor the conservative procedures but feel that their limits must be more accurately gaged.

ALKALOSIS

In the past, physicians have become more or less familiar with the picture of pyloric obstruction or obstruction of the upper part of the intestine accompanied by vomiting and evidence of renal insufficiency and with frequent culmination in attacks of so-called gastric tetany. Studies of the blood chemistry in such cases show a high plasma carbon dioxide combining

TABLE 3—Laboratory Evidence of Alkalosis

Blood plasma carbon dioxide	High	65 to 125 volumes per cent
Blood urea nitrogen	High	20 to over 50 mg
Blood nonprotein nitrogen	High	40 to over 100 mg
Serum sulfate	High	
Blood chlorides	Low	
Sulfate clearance	Low	20 or below
Phenolsulfonphthalein excretion	Low	
Urine—albumin and casts		

power and nitrogen retention and a low content of blood chlorides. Albuminuria and a deficient phenolsulfonphthalein output complete the picture. This is alkalosis well established.

The loss of hydrochloric acid by persistent vomiting in cases of obstruction, or whatever else may lead to continuous vomiting, renal disease, hemorrhage, low salt intake, excessive perspiration, hepatic disease and excessive doses of alkalis can all impair the acid-base regulating mechanism. Persons with impaired renal function are invariably sensitive to small doses of alkalis. It seems probable that alkalosis can develop in persons with normal renal function only if one or more additional factors besides excessive intake of alkalis are present. Something happens to the chlorides of the blood, rendering them no longer available, and this leads to withdrawal of tissue chloride and fluid, with consequent degrees of dehydration. The onset of alkalosis appears to precede that of vomiting and may occur in its absence. The occurrence of tetany in cases of pyloric obstruction depends on the degree of alkalosis present, it generally occurs when the plasma carbon dioxide rises above 100 volumes per cent. The blood calcium content is sometimes slightly reduced, but the reduction is much less than that found in cases of infantile tetany, parathyroid tetany, or tetany associated with chylous diarrhea.

When alkalosis develops in the course of intensive treatment with alkalis, symptoms may occur from the first to the fourteenth day, though they are generally noted from the fifth to the tenth day. Occasionally these symptoms disappear spontaneously. Anorexia

and depression are the first to appear. A distaste for milk becomes evident. The patient shows irritability, introspection and nervousness and may often be considered neurotic. Headache, nausea and often severe vomiting follow. Dizziness and vertigo may be evident. Excessive dryness of the throat develops early although neither atropine nor belladonna is used. Aching pains in the muscles and joints are of common occurrence, with pruritus and dryness of the skin. Eventually the patient becomes apathetic and drowsy, and coma may develop. Weakness and prostration with profuse perspiration precede this stage. The laboratory evidence of alkalosis is summarized in table 3.

Treatment—The treatment would appear to be obvious. Occasionally death ensues, but, as a rule, the symptoms never become very severe if recognized reasonably early, and they disappear rapidly when the administration of alkalis is discontinued.

- 1 All treatment with alkalis is stopped at once.
- 2 (a) Physiologic solution of sodium chloride is administered by hypodermoclysis, to supply fluids and chlorides. (b) Dextrose solution, 10 per cent, is given by vein, as indicated for vomiting and nutrition.
- 3 No food or fluid is given by mouth.
- 4 Stomach lavage is given every evening and often two or three times daily, this controls the degree of hypersecretion and overcomes dilatation.
- 5 Ammonium chloride is used as needed. 300 cc of a 2 per cent solution by rectum every three or four hours or 10 or 12 Gm by mouth.
- 6 The clinical signs and chemical status by the end of three or four days usually allow feeding again, possibly with emptying of the stomach at night.
- 7 The progress of the patient and the past history will determine then whether surgical treatment should follow or medical treatment with insoluble alkalis, such as tribasic calcium phosphate and magnesia or mucin, and dietary therapy.
- 8 In cases of alkalosis arising from the use of alkalis or in the presence of even a slight degree of renal disease, only the neutral or insoluble alkalis should be used.

RETENTION AND OBSTRUCTION

As judged by some form of retention of barium sulfate or food in the stomach beyond the normal time, 51 per cent of peptic ulcers show some obstructive characteristics, yet further analysis of these cases indicates that organic factors producing chronic obstruction exist in only about 20 per cent.

Obstruction in cases of peptic ulcer may be acute and temporary or chronic and prolonged. All grades of obstruction are produced by the varying factors of (1) spasm, (2) edema and inflammation or (3) the more permanent type of pyloric fibrosis and hypertrophy. The first of these factors, spasm, is functional and therefore curable, the second, edema and inflammation from an active ulcer, is organic but often curable medically, the third, pyloric fibrosis and hypertrophy, produces a stenosis that is organic and incurable, but while complete relief can be obtained only by surgical intervention, many patients obtain palliative relief by proper medical treatment and emptying the stomach by tube periodically. In some patients the stomach compensates for the narrowing at the pylorus, and with the healing of the ulcer and the subsidence of spasm they may have relatively little more trouble. I have under observation a considerable number of such patients past 50, with gastric retentions averaging 50 per cent in six hours, who, unless they abuse their diet prescription, suffer no discomfort.

In cases in which compensation of the stomach fails or the degree of stenosis becomes too extreme, the fol-

lowing symptoms and signs develop an increase in the cycles of pain, with night pain, hypersecretion, with vomiting, dilatation of the stomach, distress, nausea and emaciation, and toxic effects, due to alkalosis.

Treatment—Patients in whom this syndrome develops should be placed at rest in a hospital. Evacuation of the stomach by tube, a dietary regimen and medical management should be instituted. As soluble alkalis may be contraindicated because of alkalosis they should be used with great caution, the neutral or tribasic powders may be used instead. Under such therapy, with regular lavage at 10 p. m., the spasm is usually relieved, the edema and congestion disappear, gastric compensation is restored, the volume of evacuation at night drops from over 1,000 cc to 200 cc or less, and the patient may be restored to an ambulatory state.

If there is, however, a considerable degree of organic stenosis due to pyloric fibrosis and hypertrophy, while all the symptoms may be relieved the night volume of evacuation may remain large. The persistence of retention of a large quantity after ten days usually means marked obstruction. The patient must choose between continuing the regular emptying at night by stomach tube and submission to surgical treatment. Mechanical relief is advisable.

It is pertinent to point out here, however, that the degree or permanence of the obstruction cannot be determined by one x-ray examination. Only by repeated visualization after treatment and by noting the amount of the day's retention, after emptying the stomach at night, can one be certain of this. Retention alone is not evidence of organic obstruction, because lack of peristalsis may cause complete retention. Migraine headaches, worry and fatigue may stop peristalsis and cause such retention.

HYPERSECRETION

Hypersecretion, with its typical accompaniment of nocturnal pain and the duodenal syndrome, is practically always associated with the circumstances described in the discussion of obstruction. Duodenal ulcer and obstruction of some type are the usual causes, but now and then one encounters an unusually "hyper-tonic" person with marked peristalsis, a neurotic make-up and excessive pylorospasm who exhibits functional influences to a marked degree without much evidence of six hour retention of barium sulfate. In such a case, rest in bed, management of the ulcer, evacuation by tube at night and liberal use of derivatives of belladonna and sedatives are necessary for control.

PERFORATION

Peptic ulcers perforate or break through the parietal peritoneum in various ways. Perforations are designated acute, subacute or chronic. The first type is sudden and dramatic, the last is insidious and hardly recognizable clinically.

Acute Perforation—Probably no other disease develops with such dramatic suddenness as does acute perforated ulcer. In the series of 575 cases of peptic ulcer there were twenty-one acute perforations, or 4 per cent. Acute perforated ulcer presents one of the most definite and classic clinical pictures in medicine. There is the first stage, shock, of one or two hours' duration characterized by sudden agonizing abdominal pain and boardlike rigidity, immobility of the patient, vomiting, subnormal temperature and other signs of shock. The second stage, reaction, follows, lasting from two to

twelve hours. The pain lessens, the pulse improves and the temperature comes back to normal, but the abdominal rigidity remains the same, tenderness increases, diminishing hepatic dulness and signs of pneumoperitoneum may be noted, and by x-ray examination an air bubble under the diaphragm may be discovered. The third stage, peritonitis, supervenes. There are a rapid, shallow pulse, fever, thirst and dehydration. Paralytic ileus with meteorism is evident. The hippocratic facies, cyanosis and lividity and other evidences of circulatory failure develop, and death follows in from two to five days. If the patient is first seen in the reactionary period, the signs may be confusing and the diagnosis difficult.

This outline summarizes the signs and symptoms from onset to general peritonitis unless surgical intervention is secured in the early hours of the catastrophe.

Vomiting is common with gastric perforation but occurs with only about 25 per cent of duodenal perforations. Pain often occurs at the top of one or both shoulders.

Immediate surgical intervention is imperative for such a condition, and the mortality should not exceed 5 per cent in patients operated on within eight hours of perforation. After eight hours the mortality rises rapidly.

The San Francisco Emergency Service considers these patients excellent risks if operated on within ten hours, irrespective of the type of anesthesia used. In a series of 155 patients, thirty-eight were operated on more than ten hours after the onset, with a gross mortality of 64 per cent.

Subacute Perforation—In our series of 575 cases of ulcer, subacute and chronic perforation occurred in ninety-two, or 16 per cent. Although subacute perforation presents symptoms identical with those of acute perforation, they are less intense. The shock is less. The temperature is not subnormal. From the first the rigidity and tenderness are most marked in the neighborhood of the ulcer, and after some hours they generally become localized in the right upper quadrant, simulating the signs of acute inflammation of the gall-bladder, for which the condition is often mistaken. No symptoms of general peritonitis develop, but a localized abscess may form later.

All this means, of course, that the perforation is protected. Generally it is at once plugged by a tag of omentum, or fibrin may begin to form outside the ulcer before perforation is complete, so that a protective layer is present to cover the hole as soon as it appears.

Usually if the patient is starved and kept quiet all the symptoms subside and in twenty-four hours he is fairly comfortable, although local pain and tenderness and a certain amount of rigidity may persist for days and even continue until a local abscess is drained. If this is present it should be allowed to wall off first. It is usually best not to operate unless later developments indicate the need clearly.

Chronic Perforation—Chronic perforation occurs only in cases of old, chronic ulcers, and it is often very difficult to tell whether one is dealing with only a deep crater or penetration into the wall of the viscus or whether the ulcer has completely passed through the organ, with a walled off perforation beyond.

Statistical figures show that there are about twice as many chronic as acute and subacute perforations of peptic ulcer. Probably from 8 to 12 per cent of all chronic ulcers develop into chronic perforation. These

perforations are located at the lesser curvature or near the pylorus, and are shown by x-ray examination as canals, buds or pouches

The clinical picture is recognizable only as intractable or unimproved ulcer, although there may be slight evidence of some localized peritonitis or more rarely a deep abscess

Roentgenograms are the only diagnostic resource with any degree of certainty, and even with them a deep crater or penetration without perforation is difficult to differentiate from actual slow perforation. In chronic perforation there is a leisurely destruction of the coats of the stomach or duodenum, and by the time the peritoneum is penetrated the site is protected by lymph, fibrin and adhesions, so that general peritonitis rarely occurs and only occasionally a sub-diaphragmatic or other type of local abscess. The treatment is usually medical or whatever is needed for the type of chronic ulcer found

I have never felt the size or location of a crater should be accepted categorically as an indication for or against surgical treatment rather than medical treatment. The merits of the situation must be studied individually, but I believe the axiom can be laid down that whatever the treatment for peptic ulcer the results, to be satisfactory, must afford complete relief of the symptoms in a short time and that if distress continues the procedures being followed immediately be challenged or disastrous progression will continue

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
HOWARD A CARTER Secretary

BURDICK SWD MAGNETHERM ACCEPTABLE

Manufacturer The Burdick Corporation, Milton, Wis

The Burdick Magnetherm is a combination two frequency deep wave apparatus intended for medical and surgical diathermy. The 25 meter electromagnetic induction circuit is used with a 12 foot cable for medical purposes. A long wavelength, 70 meter, circuit is supplied for electrosurgical procedures such as cutting, coagulating, desiccating, and under-water cutting.

Burdick SWD
Magnetherm

It may also be utilized with metal electrodes for conventional diathermy. The unit is available without the 70 meter circuit. The cabinet is made of furniture steel with chrome-plated handles. The upper part of the Magnetherm may be lifted from the base to form a portable unit. The shipping weight is 150 pounds.

The oscillator uses two large size tubes in a push-pull Hartley circuit. The plate voltage transformer has two balanced secondary coils providing full wave rectification of the 60 cycle line supply. A filament voltmeter is calibrated with a special dial to indicate the proper tap on the plate transformer to correspond to the prevailing line

supply. It is tapped for line voltage variations from 105 to 125 volts. There is a separate transformer for filament supply and filament voltage. The latter is kept within proper limits, as indicated by filament meter, by means of a continuously variable control on panel.

The surgical circuit has its own control panel with three outlets and controls "Inactive", "Coagulation" and "Dissection". The coagulation current output is controlled by a switch giving three intensities of current.

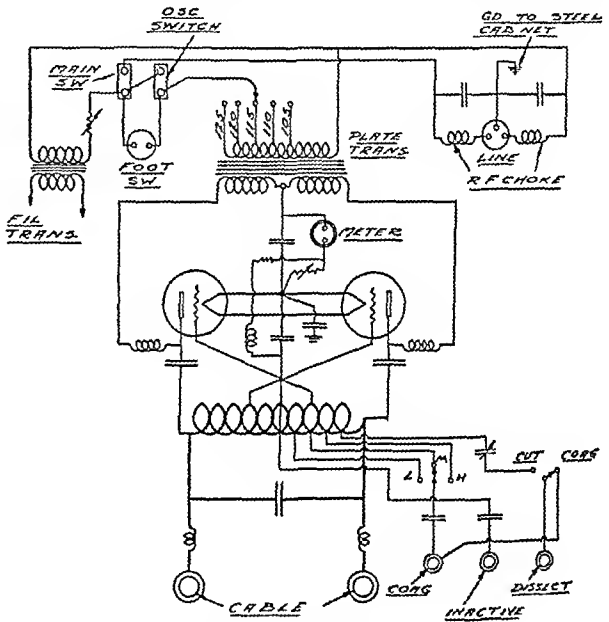

The input, when the machine is operating at full output, is 870 watts, 94.5 per cent power factor at 115 volts. Since no

reliable method has been devised for measuring output energy available to the patient, this value is not given.

It is licensed under patent Nos 1,377,405, 1,452,339, 1,507,016, 1,507,017 by the Electrical Research Products Company.

The transformer temperature rise and the rise within the cabinet taken at various levels come within the limits of safety prescribed by the Council. Burns are possible with this unit as with any other short wave machine but may be avoided by the use of proper precautions.

The firm furnished evidence with regard to the heating ability of the unit when applied to the thigh of living subjects. A reliable investigator tested the Magnetherm with coil technique, making six observations to determine its ability to produce deep heat. Two vigorous male medical students, weighing 180 and 198 pounds respectively, were the subjects for the experiments. A trocar placed in a hard rubber cannula was inserted into the thigh, perpendicular to the femur and directed through the muscular layers for a depth of 2 inches or until the bone was encountered. The trocar was removed, the rubber cannula being left in place. Temperature measurements were then taken

Schematic diagram of circuit

with a hypodermic needle thermocouple introduced through the cannula. A Leeds and Northrup Portable Potentiometer was used to measure the difference in temperature of the junctions. The thermocouples were calibrated in degrees Fahrenheit against a Bureau of Standards certified thermometer. Initial temperatures were taken and then each subject underwent a twenty-minute application of the maximum current intensity consonant with skin comfort. At the end of this period, readings were again taken until the temperature began to drop. The highest temperature was recorded as the final temperature in each instance. Oral temperatures were also recorded.

Averages of Six Observations Coil Technique

Deep Muscle		Oral	
Initial	Final	Initial	Final
98.6	105.1	98.6	98.9

Four turns of the cable were wound around the thigh with a one-half inch thickness of felt for spacing and each coil approximately 2 inches from the adjacent one. The averages of the six tests are given.

The unit was tried out in a clinic acceptable to the Council. It was found to be satisfactory. It was also employed in various electrosurgical procedures and found to give efficient service.

In view of the favorable report on the Burdick SWD Magnetherm both for general heating and for electrosurgical techniques, the Council on Physical Therapy voted to include this unit in its list of accepted devices.

Council on Pharmacy and Chemistry

PRELIMINARY REPORT OF THE COUNCIL

THE LEGERLE LABORATORIES PRESENTED FOR THE COUNCIL'S CONSIDERATION ITS ANTIPNEUMOCOCCIC SERUM CONTAINING ANTIBODIES OF TYPES V AND VII PNEUMOCOCCI. AN ASSOCIATE OF THE COUNCIL'S REFEREE MADE A STUDY OF THE EVIDENCE WHICH IS CONTAINED IN THE FOLLOWING STATEMENT. AS A RESULT OF THE ASSOCIATE'S STUDY THE COUNCIL VOTED TO POSTPONE CONSIDERATION OF THE LEGERLE PRODUCT TO AWAIT DEVELOPMENT OF FURTHER CORROBORATIVE EVIDENCE. THE COUNCIL AUTHORIZED PUBLICATION OF THE FOLLOWING PRELIMINARY REPORT.

PAUL NICHOLAS LEECH, Secretary

REFINED AND CONCENTRATED ANTI-PNEUMOCOCCIC SERUM, TYPES V AND VII-LEDERLE

TYPE V

Finland and Tilghman¹ observed ninety-three cases of type V pneumococcus pneumonia in patients over 12 years of age from June 1, 1935, to July 1, 1936, the specific organism being identified in the sputum or by blood culture. Twenty-six of these patients were treated with serum varying in potency from 2,500 to 5,000 units per cubic centimeter, beginning in no case later than four days after onset, and four of those treated with serum died. During the same period sixty-seven cases were treated without serum because serum was not available, the disease was of more than four days' duration or there already was evidence of recovery, and of these patients not treated with serum twenty-six died. Of 130 patients not treated with serum during six years previous to the period of study, sixty-nine died. The mortality of the serum-treated patients was therefore approximately one-third that in those receiving no serum. Apparently even more significant was the favorable effect of the serum on the clinical course of the disease, since changes similar to those of spontaneous crisis seemed to follow serum treatment with fair regularity.

Bullowa and Wilcox² divided their cases into two groups, those observed from 1928 to 1933 and those observed from 1933 to 1936, the average unitage of the serum used in those periods being 782 and 3,163, respectively. In the earlier group the mortality in twenty-six cases treated with serum was three, and in 108 cases treated without serum it was twenty-three, while in the latter group the mortality in forty-one cases treated with serum was two and in fifty-five cases treated without serum it was eleven. Of seventeen bacteremic patients treated with serum four died, while of forty-three bacteremic patients treated without serum twenty-six died. The mortality rate was therefore approximately half that of the controls in the earlier series and one fourth in the later series. The clinical observations indicated clearly that the duration and severity of the disease was lessened by serum treatment.

The combined mortality statistics of the two reports and more particularly the favorable effect on the clinical course of the disease indicate that type specific serum is a valuable therapeutic agent in the treatment of type V pneumonia.

TYPE VII

Finland, Rueggsegger, Dowling and Tilghman³ observed 160 cases of pneumonia from Nov. 1, 1929, to June 30, 1936, in which type VII pneumococci were identified in the sputum. In sixty-seven of the cases type VII pneumococci were obtained from the lung, blood or pleural fluid as well as from the sputum and in thirty-eight of the remaining ninety-three cases in which the sputum was the only source of the pneumococcus a second specimen was positive usually one or more days later. Thirty of the 160 cases were treated with serum and three were fatal.

1 Finland, Maxwell and Tilghman. R. C. Clinical and Immunological Observations in Cases of Pneumococcus Type V Pneumonia Treated with Specific Antibody. New England J. Med. 215: 1211 (Dec. 24) 1936.

2 Bullowa, J. G. M. and Wilcox, Clare. Therapeutic Serum for Pneumococcus Type V (Cooper) Pneumonia. J. Clin. Investigation 15: 711 (Nov.) 1936.

3 Finland, Maxwell, Rueggsegger, J. M., Dowling, H. F. and Tilghman, R. C. Infections with Pneumococcus Type VII. Am. J. M. Sc. 193: 48 (Jan.) 1937.

while of the 130 cases treated without serum fifty were fatal. In cases in which recovery occurred, the mean duration of illness was five days when serum was used and eight days when it was not used.

The same authors⁴ gave a more detailed analysis of the thirty serum-treated cases of this series and showed that definite clinical improvement consistently followed serum treatment except under well defined conditions. The three cases resulting in death were complicated, respectively, by (1) mastoiditis and late treatment (ninth day), (2) delirium tremens, pericarditis and cardiovascular syphilis, and (3) pulmonary tuberculosis. Immunologic studies indicated that a presumably significant balance of agglutinins and mouse protective substances was established and maintained in the blood of the patients by serum therapy.

Bullowa and Greenbaum⁵ observed type VII pneumococcus pneumonia during the seven years 1928-1935 in 218 patients, of whom fifty-one were treated with serum. Excluding three fatalities because of complications from the group treated with serum and three fatalities for the same reason from the group treated without serum, 62 per cent died when serum treatment was used and 171 per cent when it was not used. Of the bacteremic patients, one died of four treated with serum and twelve died of seventeen treated without serum.

Although the mortality rates of the serum-treated cases are favorable, the alteration in the clinical course of the disease should be regarded as a more significant indication of the therapeutic value of specific serum in the treatment of type VII pneumococcus pneumonia.

COMMENT

Although the volume of information now available regarding the use of antipneumococcus serum types V and VII is, of course, much smaller than that for types I and II serums, the author's observations apparently have been made with care and the evidence is qualitatively approximately as favorable. As nearly as can be determined from the clinical response, the potency of the types V and VII serum used in these studies has reached a level comparable to that of types I and II serums now available commercially. The product has the disadvantage that serum reactions are encountered, but they apparently were not more frequent than have been encountered in the use of types I and II serums and were not of sufficient frequency and severity to contraindicate its use. On the whole, there apparently is reasonable evidence that types V and VII antipneumococcus serum are valuable therapeutic agents and that their value is comparable to serums now being used in the treatment of types I and II pneumonias.

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary

ANTIPNEUMOCOCCIC SERUM, TYPE I (See New and Nonofficial Remedies, 1937, p. 381)

E. R. Squibb & Sons, New York.

Antipneumococcus Serum Type I (Refined and Concentrated)—An anti-pneumococcus serum prepared according to the method of Lloyd D. Felton. Marketed in syringes containing 10,000 units and in syringes containing 20,000 units of the type I pneumococcus.

CAFFEINE WITH SODIUM BENZOATE (See New and Nonofficial Remedies, 1937, p. 153)

The following dosage form has been accepted:

Ampoules Caffeine with Sodium Benzoate 2 cc.—An aqueous solution containing in each 2 cc. caffeine with sodium benzoate U. S. P. 0.5 Gm. (7½ grains).

Prepared by Abbott Laboratories, North Chicago, Ill.

SATURDAY, SEPTEMBER 11, 1937

VENEREAL LYMPHOGRANULOMA

Since the etiology of the disease described by this title is distinctly and definitely venereal, the term venereal lymphogranuloma is to be preferred to the numerous other eponyms or descriptive names that have been applied. The most common of the latter, which should now be relegated into the background and should be of interest only from the historical point of view, are lymphogranuloma inguinale, syphilitic bubo, Durand, Nicolas and Favre disease, climatic bubo, non-tuberculous granuloma, granulomatosis lymphatis and tropical bubo. The avoidance of the confusion caused by this unnecessary multiplicity of terms is now especially important in view of the great extension of the disease, which is spread over every quarter of the globe and is found along the coasts of Africa, in the two continents of America and in Asia, as well as in Australia.

The disease is probably due to a virus, but the specific agent has not as yet been identified with any great certainty. The greater part of the detailed investigations on this subject have been, according to Hellerstrom,¹ without result. Several investigators have been able to demonstrate the presence of microorganisms—usually differing in character with each investigator. The bacteria which have been reported most frequently are the pseudodiphtheria bacilli. From the standpoint of animal experiments, the only result gained by the attempts to transmit the disease to animals is the certainty that venereal lymphogranuloma has nothing to do with tuberculosis. This aspect of the etiology, therefore, awaits definite proof. Certain it is, however, that the disease is truly venereal and is spread by sexual congress. The period of incubation before the appearance of the primary lesion has been estimated, according to Prehn,² at from three to seven days. In patients with a positive Frei reaction the

period of incubation was from two to nine days. Frei and Hofman, however, according to Hellerstrom, distinguish between two periods of incubation, the one extending from the time of the infecting coitus to the appearance of the primary lesion and the other from the coitus to the first demonstrable swelling of the lymphatic glands. The first of these periods, in Hellerstrom's cases, has varied from a few days to approximately three weeks but for the most part was about two weeks, the second averaged about two weeks and varied from about ten days to a month or even longer.

The pathologic anatomy of the disease as described by Hellerstrom, and based on twenty-eight of his forty-seven cases, is quite characteristic. Macroscopically, the extirpated glands consist of conglomerations, with the cut surface in many instances of a red to violet tinge. Abscesses are sometimes observed, even macroscopically. The microscopic examination of the glands discloses the picture of a subacute or subchronic lymphadenitis, a typical description of which, he states, is as follows: "The highly fibrously altered gland is larded with numerous larger or smaller, round, oval or ramified abscesses, surrounded by narrower or broader zones of epithelioid cells, frequently arranged in palisade form. In addition, the gland is as good as completely filled with a granulation tissue consisting of lymphocytes, plasma cells, fibroblasts, epithelioids and fairly large cells, with one or two round or oval, highly colorable nuclei, together with a few medium large giant cells of Langhans type, which are usually situated at the edge of the border of epithelioid cells." Other descriptions conform in the main to that of Hellerstrom. Phylactos distinguishes four clinical types, a grouping which has been followed by Hellerstrom, namely, an ulcerous type, a nodular form, a papulous form and a specific urethritis. This classification is further modified by Wien and Perlstein,³ who reported three cases which illustrated various types of clinical ulceration that may occur in venereal lymphogranuloma: ulceration of the skin only (lymphitis), ulceration of the skin secondary to a previous lymph gland involvement, and ulceration developing on an existing esthiomene. The general symptoms are almost constant and consist of fever, anorexia, emaciation and a feeling of general weakness. After the adenitis has existed for some time, the temperature is usually subfebrile.

The most valuable diagnostic and differential diagnostic sign is the Frei intracutaneous test. Qualified opinion is almost unanimous in accepting this procedure as a reliable diagnostic criterion, although there is some difference of opinion as to the most satisfactory antigen to use in the test.⁴ Thus all of Hellerstrom's forty-seven patients reacted positively to Frei's test carried

Howard M E and Strauss M J. Influence of Serum on Frei Test. Arch Dermat & Syph 34 816 (Nov) 1936.

out with seven different antigens. In more than 60 per cent of Hellerstrom's cases, the intracutaneous test was carried out within a period of from one week to two months after the adenitis had been observed. Since not all strumous buboes are venereal lymphogranuloma, the specificity of the Frei test is of exceptional importance.

Opinions with regard to therapy are numerous and conflicting. Since the disease has a considerable tendency to spontaneous healing, the results of treatment must be judged conservatively. Although many drugs have been used in treatment, the results as yet remain uncertain. Hellerstrom believes that the course of the disease can be shortened considerably by early operative measures aimed at total enucleation of the involved lymph glands. Various tartrates (Hellerstrom) and the intracutaneous administration of graded doses of potent Frei antigen every other day for at least eight doses injected near the site of the lymphadenitis² seem to offer the most promising of the nonsurgical treatments. Although the prognosis as to life is good, the usual lengthy course of the disease and the apparent increase of its incidence and distribution necessitate continued investigative effort aimed at more adequate control.

CERVICAL RIB AND SCALENUS ANTICUS SYNDROME

Descriptions of supernumerary cervical rib may be found in the writings of Galen and Vesalius. In 1860 Willshire described symptoms produced by the pressure of the cervical rib on the brachial plexus and the subclavian artery. Because the vertebral column in the embryo grows faster than the spinal cord, the nerves and plexuses issuing from the latter must assume an oblique course in order to reach the extremities. They thus interfere with the growth of the ribs. Consequently the ribs in the new-born come to be represented in the cervical region by the transverse processes of the vertebral bodies. The supernumerary cervical rib may therefore be regarded as a developmental anomaly. It springs as a rule from the seventh cervical vertebra but may occasionally arise from the sixth or the fifth. The rib may extend just beyond the transverse process of the vertebra or even touch the first rib, it may reach the cartilage of the first thoracic rib as a fibrous band or even as a true cartilage. If the rib attains sufficient length the brachial plexus and the subclavian artery may be compressed in the angle formed by the rib and the scalenus anticus muscle, giving rise to nervous and circulatory disturbances.

The incidence of cervical ribs is variably given as between 0.03 and 0.1 per cent. When they are present, from 67 to 80 per cent are bilateral. Two supernumerary ribs on the same side have been reported only three times. Adson and Coffey¹ state that cervical rib is found more often on the left side but that symptoms

are more common on the right. The reason, they believe, is the greater use of the right arm, because the right plexus is in closer connection with the corresponding rib than the left, and because there is a greater drop of the right shoulder in right-handed persons. The classic clinical syndrome is met much oftener in women than in men. In reviewing the histories of a series of 540,413 patients registered at the Mayo Clinic between 1910 and 1926, Adson and Coffey found 303 cases in which cervical rib was diagnosed, an incidence of 0.056 per cent. There were eighty-four males and twenty-nine females. X-ray examination revealed a cervical rib on the right side in seventy, on the left in ninety-one, and bilaterally in 143. In 167 (55 per cent) the presence of cervical ribs was symptomless and was discovered accidentally. In 100 the symptoms were mild and of such a character that surgical treatment was inadvisable. Operation was performed in thirty-six cases. Among these there were eleven males and twenty-five females.

The most prominent symptom is pain, which may be felt in the shoulder, in the supraclavicular fossa or along the ulnar aspect of the forearm. When characteristic, it is aggravated by rotation of the head toward the affected side or by a downward pull of the shoulder. There may be various disturbances of sensation, such as hyperesthesia, paresthesia or anesthesia. Atrophy of the small muscles of the hand, of the ulnar or median type, may likewise be present. The nervous manifestations are those of involvement of the first thoracic and the seventh cervical roots and of the lower cord of the brachial plexus, although occasionally the entire brachial plexus may be involved. The circulatory disturbances are rarely severe and may be absent. The most characteristic sign of the compression of the subclavian artery is the diminution of the pulse volume on the affected side. Other vascular manifestations consist of decrease in surface temperature, numbness, coldness and formication, mild trophic changes in the tips of the fingers and, rarely, gangrene of one or more fingers.

A contribution to both the genesis of the symptoms and their surgical relief was made by Adson and Coffey¹ when they found that severance of the scalenus anticus muscle from its insertion into the rib caused immediate relief of pressure and irritation from the brachial plexus and the subclavian artery. They operated on four patients, dividing the tendinous attachment of the scalenus anticus muscle without removing the existing cervical rib. Symptoms were completely relieved in all instances. This demonstration of the importance of the scalenus anticus muscle accounts for the development of the symptoms in adults and its rarity in children. It also explains the greater frequency on the right side and the production of paresthesia and obliteration of the pulse at the wrist on elevation of the chin or extension or rotation of the neck toward the affected side.

¹ Adson, A. W. and Coffey, J. R. Cervical Rib. *Ann. Surg.* 85: 839 (June) 1927.

The fact that an identical syndrome of brachial plexus and subclavian artery compression occurs in the absence of a supernumerary cervical rib led many observers to believe that the anatomic relation of the first thoracic rib to the subclavian structures was responsible. Abnormally high position of the first rib with regard to the subclavian structures or abnormally low descent of the shoulder with a resulting pull on the plexus could furnish the mechanical conditions necessary. Thus Todd believes that the cervical rib syndrome occurs more frequently in females than in males because the descent of the shoulder is greater in the female, owing to lack of development of the suspensory muscles of the shoulder, especially the trapezius. The rectus abdominis muscle, being relatively poorly developed in the female, exerts less pull on the sternum, causing early high fixation of the anterior extremities of the clavicle and ribs. Jones believed that the symptoms occurred only in cases in which a considerable portion of the lower cord of the brachial plexus is derived from the upper thoracic segments of the cord, symptoms being due to compression and strangulation of these nerves over the first thoracic or cervical ribs. Naftziger, according to Ochsner, obtained complete relief in two cases with cervical rib syndrome without the rib by performing a scalenotomy as advocated by Adson and Coffey. Carrol reported two cases of cervical rib syndrome without cervical ribs and obtained complete relief of symptoms in one case by operation of scalenotomy. Ochsner, Gage and DeBakey² observed six cases with typical symptoms of compression of the brachial plexus and the subclavian artery in the absence of a cervical rib. All were in females. Four of the patients were operated on by resection of the lower portion of the scalenus anticus muscle, with complete relief. Ochsner suggests that the scalenus anticus syndrome is a definite clinical entity, the symptoms of which are identical with those of cervical rib. The symptoms are the result of compression of the brachial plexus and subclavian artery on the first thoracic rib. This compression may be due to abnormally low position of the shoulder, to high fixation of the sternum and ribs, to low origin of the brachial plexus and to elevation of the first thoracic rib due to spasm of the scalenus muscles, resulting from brachial plexus irritation. The first three conditions are predisposing, whereas the last is an exciting factor. The original contribution made by Ochsner is that irritation and stimulation of the brachial plexus by pressure of the first rib causes spasm and shortens the scalenus anticus muscle, resulting in elevation of the first rib, thus establishing a vicious circle.

Craig and Knepper³ point out that resection of the scalenus anticus muscle will relieve symptoms in cases in which cervical ribs cannot be demonstrated and that

in the presence of a cervical rib without tendinous attachment to the first rib scalenotomy is all that is necessary. Only in the cases in which there is evident pressure from the cervical rib or its tendinous attachment does removal of the rib become necessary. They report six cases requiring operative intervention for pressure symptoms, in three of which cervical ribs were not present, in two of which there were bilateral ribs, and in one of which there was a large right cervical rib. Relief from pressure on the subclavian structures in the first five was obtained by scalenotomy, while in the last case the cervical rib was removed because of the evident pressure on the brachial plexus and the subclavian artery.

Current Comment

SEED AND POLLEN SENSITIVITY

It seems evident from the recent studies of Farmer¹ that there is an organ-specific difference in plants from the point of view of allergic properties. He found that patients who were highly sensitive to aqueous extract of timothy, orchard grass or rye pollen often show no trace of cutaneous sensitivity with the aqueous extracts of the homologous seeds. Although at least half of the chromosomes are apparently identical in both pollen and seeds of the same plant, these observations suggest a complete divergence in protein specificity. Although Farmer has not formulated any biologic or chemical theory to account for this phenomenon, the observations are already of some practical clinical importance.

THE SEDIMENTATION RATE IN RHEUMATIC INFECTION

The urgent need for a reliable clinical method for determining the presence and degree of rheumatic infection in patients, particularly children, is generally recognized. As there is an increased rate of sedimentation of erythrocytes in certain severe infections, several investigators have studied the phenomenon in patients with rheumatic manifestations. The results of these studies, while suggestive, have not been convincing because of the lack of sufficient numbers of cases. Recently, however, the problem has been reinvestigated in a group of 140 children with rheumatic infection entering the Children's Memorial Hospital in Chicago.¹ At the time of admission the erythrocyte sedimentation rate and the complete blood count and Schilling differential count were determined by standard procedures. A general examination of the patient was also made, particular attention being paid to the detection of swollen or tender joints, annular erythema, cardiac damage and chorea. The results of the study, grouped according to the diagnosis, were rather striking. Chorea was the only rheumatic manifestation in which a normal sedimentation rate was found. Active rheumatic infection was characterized by a rapid sedimentation rate, this being equally true whether the arthritis or carditis

² Ochsner A, Gage M and DeBakey M. Scalenus Anticus (Naftziger) Syndrome. *Am J Surg* 28: 669 (June) 1935.
³ Craig W, McK. and Knepper P. A. Cervical Rib and the Scalenus Anticus Syndrome. *Ann Surg* 105: 556 (April) 1937.

¹ Farmer Laurence. *J Allergy* 8: 338 (May) 1937.
¹ Clifton W. M. The Rate of Sedimentation of the Erythrocyte in Rheumatic Infection in Children, *Am J Dis Child* 52: 1093 (Nov) 1936.

occurred alone or was accompanied by chorea. Acute pericarditis as a part of rheumatic carditis was accompanied by an extremely rapid sedimentation rate, and increased rates were observed also in patients with rheumatic nodules and with annular erythema during the period of activity of the infection. Only in cases of active rheumatic infection complicated with congestive heart failure and a resulting extreme degree of venous stasis was a normal sedimentation rate observed. Even in the normal subject, however, venous stasis tends to decrease the rate of erythrocyte sedimentation. In all instances there was a uniform decrease in the values toward normal with the subsidence of the infection and the disappearance of the clinical symptoms. The decrease in sedimentation velocity to normal, however, occurred two weeks or more after the clinical manifestations had disappeared, whereas the Schilling differential count tended to parallel the clinical course. For this reason the authors believe that the sedimentation test is more reliable than the Schilling differential count in determining the activity of the rheumatic process. These results add further support to the view that the rate of sedimentation of the erythrocyte may serve as a reliable diagnostic and prognostic measure in determining the activity of rheumatic infection.

GRANTS TO STATES UNDER TITLE V, SOCIAL SECURITY ACT

Under title V of the Social Security Act, federal grants are made available to the states for the conduct of maternal and child health work, services to crippled children, and child welfare services. The maternal and child health services are administered within the states by the several state boards of health, the crippled children's work by various state agencies according to the laws in the several states, and the child welfare services through state departments of social welfare. The United States Children's Bureau is charged with the administration of federal funds, the approval of state plans for their use, and the certification of payments to be made to the states under the act, through the United States Treasury Department. The Children's Bureau has furnished *THE JOURNAL*¹ with the following figures as to the actual grants to the states for the fiscal year ended June 30, 1937:

Grants to States		States † Participating	Payments
	Federal Funds Available *		
Maternal and child health services	\$4 379 849 40	51	\$2 989 014 72
Services for crippled children	3 527 675 98	45	2 011 606 04
Child welfare services	1 823 017 08	45	969 827 23

* Including balances available from 1936 allotments.

† Including Alaska, the District of Columbia and Hawaii.

Since July 1 the Hawaii and South Carolina plans for child welfare services for the fiscal year 1938 have been approved, giving a total count of forty-seven participating in grants for child welfare services.

The figures given represent participation of forty-seven out of fifty-one state and territorial units entitled to federal subsidies under the program of child and maternal health, crippled children's services and child welfare authorized by the Social Security Act. Physicians whose practice is related to all the activities arising out of the expenditure of these funds should keep well

informed through state and local medical societies. The Children's Bureau has expressed frequently the desire to have the counsel of the medical profession. A general advisory committee to the Children's Bureau includes many physicians, and an official representative of the American Medical Association.

THE NATURE OF FATIGUE

Collier¹ provisionally defines fatigue as a state of the human organism in which there is a significant lack of balance between intake and output of biologic energy. This absence of harmony may exist between the organism and its environment or between the various subordinate parts within the organism itself. It is frequently manifested by deterioration of efficiency, feelings of tiredness, physiologic changes in the bodily organism (pulse rate, pulse pressure and so on) or as combinations of all these. It is not a disease, but it may be prodromal to disease. The human organism, he says, begins to suffer from fatigue whenever the available reserves required for any particular kind of activity have become dangerously depleted. The degree of the exhaustion of the reserves of energy of a part or the whole of the organism may be so profound that a brief rest serves only partially to restore those reserves. It is clear, however, that chronic morbid fatigue, even when it occurs among industrial workers, is not always due to the industrial activity. Neither illness nor fatigue is ever due to single isolated causes, but both are the outcome of a number of causes acting together. The diagnosis of morbid industrial fatigue is suspected by the experienced practitioner when faced with a patient who looks tired, whose eyes are heavy, who yawns, whose shoulders droop, who moves slowly and whose complexion is pallid. The individual usually complains of tiredness in the morning, saying that he sleeps heavily but is unrefreshed. The patient frequently suffers from headache and complains of vague pains in some part of his body. Differential diagnosis must take into account and exclude illness, normal tiredness and learning fatigue. After exclusion of these other disorders, if inquiry fails to reveal any reasonable explanation of fatigue from which the patient is suffering because of personal factors, a tentative diagnosis of industrial fatigue may be made. As soon as this diagnosis has been made it is necessary to be able to discover the actual (industrial) cause or causes of the fatigue in the particular group of workers. The latter may be roughly classified into conditions within the factory, composed of physical causes such as temperature, humidity, hours of work and exposure to industrial poisons, or to emotional components such as monotony of work, group harmony and psychologic fitness. Furthermore, industrial conditions operating largely outside the factory must be studied, including the regularity and adequacy of meals, the selection of personnel, night work and traveling to and from work. The problem of industrial fatigue is as important as it is complex. It requires an impartial scientific study in all its aspects by a team of trained specialists. Thus only will it be possible to abolish morbid fatigue from industry.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH)

ALABAMA

Health Department Activities—A full time health department has been organized in Choctaw County with Dr Herbert A McClure, Double Springs, as health officer. Dr McClure has been health officer in Winston County and has been succeeded in this post by Dr Thomas T Box, Double Springs. Choctaw is the fifty-ninth county in the state to establish a local health unit, leaving only eight unorganized counties, newspapers reported. Dr Albert S Dix, Mobile, has been named health officer of Jackson County, succeeding Dr George E Newton, formerly of Scottsboro, who was appointed to a similar position in Lauderdale County. Dr George E Maddison, Moncton, N B, has been appointed health officer of Monroe County, following the resignation of Dr Martie F Parker, Boaz, to begin the private practice of medicine. Dr Elihu F Sloan, Shannon, has been appointed in Shelby County, succeeding Dr Hugh C Nickson, formerly of Columbiana who also resigned to enter private practice. Dr Thomas M Towns, Clarence, has been appointed health officer of Blount County, succeeding Dr Samuel D Sturkie, Oneonta, who accepted a similar position in Calhoun County.

CALIFORNIA

Syphilis Survey of Volunteer Citizens—A serologic survey of 500 volunteer citizens was conducted by the San Francisco Department of Health, August 18, to determine the extent of syphilis in the city. For diagnosis only, the tests were conducted at the Central, Park, Harbor, Mission and Alemany emergency hospitals. Results of the tests will be reported later, the San Francisco *Bulletin* announced.

Course on Venereal Diseases—A special course on the handling of venereal diseases was begun at the University of California Medical Center, San Francisco, August 23, to continue for five weeks. It consists of ten sessions, the first two sessions devoted to bacteriology and pathology, the next three to the pharmacology of the drugs concerned, the next four to the practical clinical management and the final session to the public health aspects of the problem. There is no charge for the course, which is open to any qualified physician.

COLORADO

State Medical Meeting at Colorado Springs—The sixty-seventh annual session of the Colorado State Medical Society will be held at the Antlers Hotel, Colorado Springs, September 22-25 under the presidency of Dr Arthur J Markley, Denver. The program includes the following speakers:

Dr James P Rigg Grand Junction Nasal Hemorrhage Its Cause and Treatment
Dr Roderick J McDonald Jr Denver Erysipelas
Dr John R Evans Denver Short Wave Therapy in the Pelvis
Dr Clyde T Knuckey Lamar Respiratory Problems in the Dust Bowl
Dr Alfred R Masten Denver Tuberculosis Control in Colorado
Dr Wilford W Barber Denver Modern Infant Feeding
Dr Guy H Hopkins Pueblo Reading Defects in Children
Dr Clifford Lee Wilmoth Denver Inguinal Hernia
Dr Gerrit Heusinkveld Denver Some Toxemias of Late Pregnancy
Dr William P McCrossin Jr Colorado Springs Treatment of Pelvic Infections
Dr Thomas Leon Howard Denver Present Status of Urinary Bactericides
Dr Joseph Raymond Plank Denver Treatment of Intestinal Obstruction Its Chemistry and Physiology
Dr Kenneth D A Allen Denver Radiation Therapy of Selected Non-malignant Diseases
Drs James J Waring and William A H Retthberg Denver Sulfanilamide Clinical Trials
Dr Douglas W Macomber Denver Recent Developments in Plastic Surgery
Dr Casper F Hegner Denver Practical Approach to the Cancer Problem
Dr Roy L Cleere Denver The Changing Concept of Public Health
Dr Ralph H Verploeg Denver Differentiation of the Rash Producing Epidemic Diseases
Dr James Rudolph Jaeger Denver Intervertebral Disk Injury Its Relation to Sciatica and Intervertebral Neuralgias

A clinicopathologic conference will be conducted by the El Paso County Medical Society and guest speakers will include Dr Walter M Simpson Dayton, Ohio on 'Fever Therapy', Ruben G Gustavson, Ph D, Denver 'The Influence of Endo-

crine Secretions on the Etiology of Cancer,' and Dr Arno B Luckhardt, Chicago, 'Academic or Unsuccessful Research'. The guest speakers will also conduct round table discussions. At the annual banquet, Saturday evening, Hon Haslett P Burke, chief justice, supreme court of Colorado, will give an address entitled 'A String of Pearls'.

DISTRICT OF COLUMBIA

Annual Alumni Extension Course—The second annual alumni extension course of Georgetown University School of Medicine will be held September 13-17 at the university, Washington. There will be general sessions and clinics in various branches of medicine and the specialties. Guest speakers will include:

Dr Maurice C Pincoffs professor of medicine University of Maryland School of Medicine Baltimore
Dr Irving S Wright assistant professor of clinical medicine New York Post Graduate Medical School and Hospital New York
Dr Irvine H Page Rockefeller Institute for Medical Research New York
Dr Sanford M Rosenthal National Institute of Health Washington

A feature of the course on obstetrics will be an address by Dr Emil Novak, associate professor of obstetrics, University of Maryland School of Medicine, Baltimore, entitled 'Endocrinology as Related to Obstetrics and Gynecology'. Entertainment will include the annual banquet and golf tournament.

FLORIDA

Malaria Study Course—A course for malaria study opened August 2 at the Florida State College, Tallahassee, for public health workers and engineers, newspapers announce. Said to be the first of its kind ever given in the United States, the course is one of four being conducted in different parts of the country by the U S Public Health Service. In Tallahassee it is given in cooperation with the station for malaria research, which has been maintained on the state college campus for six years by the Rockefeller Foundation and the state board of health. According to the report, other parts of the instruction are offered at the Henry Carter Memorial Laboratory, Savannah, Ga., the U S Bureau of Entomology Laboratory, Orlando, and the Tennessee Valley Authority, Wilson Dam, Ala. Dr Louis L Williams Jr, Washington, D C, is in immediate charge, Dr Mark F Boyd, director of the malaria research station, local supervisor, and Dr Charles M McGill, U S Public Health Service, administrative officer in charge of students. The course will continue through September.

GEORGIA

Personal—Dr Thomas F Abercrombie, Atlanta, was guest of honor at a dinner at the Capital City Club, August 11, to celebrate his completion of twenty years as state health officer. He was presented with a gold watch by the assistant state health officer, on behalf of the staff of the health department. —Dr Thomas O Vinson, Macon, formerly assistant health officer in Bibb County, has been appointed health officer of Spalding County.

New Cancer Facilities—A new clinic for the treatment of cancer has been made possible at Emory University Hospital, Emory University, by a recent donation, newspapers report. It covers the ground floor of one wing of the hospital and is equipped with the latest facilities in the treatment of cancer. Dr James Elhott Scarborough Jr, formerly of Mount Willing, Ala, is director of the new clinic, which, under the terms of the gift, will be a memorial to the late Robert Winship, an Atlanta business man.

IOWA

District Meeting—The first meeting of the combined Austin Flint-Cedar Valley Medical Society and the societies of the first, second and sixth districts of the Iowa State Medical Society was held at the Cedar Valley Hospital, Charles City, September 9. The following program was presented:

Dr Harold C Hahen Rochester Minn. Indications and Use of Sulfanilamide
Dr Myne G Peterman Milwaukee Convulsions in Childhood
Dr Elmer L Sevringhaus Madison Wis. Practical Endocrinology
Dr Jacob R Buchhinder Chicago Address in Surgery

KANSAS

Society News—A new county medical society has been organized in Barber County with Dr Joseph D Warrick, Kiowa, as president and Dr Kenneth R Grigsby, Medicine Lodge, secretary. —Dr Victor E Chesky, Halstead among others addressed the Golden Belt Medical Society in Manhattan, July 1, on 'The Heart in Relation to Thyroid Diseases'.

State Ophthalmologist Appointed—Dr Clifford J Mullen, Kansas City has been appointed state ophthalmologist for the Kansas Social Welfare Board. According to the state medical journal, this office, which is required by the federal social welfare board, will be part time and will consist mainly of administrative activities in the handling of assistance to the blind under the social security act. Dr Mullen graduated from Creighton University School of Medicine, Omaha, in 1923 and has practiced in Kansas City since 1930. He served as secretary of the Wyandotte County Medical Society in 1936.

KENTUCKY

State Medical Meeting at Richmond September 13-16—The annual meeting of the Kentucky State Medical Association will be held in Richmond, September 13-16, at the Eastern Kentucky State Teachers' College. Drs Irvin Abell, Louisville, President-Elect of the American Medical Association, and Arthur T McCormack, Louisville, president of the American Public Health Association, will be the guests of honor at the annual banquet Wednesday evening, at which Dr Henry W Cave, New York, will be the guest speaker. Dr Cave will give an address on "Chronic Ulcerative Colitis, with Special Reference to Surgical Management." Dr James A Ryan, Covington, will deliver the annual oration in surgery and Dr Asa W Nickell, Louisville, the oration in medicine. Among Kentucky physicians who will appear on the program are:

- Dr Morris Flexner, Louisville: Sulfanilamide
- Dr Charles N Kivanaugh, Lexington: The Role of the Electrocardiograph in Cardiac Infarction
- Dr Adolphus D Butterworth, Murray: Management of Eclampsia

LOUISIANA

Dr D'Aunoy Appointed Dean at Louisiana Medical Center—Dr Joseph Rigney D'Aunoy, professor of pathology and bacteriology, Louisiana State University Medical Center, and executive adviser, Charity Hospital, New Orleans, has been appointed dean, succeeding Dr Arthur Vidrine, resigned. Dr D'Aunoy graduated at Tulane University of Louisiana School of Medicine, New Orleans, in 1913. In 1933 he was awarded an honorary fellowship by the Gorgas Medical Society of New Orleans for his work on electrocardiography. In 1931, three years after he had been appointed superintendent of Charity Hospital, New Orleans, Dr Vidrine was made dean of the newly organized school of medicine of Louisiana State University. In 1936 he resigned his post at Charity Hospital to devote his full time to the medical school, where he was also professor of surgery. He graduated at Tulane in 1921. He will remain as professor of gynecology at the medical center.

MARYLAND

First State Owned Hospital for Negroes—The dedication of a group of three buildings for the care of feebleminded Negro children took place in Crownsville, Anne Arundel County, July 23. Erected at a cost of about \$283,000, the hospital is said to be the first state owned institution of its kind in Maryland. Equipped with 100 beds, half for boys and half for girls, the buildings were laid out so as to facilitate enlargement to care for 500 children. They are of the cottage dormitory type, connected by covered corridors. The unit is about half a mile from the Crownsville Hospital, the superintendent of which Dr Robert P Winterode is head of the division for feebleminded children. Twenty children were admitted July 26.

MASSACHUSETTS

New Surgical Building Completed—The new Dr John J Dowling Surgical Operating and Ward Building at the Boston City Hospital, named in honor of the late superintendent, was to be opened to patients the latter part of August. The ten story structure at the corner of Albany Street and Massachusetts Avenue, cost about \$1,300,000, will accommodate 300 patients. It contains twenty operating rooms, six on the seventh and eighth floors, one for eye operations on the second floor, two for first aid operations on the ground floor and the remaining ones for tonsil and adenoid, mastoid and x-ray operations. There are ten examining rooms, ten sixteen bed wards and the remaining wards are divided into two and four bed wards.

The amphitheater for lectures and meetings will accommodate 264 students. The building was begun two and one-half years ago, it was reported and was made possible with the assistance of a PWA grant. At the time of his death, July 10, 1935, Dr Dowling was medical director and superintendent of the Boston City Hospital.

MINNESOTA

Society News—Dr Roger L J Kennedy, Rochester, was elected president of the Northwestern Pediatric Society of Minnesota, August 21, at its annual meeting in Duluth and Dr Robert Rosenthal, St Paul, secretary-treasurer. Dr John M Adams, Minneapolis, addressed the society on "The Conservative Treatment of Appendiceal Peritonitis in Children."

Personal—Dr Francis E Harrington, health commissioner of Minneapolis, has been appointed a member of the Hennepin County Sanatorium Commission, succeeding Dr Solon Marx White. Recently newspapers reported that Dr Harrington had resigned as director of hygiene of Minneapolis schools and that Dr Malvin J Nydahl had been appointed to succeed him (THE JOURNAL, July 24, p 282). Later reports indicate that Dr Harrington will continue in this position and that Dr Nydahl will be assistant director.

NEW JERSEY

Maternal Welfare Program—The committee on maternal welfare of the Medical Society of New Jersey, in cooperation with the state department of health, has announced its program for 1937-1938. According to the plans, a field physician will be appointed in every county and adequate provision will be made for antepartum care and for hospitalization. Hospitals are to be open to general practitioners to attend their own cases subject to supervision by an obstetric staff and with rules for consultation in abnormal cases. The committee recommends regular conferences of maternal welfare groups with all physicians interested in obstetrics; this year the committee will on request send an experienced obstetrician to lead discussion at these conferences. It also urges investigation of every maternal death to check the diagnosis and cause of death. Free nursing delivery service and free consultation for the low wage group of patients and free consultation for midwives are also to be furnished. Other points in the program are refresher courses for physicians, a maternal welfare article each month in the state medical journal and continuation of statistical studies. Dr Arthur W Bingham, East Orange, is chairman of the committee.

NEW MEXICO

Fluorine Study—The state department of health and the chemistry department of the University of New Mexico are conducting a study of municipal water supplies for the presence of fluorine. Mottled enamel of the teeth, believed to be the result of drinking water containing fluorine, is known to exist in certain areas of the state.

Changes in State Health Department—Dr Elroy F McIntyre, Santa Fe, has been appointed state epidemiologist to succeed Dr Leonard A Dewey, who resigned to become state epidemiologist of Washington. Dr Frank W Parker Jr, formerly of Clovis, succeeded Dr McIntyre as health officer of the first district. A division of health education has been established in the department under the direction of Mr Charles M Cree.

NEW YORK

Interstate Meeting at Chautauqua—The Medical Society of Chautauqua County sponsored the sixth annual Interstate Medical Meeting at Chautauqua July 28. At the morning meeting there were addresses by Drs Winfield W Scott, Rochester on "Hematuria: Its Significance," Russell L Cecil, New York, "Influenza and the Common Cold" and Walter C Alvarez, Rochester, Minn "Abdominal Pain." In the afternoon the meeting was open to the public. Dr Cecil spoke on "The Plight of the Arthritic" and Dr Alvarez on "Nervous Indigestion."

Air Conditioning Test for Allergic Patients—A practical study of the effects of air conditioning on allergic conditions of the respiratory tract has been arranged by the chairman of the committee on public health of the Medical Society of the County of Erie. Three rooms of a model home on the main floor of the Electric Building, Buffalo, conditioned to a degree that pollen is almost entirely removed from the air, will be used for the study, which will last six weeks coinciding with the hay fever season. The rooms will accommodate twelve patients and nurses and attendants will be present. Applications of patients must be accompanied by a written recommen-

ation from the physician, limited to members of the society, and the patient agrees to report back to the family physician. A report will be presented at the October meeting of the society.

Court Decides Pledge to Hospital Must Be Paid—Payment of a pledge of \$7,200 made in 1929 to the Tioga County General Hospital, Waverly, was ordered in a decision by Supreme Court Justice Andrew J. McNaught, August 18. The decision held that there had been no misrepresentation in the solicitation of the subscription, as the defense had contended, that there was a consideration for the promise to pay, the consideration being that an x-ray room be constructed in memory of the donor's father, that there was a sufficient note or memorandum of the promise in the subscription card and the endorsement thereon, and that the hospital had a sufficient interest in and was in possession of the obligation on which the action was based to maintain its position and was a real party in interest. The record indicated that the donor canceled his subscription at the solicitation of another hospital, the judge's decision stated.

Society News—Drs. David M. Kydd and John H. Powers, Cooperstown, addressed the Otsego County Medical Society, Oneonta, recently, on "The Use of Protamine Insulin" and "Mandelic Acid in the Treatment of Infection of the Urinary Tract" respectively. Dr. Joseph H. Green, Rochester, addressed the Canandaigua Medical Society, recently, on "Differential Diagnosis of Chest Conditions by X-Ray."—At a joint meeting of the Wayne County bar and medical societies in Newark, June 22, Dr. Floyd S. Winslow, Rochester, spoke on malpractice.—At a recent meeting of the Orange County Medical Society in Newburgh the speakers were Drs. Harold H. Snyder, Newburgh, on "Tuberculosis of the Genito Urinary Tract", Ian G. Macdonald, Cornwall, "Tumors of the Neck" and David Tolmie, Tuxedo Park, "Amnesia-Analgesia in Labor."—Speakers at a meeting of the Medical Society of Washington County in Fort Ann July 6 included Dr. Harold A. Peck, Glens Falls, on "The Friedman Modification of the Aschheim-Zondek Test for Pregnancy."

New York City

Tuberculosis Hospitals Overcrowded—A recent survey of tuberculosis hospital service showed that the number of patients being cared for was 4,980 and the total normal capacity in the city's tuberculosis hospitals and wards in twenty-one public and private institutions was 4,578. In addition, the admission bureau of the department of hospitals has knowledge of 392 cases waiting for hospital care. The department now has in progress four building projects that will add 1,000 beds to the supply now available. They include 250 in a new children's building at Sea View, Staten Island, 150 in new wards at Bellevue Hospital, a hospital adjoining the new Queens General Hospital for 500 patients, and a project for more wards in the Bronx.

Pneumonia Control Program—The board of estimate has appropriated about \$100,000 for a pneumonia control program to be carried out by the New York City Health Department during the remainder of 1937. The department will be able to provide clinical assistance by a corps of trained advisers to physicians and hospitals on request, they will demonstrate the technique of administering the serum and give advice as to the size and frequency of the dose. Facilities for typing serum are to be established in each borough to supplement the service already available in Manhattan, instruction in typing will also be provided for technicians. Therapeutic serum of types I, II, V, VII and VIII will be generally available through typing stations and for hospitals. Limited supplies of serum of some of the rarer types will be distributed as rapidly as possible.

OKLAHOMA

New Health Officers—Dr. Maurice L. Peter, Blackwell, has been appointed medical director of a new health unit established in Kay County.—Dr. Glen W. McDonald, Ada, has been appointed health officer of Pontotoc County and Dr. James T. Lowe, Mangum, of Greer County.

Plans for Fall Clinical Conference—The Oklahoma City Clinical Society will present its eighth fall clinical conference November 1-4 at the Biltmore Hotel, Oklahoma City. The guest speakers will be Drs. John H. J. Upham, Columbus, Ohio, President of the American Medical Association, John W. Ames, Denver, William L. Benedict and Claud F. Dixon, Rochester, Minn., William Boyd, Toronto, Ont., Cyrus E. Burford, St. Louis, Frederick Christopher, Evanston, Ill., H. Earle Conwell, Birmingham, Ala., Walter T. Dannreuther, New York, Frederick D. Weidman and Chevalier Jackson,

Philadelphia, Samuel A. Levine, Boston, Bernard H. Nichols and Ernest Perry McCullagh, Cleveland, Norman F. Miller and Cyrus C. Sturgis, Ann Arbor, Mich.

PENNSYLVANIA

Hospital Appointments—Dr. Walter I. Buchert, Cleveland, has been appointed head of the department of the Geisinger Memorial Hospital, Danville, and Dr. Reed O. Dingman, formerly of St. Louis, who is also a doctor of dental surgery, has been made head of the department of oral, maxillofacial and plastic surgery.

Plan Pneumonia Control Campaign—The commission on pneumonia control of the Medical Society of the State of Pennsylvania and the state health department will sponsor a luncheon during the annual session of the Medical Society of the State of Pennsylvania in Philadelphia, October 4-7, to plan a campaign for the fall and winter. County medical societies have been asked to create pneumonia control committees to be represented at the luncheon. Seventeen counties had done so up to the publication of the August issue of the *Pennsylvania Medical Journal*. Points in the program will be to develop laboratories throughout the state for diagnostic typing and to have the state, in cases properly certified, furnish pneumonia serum to those unable to pay for it. Dr. Edward L. Bortz, Philadelphia, is chairman of the commission. Members are Drs. Edward W. Bray, Wilkes-Barre, Mathew H. Sherman, Harrisburg, Clifford W. Skinner, Meadville, Clifford C. Hartman and George J. Kastlin, Pittsburgh, Leon H. Collins Jr., Thomas Grier Miller, Henry K. Mohler and Hobart A. Reimann, all of Philadelphia. The advisory board of the state health department at a meeting July 26 adopted a regulation making pneumonia a reportable disease.

RHODE ISLAND

Personal—Dr. Hilary J. Connor, of the staff of the state department of health, Providence, has been appointed superintendent of State Sanatorium, Wallum Lake, to succeed Dr. Robert Lemley Garrard, resigned.

WEST VIRGINIA

Personal—Dr. J. W. Ruckman, West Liberty, has been appointed college physician to the West Liberty Teachers College.

Society News—Dr. Royd R. Sayers of the U. S. Public Health Service, Washington, D. C., addressed the Preston County Medical Society at a meeting at the Hopemont Sanatorium, near Terra Alta, July 23, on silicosis.

WISCONSIN

Personal—Dr. Henry H. Christofferson, Colby, has been appointed to the state board of medical examiners to succeed Dr. Bartholomew E. McGonigle, Ableman.—Dr. Frank O. Hunt, Fall River, was honored on his seventieth birthday June 27 by 1,200 of his patients, who came from many states, according to the *Wisconsin Medical Journal*, and presented him with a watch.

GENERAL

Dr. Clarke Returns to Social Hygiene Association—Dr. Charles Walter Clarke, formerly medical director of the American Social Hygiene Association, New York, who was lent to the New York City Department of Health in 1935 to organize its bureau of social hygiene, has returned to active duty with the association with the title of executive director. Dr. William F. Snow is general director of the association.

Military Surgeons' Meeting—The forty-fifth annual meeting of the Association of Military Surgeons of the United States will be held in Los Angeles at the Hotel Ambassador, October 14-16. Among the speakers will be:

Capt. George F. Cottle, Medical Corps, U. S. Navy Fleet Medicine.
Lt. Comdr. Albert G. Bower, U. S. Naval Reserve Corps, Glendale.
Calif. Modern Typhoid Treatment.
Lt. Comdr. Howard L. Updegraff, U. S. Naval Reserve Corps, Los Angeles.
Emergency Plastic Surgery.
Col. Howard C. Naffziger, U. S. Army Medical Reserve Corps, San Francisco.
Surgical Treatment of Low Back Pain.
Capt. Charles Leroy Lowman, U. S. Army Medical Reserve Corps, Los Angeles.
Physiotherapy in the Next War.

The Funeral of Dr. Simmons—In the chapel at Graceland Cemetery in Chicago numerous friends of Dr. George H. Simmons, Editor and General Manager Emeritus of the American Medical Association, paid their last respects, September 2. The casket was all but covered with floral tributes, and telegrams and cablegrams expressing condolence were received from almost the entire world. The impressive service was conducted by the Reverend Herbert W. Prince, Episcopalian minister,

Lake Forest, Ill., who also gave a brief address. Following the services, the body was cremated. The ashes were later returned to Lincoln, Neb., where Dr. Simmons practiced medicine for many years previous to his appointment in 1899 as Secretary of the American Medical Association and Editor of *THE JOURNAL*.

Warning Against Worthless Checks—An optical goods firm in Chicago reports that several physicians in Wisconsin and upper Michigan have been swindled by a man who orders glasses and gives worthless checks for them. He has his eyes examined and asks the physician to mail the glasses to his rural address. In most cases he selects glasses that cost from \$12 to \$15 and tenders a check for from \$30 to \$40, asking the doctor to reimburse him for the difference in cash. When the glasses are mailed to the name and address given, they are returned. A representative of the optical firm gives the following description of the man: about 46 years old, about 5 feet 8 inches tall, weighs about 190 pounds, has a tendency to baldness and dresses 'like a farmer dressed to go to town'. He tries to buy glasses for reading as glasses are not needed for his distance vision. One check was signed J. P. Dyer.

Bequests and Donations—The following bequests and donations have recently been announced:

Woman's Medical College of Pennsylvania Philadelphia \$25,000 and Jefferson Medical College Philadelphia \$10,000 by the will of Mrs. Jane M. Jenks, Southern widow of Dr. Frank L. Southern, an alumnus of Jefferson.

Roper Hospital Charleston S. C. \$12,000 by the will of James R. Roper.

Wisconsin Anti-Tuberculosis Association \$25,000 by the will of the late Howard E. Mitchell, Milwaukee.

Orange (N. J.) Memorial Hospital \$1,000 from an anonymous donor. Hackensack Hospital Association \$15,000 by the will of the late R. Blecker Rathbone, New York.

St. Francis Hospital Hartford Conn. \$5,000 from the estate of the late John J. Brady.

The late Richard Greene Jackson, Miss, left his residuary estate, estimated at about \$350,000, to build a free hospital for Negroes or wards for Negro patients in some established hospital.

New York Nursery and Child's Hospital, \$30,000 by the will of Miss Emma Elizabeth Conner.

Presbyterian Hospital Philadelphia, \$5,000. Lankenau Hospital Philadelphia \$1,000 and Pennsylvania Institute for the Blind Overbrook \$3,000 by the will of Frederick A. Rakestraw, Overbrook.

Annual Congress of Physical Therapy—The sixteenth annual session of the American Congress of Physical Therapy will be held in Cincinnati, September 20-24, at the Netherland Plaza Hotel. At the opening session Dr. Frederick L. Wahrer, Marshalltown, Iowa, will be installed as president and deliver his official address on "The Future Development of Physical Therapy." Dr. Melvin S. Henderson, Rochester, Minn., will speak on "Deformities Following Fractures: Their Prevention and Treatment," and Dr. Anton J. Carlson, Chicago, The Physiologist Looks at Physical Therapy." Tuesday evening, September 21, the congress will hold a joint session with the Academy of Medicine of Cincinnati with the following speakers:

Dr. J. Van Breemen, Amsterdam, Holland: The Conception of Reaction in Physical Treatment.
Dr. Eugen Weissenberg, Vienna, Austria: Ultrashort Wave (Diathermy) Low Intensity Treatment.
Dr. Harry A. Mock, Chicago: Physical Therapy—What Is It and What Will It Do?

There will be symposiums on hyperpyrexia, x-ray therapy, ionization fractures, vascular diseases and short wave therapy. Thursday evening an educational conference will be held with the following as the speakers:

Dr. William H. Schmidt, Philadelphia: The Function of the County Medical Society in Physical Therapy: Education of the General Practitioner.
Dr. Oswald N. Andersen, Chicago: Function of the Council on Medical Education and Hospitals in the Standardization of Schools for Physical Therapy Technicians.
Dr. Joseph A. E. Syracuse, Buffalo: Ten Years of Hospital Physical Therapy.

Among other speakers in the general sessions are included: Dr. Francis H. Redewill, San Francisco: Electrotherapy and Chemotherapy: Including Sulfanilamide in Gonorrhea and Its Complications.
Dr. Burton E. L. Hyde, Troy, Ohio: Clinical Observations on the Uses of Irradiated Blood.
Dr. Charles S. Venable, San Antonio, Texas: Electrolytic Action Between Metals as Used in Bone Surgery.
Dr. Upton W. Giles and Mr. A. L. Harvey, New Orleans: Experiments in Sterility of Male Animals Induced by Radiant Heat.
Dr. Richard Kovacs, New York: Ultraviolet in Secondary Anemia.
Drs. William C. Menninger and Byron L. Shifflet, Topeka, Kan.: Psychological Aspects of Physical Therapy.

Tuesday and Wednesday mornings will be devoted to section meetings.

Prevalence of Infantile Paralysis—The U. S. Public Health Service reported September 1 that 4,053 cases of infantile paralysis had been reported for the first thirty-four weeks of 1937 as compared with 1,618 for the corresponding period of 1936. For the week ended August 28 with no reports from North Dakota and South Carolina, 621 cases were listed as against 133 cases for the corresponding week of last year, and

807 for the corresponding week of 1935.—Chicago newspapers reported September 7 that there were sixty-four new cases and seven deaths during the week ended September 5. Ninety-five cases with eight deaths had been reported since August 1. Opening of public and parochial schools was postponed.—Buffalo also postponed the opening of schools for two weeks because of twenty cases with three deaths since August 4, newspapers reported September 3.—Children under 7 years of age are barred from attending school or appearing in public places until September 20, in Milwaukee, twenty-five cases, seven nonresident, were reported under treatment September 1.—The opening of schools was also deferred in Kansas City, Mo., and in Fort Collins, Colo., most of the sixty-two cases in Colorado are said to be in the Fort Collins area.

CANADA

The Poliomyelitis Epidemic in Ontario—Reports dated September 5 showed that 1,145 cases of poliomyelitis with thirty-nine deaths had occurred in the province of Ontario since the beginning of the present outbreak in June. Toronto has had 347 cases. School and county fairs have been canceled in several counties and the opening of schools was postponed in a number of towns. The annual baby show at the Canadian National Exposition in Toronto was also canceled. Several thousand children have received preventive treatment with the nasal spray of zinc sulfate. Montreal has begun the collection of blood serum from recovered patients to provide treatment for those stricken in Toronto. Arrangements have been made to bring patients from remote districts by airplane to Toronto hospitals and the planes will also be used to transport serum and other medical supplies to outlying districts.

Government Services

Civil Service Examinations for Bacteriologists

The U. S. Civil Service Commission announces open competitive examinations for the positions of associate and assistant bacteriologist in the U. S. Public Health Service at salaries of \$3,200 and \$2,600 a year, respectively. Optional branches of the subject are brucellosis, anaerobes, physiology of bacteria and viruses. The duties of the positions are to conduct research in these branches and present the results in reports or papers for publication. Applications must be received by the civil service commission in Washington not later than September 20 or, if from Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, Washington and Wyoming, not later than September 23. Application forms may be obtained from the Secretary, Board of U. S. Civil Service Examiners, at any first class post office from the commission at Washington or from its district offices in any of the following cities: Atlanta, Boston, Chicago, Cincinnati, Denver, New Orleans, New York, Philadelphia, Seattle, St. Louis, St. Paul, San Francisco, Honolulu, Balboa Heights, Canal Zone, and San Juan, Puerto Rico.

New Buildings for National Institute of Health

Three new buildings will be erected on a site in Bethesda, Md., to provide improved facilities for the National Institute of Health, it is announced. Construction is expected to begin immediately. An allotment of \$1,143,000 from the emergency construction program acts of 1934 and 1936 is available for erection of the buildings which will serve as a nucleus of a national medical center. Until they are completed headquarters of the institute will remain at Twenty-Fifth and E streets, Washington, D. C. The site is a forty-five acre tract of wooded land on the Rockville Highway near Bethesda, which was donated to the U. S. Public Health Service for this purpose in 1935 by the late Luke I. Wilson, a Washington business man. The new units will include a central administration building flanked on each side by an industrial laboratory building and a public health methods building. This last unit will house numerous activities, including child hygiene and chronic disease work, and provide space for the inoculation of animals in the preparation of various vaccines. The structures will be of Georgian design with exterior brick walls, stone trim and pitched hip slate roof fireproof throughout. There will be a modern air conditioning and air heating system. Each building will consist of basement, sub-basement, three stories and attic, it was stated. According to the report, it is expected that the new National Cancer Institute which was recently authorized by Congress, will be erected on the same property.

Precautions Against Air Raids

The elaborate scale on which precautions against air raids are being taken is illustrated by the case of Sunderland, a shipbuilding town of 185,000 inhabitants on the northeast coast. An emergency organization 3,500 strong, including 2,000 volunteer air wardens, is being formed. Preparations are being made for the treatment of casualties, rescue work and demolition of unsafe buildings, decontamination of streets, repair of damage to roads and sewers, fire fighting, gas detection, emergency communications, protection of the public, and lighting restrictions. Control of these arrangements will be delegated to the chief executive officers of the town corporation, who will be responsible for their being kept down to date and ready for use. Headquarters will be arranged in various public buildings, and portions of them will be rendered gas and splinter proof, with living and sleeping accommodation. These men must have their telephones manned day and night in time of war, so that prompt warning of air raids shall be received. Arrangements for the darkening of the streets and houses will be drawn by the electrical engineer. The air raid wardens will be leaders and advisers of the public, who will occupy posts previously selected and be provided with fire extinguishing equipment. A large emergency fire department is to be organized. The police and others will be instructed in gas detection, but there will also be twenty-nine special gas detection officers, who will be recruited from chemists, chemistry masters in schools and sanitary inspectors. They will undergo a course of training. Medical services will be organized under the health officer of the town. There will be thirty first aid parties, of four men each, for treating casualties in the streets and bringing them to first aid posts. The hospitals will be used as casualty clearing stations. It is estimated that a maximum of 400 beds will be required, and to provide these patients will be moved out of the hospitals in the danger area. For ambulance work the corporation ambulances will be called into use, with improvised ambulances in busses and private vehicles. Arrangements will be made with the local laundries for the treatment of contaminated clothing, selected members of their staff having been trained in this work. Each householder must set aside a room and equip it as a gas-proof shelter and store sand for use on incendiary bombs.

Cancer of the Breast

In the Skinner lecture delivered before the British Association of Radiologists, Dr. Francis Herniman-Johnson said that the five year survival statistics have been greatly improved by postoperative irradiation of cases of cancer of the breast but that the ultimate mortality had not been affected. Great advances, however, had been made in alleviating the lot of these patients. By after-care he meant the care of the patients after the primary growth had been dealt with. He preferred surgical removal provided it was not too drastic. An axilla in which the glands were not palpable was best left alone. If there was microscopic invasion it could be dealt with by irradiation. He preferred operation, because it made radiologic access to the inside of the thorax easier and one did not have to deal with a large area of tissue, much of which had already been irradiated to the limits of safety.

Efficient supervision of all breast cases from the time of operation was best carried out by one man and as the radiotherapist would inevitably be called on to deal with them when

they go wrong, he should have the supervision of them from the beginning. There should be a special clinic to which all patients are sent as soon as possible after operation. For purely prophylactic treatment in the sort of case which, if treated by surgery alone, would stand a good chance of some years' survival, heavy doses of x-rays, carried to a point at which healthy tissues might be damaged or severe constitutional symptoms produced, was not justified. Prophylactic x-ray treatment should be of wide distribution but of low intensity, and be given with the idea of increasing resistance, both local and general. When there was localized recurrence not of a kind that could be suitably dealt with by operation, heavy dosage over a strictly localized area was valuable as a palliative and might prolong useful life for many years. The later stages of breast cancer must be treated as a general disease, the rapidity of its progress being determined to a large extent by constitutional factors. This particularly held when there were multiple small metastases in bones. Change of air and scene might temporarily avert the decline. Ultraviolet treatment might have a truly remarkable result in prolonged arrest of the disease, with gain of weight and strength.

Isolated recurrences in the skin were of little importance from the prognostic point of view. They could be dealt with by surface radium or by the Chaoul tube and did not tend to come back. A recurrence in the axilla might be held in check for years by irradiation alone, but if it appeared reasonably discrete it was best eventually removed surgically. Malignant invasion of supraclavicular glands was more serious because it was practically impossible to deal with it surgically. But heavy localized x-ray dosage might maintain the status quo for long periods. Isolated metastasis in the pelvis or long bones was often quite amenable to treatment. Spontaneous fractures might be caused to unite and the patient be restored to active life for years. For generalized metastases of bones he could recommend only Todd's method (administration of selenium). Even cases of thoracic invasion were not beyond radiotherapy. It was astonishing how dyspnea might be relieved for a long time. But in his experience invasion of the liver was beyond human aid. Swelling of the arm might make life completely miserable. The patient was by no means necessarily near the end even if the swelling was due to actual growth. If she did not improve under heavy doses of x-rays, surgical intervention was worth considering. Sir Harold Gillies had devised an operation for these cases. In a case of lymphatic obstruction of the right arm, with no evidence that it was due to secondary carcinoma, he short circuited the lymphatic blockage in the right axilla by transplanting the left breast, with its lymphatics, to the right, in such a way as to leave untouched the drainage of the left axilla. The edema of the hand and forearm almost disappeared.

Should Orchidectomy Be Performed in Pseudohermaphroditism?

In a letter to the *Lancet* Mr. Kenneth Walker (genito urinary surgeon) criticizes the recorded treatment of the following case. A child of 7, externally apparently a female, had two testes with epididymides, which were discovered during exploration of a supposed bilateral inguinal hernia. As usual in such cases, the operator could not resist the temptation of removing the offending organs. He commented, "It might be considered that the bilateral orchidectomy was unwarranted and too radical a procedure, but it is in accordance with the teaching of Blair-Bell that when the external genitalia and secondary characteristics are feminine and the child had been brought up as a girl, removal of the testes is the correct practice." Mr. Walker considers that this view is based on three misconceptions that are extraordinarily prevalent: (1) that the only function of the gonads is the determination of the secondary sex characteristics, (2) that these characteristics arise simply

as the result of the action of the sex hormones on a neutral body, (3) that if the testes are left, male characteristics will inevitably appear later

The pseudohermaphroditism described is almost certainly explained by failure of the body to respond to male hormones in the direction of maleness. Hence the body is carried by its natural bias in the direction of femaleness. Why therefore should it be assumed that in later years the child will develop maleness? Certainly this has happened, but more often than not the failure to react to the male hormone persists through life. Should however signs of maleness develop later, castration can then be carried out. Castration in the first instance is not the correct treatment and may upset the metabolism of the body. In the case of a good looking girl of 25 it caused her rapidly to put on two stone (13 Kg) in weight and only as the result of a year's work and administration of much anterior pituitary and thyroid was the upset of metabolism to some extent readjusted.

Abuse of Free Medical Care Becomes More Prevalent

The present crisis in the medical profession here is due in great measure to the admission to public hospitals and dispensaries of patients whose circumstances permit them to enter private institutions or to be treated in the offices of local practitioners. So far, this abuse has been confined to larger cities, especially Paris, and the country practitioner has suffered less than his city colleague. In a complaint addressed to the editors of the *Concours medical* which appears in the July 11 issue, it would seem as though this abuse of free medical care is extending to smaller communities. The correspondent states that the mayor of a small community maintains that, in the future, all persons covered by social insurance must be admitted to the nearest hospital as indigents. Two seriously ill persons who required emergency treatment were recently placed on the free (indigent) list. According to the correspondent, these patients were amply able to pay for medical attendance and hospital service. The correspondent asks what can be done under such circumstances. In the answer it is stated that the law governing those covered by social insurance is quite different from that of medical care for the indigent. The former are reimbursed for any outlays on presentation to the local caisses or disbursing offices, of certificates signed by physicians or others as to how much they have paid for medical and hospital services. Such an insured person has the right to choose his medical attendant and the hospital, provided the latter has a contract with the social insurance organization. If, in emergency cases, the mayor sends an insured person to the nearest hospital as a free patient, such admission is subject to revision by the departmental (county) committee on complaint being received from a physician. This is the only method by which those able to pay for medical care can be prevented from entering as free patients. It would appear, however, as though this is another example of locking the stable after the horse is stolen.

A Symposium on Decrease in Population of France

The June 29 meeting of the Académie de médecine was devoted to the discussion of the decrease in population, which is causing much concern in France. Two of the papers were read by Professors Couvclaire and Brindeau leading obstetricians, and the third by Dr Renault, a well known pediatrician. Professor Couvclaire, in discussing the measures to raise the natality rate, stated that the voluntary restriction of the number of births has been responsible for the lack of increase in French population for more than a century hence a policy in the opposite direction was urgently necessary. Immigration will be of little help unless care is taken not to let in every one who

wishes to settle here. A strict moral and physical control of every newcomer is indispensable, before naturalization is permitted. The solution to the question of denatality lies in bringing home to young couples their own interest and duty in maintaining the existence of the country. An average of three children per family is the minimum to overcome the disproportion between the number of births and deaths. If the state wants children, it should be its duty to see that young couples should have some interest in the matter. Material advantages check, at least temporarily, contraceptive methods, as has been shown several times for nearly the past century and a half in France. Measures taken to lighten the financial burden for heads of families at present includes either reduction of taxes or a direct payment. The Strauss law in France allows maternity premiums to be paid and there are four other laws to encourage natality by financial aid for large families. A movement which began in the industrial region of northern France to make extra payments to employees who have children was made obligatory for all employers in 1932. Nearly two billion francs was paid up to May 1937 and the natality rate is 22 per cent higher than the average in the families of such workers. The reductions in income tax for heads of families have been insufficient. The sales tax which retailers pay affects the head of a family in proportion to the number of children and is still quite an unwelcome addition to the daily outlay for food. Instead of relative deductions on income taxes and allowances for large families it would be better, according to Professor Couvclaire, to adopt the methods now employed in Italy and Germany. A loan is made to newlyweds, which is reduced by increasing percentage with each birth until, after the fourth child, the remainder of the loan is converted into a gift. Assistance and encouragement are necessary but these measures will not be adequate to solve the denatality problem until a moral social environment is created which favors family life. The problem of natality is intimately related to the education of young girls. Professor Brindeau spoke on the decrease in population from the obstetric point of view. The campaign against involuntary sterility has made a great deal of progress. Secret abortion is one of the most frequent causes of denatality, and the complications incident to such procedures often render women sterile for life. Although the medical profession is almost powerless in combating induced abortion, much can be done to prevent the spontaneous form, in treating the more common causes, such as syphilis, endometritis, uterine displacements and endocrine dysfunction. One should not place too much reliance on a negative Wassermann reaction. A second source of denatality is death of the fetus at term. The causes of intra-uterine death are about the same as those of spontaneous abortion, syphilis having the predominant part. In many cases, death of the fetus during birth is the result of hereditary stigmas on the maternal side, such as syphilis, albuminuria and organic or infectious diseases, the enfeebled fetus being less capable of tolerating obstetric trauma than a normal one. Statistics which show only the number of deaths at term do not give an accurate picture, because more infants die during the first ten days from premature birth effects, syphilis, meningeal hemorrhage and amniotic infections than at birth. The number of deaths at birth and during the first ten days shows a steady decrease, as the result of better antepartum care and of the progress made during recent years in obstetrics. Better technique and asepsis combined with the more widespread use of operative methods have had an important influence in saving many a mother and child. The social insurance law compels every expectant mother to attend antepartum clinics at least twice during every pregnancy. Brindeau protested against the indiscriminate use of anesthetics and of oxytocics during labor as not being free from danger to both mother and child.

The third paper in the symposium was by Dr Jules Renault and Miss Labeaume on the development of the movement for the protection of infants. The best way to aid the mother was to permit her to remain at home and to nurse her child. Various organizations, one more than 150 years old, have devoted their energies toward reaching this goal. Instead of creating creches, the present tendency is to give ample remuneration to mothers to stay at home and nurse their infants. The lack of team work between government bureaus and societies founded to aid home care of the new-born has been improved by two comparatively recently organized associations, the League Against Infant Mortality and the Bureau of Maternal and Infantile Protection. More than 60,000 new-born infants still remain under the care of wetnurses. Their surveillance has been better since the passage of the Roussel law, but there is still room for improvement.

The Treatment of Agranulocytosis

Dr. H. E. Bock discussed, in the Frankfurt Medical Society, the treatment of agranulocytosis on the basis of investigations carried on at the Frankfurt University Medical Clinic, of which Professor Volhard is director. Agranulocytosis is a disease entity first described by Werner Schultz in 1922. The discovery of aminopyrine agranulocytosis, the importance of which according to the German point of view is greatly exaggerated, not only contributed substantially to the explanation of the pathogenesis but constituted an important landmark in therapeutics, since it demonstrated that, like barbituric acid preparations, aminopyrine preparations are to be avoided in disturbances resembling agranulocytosis. Aside from this discontinuation treatment and the enormous importance of nursing care there is also an active therapy. Whereas protein substance, epinephrine, thyroxine and liver substance (the last named important because of its general effect) represent only subthreshold granulotactic stimuli, induced turpentine abscess has a more durable effect. The three principal therapeutic procedures in agranulocytosis are roentgen stimulation-irradiation of the medullated bones, blood transfusions and administration of pentnucleotide. Although nucleotide in large doses has heretofore represented the most effective medication for the building up of leukocytes, a blood transfusion exerts the optimal general effect. Copious and frequent transfusions should be performed and the utmost caution exercised in the selection of donors. Cases have been reported in which three transfusions of 675 cc each were given and in other cases the quantity even reached 1,000 cc per transfusion. Satisfactory bridging over of the most dangerous four initial days, that is, an effective compensation for granulocyte deficiency in the face of the threatening sepsis, is however not always achieved even by maximal transfusions if normal blood is used. Schittenhelm attained favorable results in a single case by utilization of the blood of a patient with myeloid leukemia. Bock's employment of a similar procedure, undertaken without knowledge of Schittenhelm's case, was also successful. At the Volhard clinic a woman typist, aged 40, who presented a severe agranulocytosis, was placed out of danger within nineteen days by twelve 500 cc transfusions of leukemic blood. The patient on admission exhibited all signs of the disease in its most exaggerated form, for five days no granulocytes could be observed, the total number of leukocytes fluctuated between 200 and 1,100 and there was no monocytosis. The patient was highly feverish, the erythrocyte sedimentation rate was elevated, and marrow of the tubular bones exhibited a purely myeloblastic-reticular high grade cell-deficient character. Further complications were pneumonia and necrosis of the gums. The total value of leuko-

cytes transplanted corresponded to that contained in 250 transfusions of normal blood. The transfusions were unaccompanied by any incident. The colossal consumption of leukocytes was especially exacerbated by a femoral abscess, which was opened at the end of the third week. Only in the fourth week did the leukocyte balance become positive. The high grade destruction of the myeloid tissue and the regeneration of myelopoiesis toward normal under the influence of the leukemic blood could be observed at all stages of the illness both in the hematogram and in the histologic section of the sternal punctate.

Changes in the Blood During Pregnancy

The Berlin hematologist Prof. Werner Schultz pointed out in a session of the Medical Society of Hamburg that, whereas changes in the blood are frequent enough during pregnancy, defective states of the blood are seldom manifested. Nearly one half of all gravidas present declines in the hemoglobin and erythrocyte values of some 10 per cent below normal. This is an innocuous phenomenon that does not require treatment. More recent investigations have disclosed that these alterations in blood, usually designated "pseudo-anemias," may vary within the course of the same pregnancy, at one time the blood values may be normal at another depreciated. The water economy of the pregnant organism plays a part in these phenomena, however, this aspect of the problem has been studied but little as yet. Even the amount of plasma can fluctuate a good liter in the same gravida. The borderline between this benign pseudo-anemia and genuine "essential anemia of pregnancy" is therefore flexible. Symptoms that first permit a diagnosis of the anemia of pregnancy to be established are severe fall in the hemoglobin and erythrocyte values, pronounced malaise, spells of syncope and vertigo. The anemia of pregnancy is rare. Strictly speaking, an anemia cannot be regarded as conditioned by the pregnancy unless the physician possesses a record of the pregravidic and postpartum blood value. One should also consider cases of pernicious appearing anemias of pregnancy and cases of pregnant pernicious anemia patients. Then too, women affected with "poorly regenerating hemorrhagic anemias" and "essential anemias" may become pregnant, a fact to be considered in the differential diagnosis of true anemia of pregnancy.

The Chiasma Syndrome

The Berlin Medical Society met recently in joint session with the Society of British Neurological Surgeons. Prof. A. A. McConnell of Dublin spoke first on the chiasma syndrome. The most important symptom is impaired vision either unilateral or bilateral. Especially characteristic are the central scotoma and the limitation of the visual field. He mentioned, among other conditions, the chiasmal aneurysms, subdural cysts, meningiomas, hypophysial adenomas, craniopharyngiomas, chiasmal gliomas and internal hydrocephalus. A predominant symptom in all cases is an impairment of vision that usually first causes the patient to consult a physician. Other symptoms are headache, vertigo and syncope. Total blindness of one or both eyes often eventuates. Of great significance is the observation that not infrequently the sight returns following removal of the pathologic process. Operative treatment, if at all feasible, is indicated. Differential diagnosis often presents formidable difficulties, as there is no group of symptoms indicative of a particular type of chiasmal process. Accordingly, each individual case represents a special problem. As diagnostic aids ventriculography, arteriography and the roentgenogram are to be utilized. The prognosis in many cases is favorable.

In the discussion that followed Dr. McConnell's lecture Professor Olivecrona of Stockholm spoke on aneurysms of the internal carotid artery. Smaller aneurysms produce a central scotoma and impairment of the temporal field of vision on the affected side. By way of contrast, larger aneurysms give rise

to a homonymous hemianopia and bilateral central scotoma Professor Foerster of Breslau reported seventy one cases of chiasma syndrome among a material of 12,000 neurologic cases covering a period of sixteen years The most frequent cause was hypophysial tumor, although arachnitis also loomed large as an underlying condition Foerster observed several cases in which surgical intervention for a hypophysial tumor was followed by an unequivocal manic syndrome Operation often discloses a much more extensive area of deterioration than preliminary examination would lead one to anticipate Occasionally chiasma syndrome is merely a consequence of pressure exerted by more deeply situated processes such as ventricular cysts, neurocytomas at the base of the brain and deep-lying tumors along the hypophysial infundibulum In one case it was possible to terminate completely a diabetes insipidus by means of operation Professor Tonnis of Berlin has treated seventy-three patients who presented chiasma syndrome Frequently the anamnesis reveals a history of psychic disturbance reminiscent of Korsakoff's psychosis Careful observation of the condition of the fundus oculi is indispensable The variations in the incidence of particular types of tumors according to age groups is a further important consideration craniopharyngiomas tend to be manifested in the second decade of life, hypophysial adenomas in the third decade and meningiomas in the fourth The tumor presses on the chiasma from above, thus causing a scotoma in the inferior-exterior region Puncture of the shadows situated in the region of the sphenoid sinus which appear suggestive in the roentgenogram may under certain circumstances be extremely dangerous (as cerebrospinal fluid may be aspirated) According to the observations of Tonnis, the prognosis of operative treatment is most favorable in adenomas, the mortality of patients who presented this type of tumor was 25 per cent, against 20 per cent in cases of meningioma In conclusion Nonne of Hamburg pointed out that chiasma syndrome may also be of syphilitic origin He has observed several cases of hereditary syphilis in which the syndrome was present A syphilitic endarteritis as well as the gummas form the morphologic substrata of this interrelation, at the same time the Wassermann reaction of the fluid may be negative Antisyphilitic therapy often affects such cases favorably

Can Short Wave Irradiation Impair the Germinal Factors?

Injuries to the germinal factors, caused by roentgen rays, has become the subject of vigorous discussion Since short waves have come to be utilized extensively in the treatment of inflammatory disorders, especially in gynecology, it is necessary to determine whether the high frequency waves are capable of producing genetic effects similar to those produced by roentgen rays A Pickhan director of the roentgenologic section of a Berlin hospital, has conducted an investigation of this problem and reports his observations in the *Deutsche medizinische Wochenschrift* He selected the fruit fly *Drosophila melanogaster*, since in the entire animal and vegetable kingdoms no other creature is more suitable for the study of experimental genetics The basic laws of genetics, the durability of germinal factors, the manifestation of spontaneous mutations and the elicibility of hereditary changes by certain irradiations are, as Pickhan emphasized identical for all members of the animal and vegetable kingdoms At the same time the dose that is harmful to man is of only secondary importance *Drosophila* was tested in two series of experiments, for its reaction both to the short waves alone and to a combined short wave and roentgen irradiation A wave of 6 meters was used throughout In the course of a year more than 6,000 cultures of 100 flies each were developed The results of these experiments may be summarized as follows Treatment with a high frequency current did not produce a statisti-

cally certain increase in the rate of mutation An increased sterility in the second filial generation (F₂) was not observed The high frequency field exhibited no statistically demonstrable influence on the mutation-eliciting effect of roentgen irradiation For clinical purposes it may be concluded that the 6 meter waves thus far studied do not influence the genes even if applied in great intensities No heightening of the mutation-eliciting effect of roentgen irradiation was observed to follow combined roentgen and short wave irradiation Naturally, this does not mean that an increase in both physiologic and biologic reactions of another sort may not be present

JAPAN

June 26, 1937

The Nation's Health Control Bill

The home office has decided to submit to the next regular session of the imperial diet a bill providing regulations for the compulsory physical examination of the population from infancy up to 40 years of age The principal object is to gather data on national health conditions Measures, based on this, to expand the state health provisions will be devised The home office and the war office are expected to go hand in hand in the way of the national health promotion campaign that was recently started This bill is reported to be a first preparatory step toward completion of the army's national mobilization scheme According to the draft plan, infants four months after birth will be ordered by the state to undergo a health examination at the city, town or village office and enrolled on the national health list The primary schools will be in charge of the matter while children are attending schools The health examination will be conducted every year for those who have finished the primary school and do not reach the conscription age, and young women For the others, the examination will be carried out every three years Health cards will be prepared at the city, town or village offices, and detailed records will be kept concerning the health of every person The administration of this project will be by the ministry of health, which is expected to be newly established in the cabinet

Hundreds of New Health Centers

The chief object of the 550 health centers which are to be newly established during this fiscal year is to give instruction in preventive medicine The centers are to make the people health conscious through improvement of nutrition and the selection of wholesome food, in which the housewives are to be instructed, hygienic clothing, sanitation in dwellings, enlightened treatment of pregnant women and of infants, and the prevention of tuberculosis, venereal diseases and parasitic diseases The health centers will be established and maintained by the prefectures, the local governments, and the appointed greater municipalities They will have, if necessary, branches in the country There will be at least two medical experts one pharmacist, one clerk and three women The government will grant half of the expense to the establisher for its foundation, and one third of the annual working expenses will be granted by the government At the health center any kind of treatment is free of charge

New Gymnasiums to Commemorate the South Manchurian Railway

The thirtieth anniversary of the foundation of the South Manchurian Railway will be celebrated by establishing seven gymnasiums as a memorial, with the aid of the Manchukuo government The memorial was limited to medical work because the authorities consider that the most important business for the Manchukuo empire at present is the promotion of the health of the people there The gymnasiums will benefit the Japanese residents there as well as the Manchurian natives Special attention will be paid to equipment for use in winter

when outdoor sports and games are prohibited by the extreme cold. Another memorial of this kind is the establishment of five tuberculosis sanatoriums. There are about 20,000 tuberculosis cases among the 500,000 Japanese residents there. Four hundred beds will be newly furnished and ready for use in 1939.

Notification of Tuberculosis Cases

The revised regulations for the prevention of tuberculosis were expected to be put in force July 10. Among others, one of the most important changes is the notification to the authorities of the name, address, age and the diagnosis. By "the authorities" is meant the chief of the local government under whose control the doctor is. If the doctor fails to give notice to the authorities he will not be punished, for no penal law is announced, all being left to the conscientiousness of the doctors. A good result, however, is expected on all sides.

BELGIUM

July 22, 1937

A National School of Aerial Protection

Since Belgium is in an exposed and crucial position with respect to any general European conflict, it is necessary to pay the utmost attention to the problem of defense against aerial attack. The government has accordingly just initiated a complete innovation: the foundation at Brussels of the *Ecole Supérieure pour la Protection Aérienne*—the first institution of the kind. Previously activities in this sphere had, generally speaking, depended on mutual agreements between various well intentioned officials and there was a marked lack of scientific discipline and administrative coordination.

Prof. Lucien Dautrebande, who conceived the idea of this school, had in mind the abolishment of these administrative difficulties. In the dedicatory address delivered at the war college he enunciated three principal national objectives with respect to aerial protection. These were (1) unity of purpose, (2) improved coordination of efforts and (3) consolidation of progress achieved. The new school will be essentially a scientific institution. Not only will it seek to profit by the experiences of the World War but it will in addition keep constantly abreast of the latest relevant innovations in the fields of chemistry, physics, physiology and therapeutics. The school plans to organize a central library in which a collection of international material will be housed. The creation of practical research laboratories is also contemplated. The curriculum will include courses in (1) international law, (2) general and specific chemistry of war gases, (3) general and specific pathology of war gases, (4) therapeutic measures employed in gas casualties, (5) identification and dosage, (6) principles of individual and group protection and (7) organization of general protective measures. Students are selected from among physicians, pharmacologists, chemists and engineers. Graduates will serve as expert advisers in various centers throughout the country. The ministry of the interior hopes in this way to build up a substantial scientific defense armament for Belgium and this in turn will tend to make all classes of society conscious of the importance of protection against aerial attack.

The Diagnosis of Intoxication

Dr. Leduc, in the *Société de Médecine légale en Belgique*, discussed measures undertaken for evaluation of the state of intoxication by the amount of alcohol consumed. The importance of eliminating inebriates from services which involve the safety of the public and of fellow employees has led the medical department of the National Railway Association to undertake systematic detection of the existence of alcoholism among railway employees.

The immediate superior of an employee suspected of drunkenness must call in a physician to examine the suspect or send

the latter to the dispensary. The boss will first of all have the employee write down a simple dictated text as a test of motor coordination. The medical examination consists of simple tests and observations: writing, orientation in time and space, efficiency, equilibrium, pulse and respiration and finally blood and urine examination by means of Nicloux's bichromate method. The physician should keep in mind that either evaporation or fermentation of the urine is a possible source of errors which require correction. Above all, the evaluation of a state of alcoholic intoxication is arrived at on the basis of the clinical picture.

As a general rule, clinical ebriety exists in those cases in which 15 per thousand parts of alcohol has been found to be present in the blood. The author cites numerous examples which illustrate the paramount diagnostic importance of the clinical picture.

Museum of Dermatosyphilographic Models

A museum of models has been opened in connection with the dermatologic and syphilographic clinic of Professor Dujardin. In the presence of a distinguished audience, Professor Ley congratulated Dr. Deleeuw on his admirable execution of some 500 splendid models which he has so generously contributed to the university. Deleeuw's work, said Ley, reflects remarkable artistic talent and rare powers of observation. The speaker further recalled that Deleeuw's first surgical collection of 400 models executed between 1904 and 1910 was destroyed by fire at the time of the Brussels exposition of 1910. He then made an apt allusion to the importance of the new collection, assembled since 1924, for the study of pathologic anatomy, dermatosyphilography and cancerology. He also praised the fine drawings and photographs with which Professor Dustin and his laboratory staff have enriched the Deleeuw collection.

Professional Disability of Radiologists

The National Antituberculosis Foundation points out that, although nurses and the lay personnel of hospitals and sanatoriums are eligible for disability benefits, the law does not provide similar insurance for the physician. The executive committee of the foundation suggests that the *Fédération Médicale Belge* propose to the minister of labor and public welfare the grant of regular disability compensation to radiologists who become incapacitated through the exercise of professional functions. The committee has agreed that, if proper contracts exist, the same obligations with regard to disability insurance which an employer assumes toward the lay personnel can be made applicable to a physician.

Marriages

HENRY BUNTING, Madison, Wis., to Miss Mary A. Ingraham of Brooklyn, in Northport, L. I., N. Y., June 22.

MORGAN SARGENT, Quincy, Mass., to Miss Margaret Louise Crane of Stamford, Conn., June 23.

CHARLES H. LAMON to Miss Jean Elinor Mains, both of New Kensington, Pa., July 31.

MAURICE L. LE BAUER to Miss Carolyn Weill, both of Greensboro, N. C., June 19.

HENRY DOWS STEBBINS, Boston, to Miss Rebecca Rhodes of Brookline, Mass., June 26.

JESSE A. RUST JR. to Miss Janet Hazen Dodds, both of Burlington, Vt., July 10.

CARL S. LYLE, Dunnellon, Fla., to Miss Carolyn Endsley of Brooksville, May 30.

NORMAN VAN WEZEL to Miss Hannah P. Wainman, both of Cleveland, July 11.

JOHN ELMER LEWIS to Miss Josephine Carter Barney, both of New York, June 5.

JARRETT WILLIAM PALMER to Miss Marie Peterson, both of Ailey, Ga., June 22.

Deaths

Minor McDaniels ♂ Ithaca, N Y, University of Buffalo School of Medicine, 1904, formerly member of the state legislature, consultant in medicine on the staff of the Tompkins County Memorial Hospital, member of the Tompkins County Alcoholic Control Board and of the Tompkins County Welfare Board, vice president of the board of managers of the Tompkins County Laboratory and a member of the board for nine years, served during the World War, aged 65, died, June 4, of cerebral thrombosis and arteriosclerosis

Munford Smith ♂ Los Angeles, University of Maryland School of Medicine, Baltimore, 1919, past president of the American Sanatorium Association, a director of the National Tuberculosis Association, fellow of the American College of Physicians, medical director of the Barlow Sanatorium, on the staffs of the Los Angeles General Hospital and the Hospital of the Good Samaritan, aged 45, died, June 28, of cerebral thrombosis, on board the *M S Canada* en route to Panama and England

Mitchell P Warmuth ♂ Philadelphia, Medico-Chirurgical College of Philadelphia, 1894, at one time lecturer of surgery and demonstrator of operative surgery at his alma mater, aged 66, for many years on the staffs of the Eastern State Penitentiary, Philadelphia General Hospital, Friends Hospital and the National Stomach Hospital, where he died, June 15, of chronic myocarditis

Charles Dexter Ball ♂ Santa Ana, Calif, University of Bishop College Faculty of Medicine, Montreal, Que, Canada, 1884, past president and secretary of the Orange County Medical Society, for many years president of the library board and the city board of education, formerly county physician and health officer, at one time member of the state legislature, aged 77, died, June 16

Freas Benjamin Kleintob, Wyoming, Pa, Jefferson Medical College of Philadelphia, 1916, member of the Medical Society of the State of Pennsylvania member of the school board, aged 51, on the staff of the Pittston (Pa.) Hospital, where he died, June 6, of an infection of the jaw and pulmonary embolism following the extraction of teeth

Hazley Thomas Groody ♂ Manhattan, Kan, Chicago College of Medicine and Surgery, 1913, past president and secretary of the Riley County Medical Society, for many years assistant student health physician to the Kansas State Agricultural College, aged 53, died, June 2, in St Luke's Hospital, Kansas City, Mo, of heart disease

Forbes Robert McCreery ♂ New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York, 1888, an Affiliate Fellow of the American Medical Association, aged 72, died, June 29, in Cornwall, Conn, of arteriosclerosis, cerebral hemorrhage, pneumonia and diabetes mellitus

Jacob Fowler Avery ♂ Minneapolis University of Minnesota College of Medicine and Surgery Minneapolis, 1899, fellow of the American College of Physicians, served during the World War, on the staffs of the Northwestern and Abbot hospitals, aged 64, died, June 25, at La Jolla, Calif, of heart disease

John Francis Bigony, Hinton W Va, National Normal University College of Medicine Lebanon Ohio, 1892, member of the West Virginia State Medical Association, for many years member of the school board, formerly city and county health officer, aged 68, died, June 12, of coronary thrombosis

George Edward Reynolds, Providence, R I, Georgetown University School of Medicine, Washington, D C 1906 member of the city school board served during the World War, on the staff of St Joseph's Hospital, aged 55, died suddenly, June 6, probably of coronary thrombosis and angina pectoris

Ernest Guthrie Mark ♂ Kansas City Mo University of Louisville (Ky) Medical Department, 1899 member of the American Urological Association fellow of the American College of Surgeons on the staff of the Research Hospital, aged 59, was found dead, June 7 of potassium cyanide poisoning

Joseph Michael Scanlon, Lawrence Mass, Tufts College Medical School, Boston, 1914 member of the Massachusetts Medical Society, served during the World War, on the staffs of the Massachusetts Eye and Ear Infirmary and the Boston City Hospital, aged 50 died June 14 of pneumonia

Henry Lincoln McClusky, Worcester, Mass, Jefferson Medical College of Philadelphia 1896 member of the Massachusetts Medical Society, at one time physician for the county

jail, formerly on the staff of the Hahnemann Hospital, aged 69, died, June 2, of cardiorenal degeneration

Erastus Hardy Tubb, Cordova Ala, Medical Department of Grant University, Chattanooga, Tenn, 1903, member of the Medical Association of the State of Alabama, aged 56, died in June at a hospital in Jasper of gangrenous cholecystitis and stone in the common duct

Henry Arthur Greenebaum ♂ Chicago, Rush Medical College, Chicago, 1929 assistant in medicine, University of Illinois College of Medicine, associate attending physician to the Cook County Hospital, aged 34, died, June 24, of meningitis and pyelonephritis

D Watson Grear ♂ Anna, Ill, Missouri Medical College, St Louis, 1890, formerly coroner of Union County, for many years on the staff of the Southeastern Hospital for the Insane, North Madison, Ind, aged 74, died, June 5, of angina pectoris and chronic myocarditis

Louis William Schwindt ♂ Philadelphia, Medico Chirurgical College of Philadelphia 1911, for many years police surgeon, aged 51, on the staff of the National Stomach Hospital, where he died, June 15, of brain tumor of the right frontal lobe and bronchopneumonia

Maurice D Kefauver, Smithsburg, Md, Baltimore Medical College, 1904, member of the Medical and Chirurgical Faculty of Maryland, aged 57, on the staff of the Washington County Hospital, Hagerstown, where he died, June 19, of carcinoma of the kidney

Isaac Errett Graham, Mechanicsburg, Ohio, Western Reserve University Medical Department Cleveland 1889, formerly demonstrator of anatomy at St Louis University Medical Department, aged 71, died, June 19, at the McClellan Hospital, Xenia

Winfred Lee Reid ♂ Phoenix, Ariz, Northwestern University Medical School, Chicago, 1924, associated with the Phoenix Clinic, aged 39, died in June of a skull fracture and fracture of the left clavicle and pelvis, received in an automobile accident

Green Herschel De La Perriere, Irving, Texas Kansas City College of Medicine and Surgery, Kansas City, Mo, 1919, member of the State Medical Association of Texas, aged 54, died, June 14, in Hoschton, Ga, of coronary thrombosis

Meyer Joseph Epstein, Jonesboro, Ark, Missouri Medical College, St Louis, 1877, member of the Missouri State Medical Association, aged 80, died, June 17, in Chicago of arteriosclerotic heart disease and acute pulmonary edema

Shelby Mumaugh, Lima, Ohio, Medical College of Ohio, Cincinnati, 1888, member of the Ohio State Medical Association, formerly on the staffs of the Lima Memorial and St Rita's hospitals, aged 70, died, June 3, of heart disease

Barnet Lemchen, Chicago, St Louis University School of Medicine, 1908, member of the Illinois State Medical Society, for many years connected with the Chicago State Hospital, aged 66, died, June 18, of coronary thrombosis

James R Phillips, Preston, Md, University of Maryland School of Medicine, Baltimore, 1869, formerly member of the state legislature, aged 92, died, June 18, of primary benign hypertrophy of the prostate and arteriosclerosis

John Henry Moore, Liberty Center, Iowa, Keokuk Medical College, College of Physicians and Surgeons, 1906, member of the Iowa State Medical Society, aged 66, died, June 10, in a hospital at Osceola, of cerebral hemorrhage

Eugene C Gordon, Columbus, Texas, Jefferson Medical College of Philadelphia, 1882, member of the State Medical Association of Texas, county health officer, aged 75, died, June 10, of chronic myocarditis and arteriosclerosis

George Alexander Wagner ♂ Van Horne, Iowa, University of Illinois College of Medicine, Chicago, 1913, past president of the Benton County Medical Society, aged 59, died, June 5 probably of coronary occlusion

Alonzo Burton Eckerdt ♂ Kaneohe, Hawan, College of Physicians and Surgeons, Baltimore, 1911 member of the American Psychiatric Association, medical director of the Territorial Hospital, aged 50, died, June 18

Walter A Murphey, Parkersburg Pa, University of Pennsylvania Department of Medicine, Philadelphia 1878, formerly school director and member of the board of health in Parkersburg, aged 82, died June 18

Robert Paul Jones, Norfolk Va University of Virginia Department of Medicine Charlottesville, 1900 formerly member of the city health department, aged 60, died, June 3, in the Norfolk General Hospital of uremia

Ernest Frederick Apeldorn, Philadelphia, Jefferson Medical College of Philadelphia, 1881, Hahnemann Medical College and Hospital of Philadelphia, 1904, aged 78, died, June 12, of chronic myocarditis and nephritis

Peter Jurgens Pothuysje @ Denver, Starling Medical College, Columbus, 1893, fellow of the American College of Physicians, on the staff of St Joseph's Hospital, aged 71, died, June 4, of bilateral pyelonephritis

George Fred Hart, Webster, Mass., University of Vermont College of Medicine, Burlington, 1884, member of the Massachusetts Medical Society, formerly state senator and bank president, aged 77, died, June 1

Seth Eugene Miller @ Oberlin, Ohio, Starling Medical College, Columbus, 1896, formerly coroner of Lorain County, aged 66, on the staff of the Allen Hospital, where he died, June 10, of chronic myocarditis

George Frederick Laidlaw, New York, New York Homeopathic Medical College and Hospital, 1890, aged 66, died, June 22, of carcinoma of the bladder with metastases to the lungs, pubic bones and skin

Joseph Patrick O'Reilly, Staten Island N Y, University and Bellevue Hospital Medical College, New York, 1909, on the staff of the Richmond Memorial Hospital, aged 63, died, June 6, of heart disease

William Beckwith Fuqua Jr, Radford, Va., Medical College of Virginia, Richmond, 1931, college physician at the Radford State Teachers College, aged 34, died, June 29, in the Gale Hospital, Roanoke

Lila Gertrude Schieffelin, Buffalo, Woman's Medical College of the New York Infirmary for Women and Children, New York, 1891, aged 69, died, June 6, of carcinoma of the uterus with metastases

Isaac W Young, Langston, Okla., Flint Medical College of New Orleans University, 1900, past president of the Agricultural and Normal University, at one time mayor of Boley, aged 63, died, June 8

Hugh Hodge Hill, Locust Dale, Va., University of Pennsylvania Department of Medicine, Philadelphia, 1895, member of the Medical Society of Virginia, aged 79, died, June 16, of cerebral hemorrhage

William Grant Huffman, Richmond, Ind., Western Reserve University Medical Department, Cleveland, 1896, served during the World War, city physician, aged 68, died, June 21, of chronic myocarditis

Reinhold Willman, St Joseph, Mo., Ensworth Medical College, St Joseph, 1902, member of the Missouri State Medical Association, aged 81, died, June 14, in Kansas City, of chronic myocarditis

Howard W Day @ Monessen, Pa., Northwestern University Medical School, Chicago, 1899, formerly member of the state legislature, aged 66, died, June 1, of carcinoma of the liver and intestine

Philip Francis O'Hanlon, New York, University of the City of New York Medical Department, 1886, formerly police surgeon, served during the World War, aged 74, died, June 10, of heart disease

Harvey Alexander Price @ Port Carbon, Pa., Medico-Chirurgical College of Philadelphia, 1916, aged 49, died, June 17, of a compound fracture of the base of the skull and suffocation, due to a fall

John Edward Medley @ Philadelphia, Medico-Chirurgical College of Philadelphia, 1898, served during the World War, aged 63, died, June 4, of carcinoma of the pancreas with metastasis to the liver

Frederick Carl Rawolle Jr, Greenwich, Conn., Johns Hopkins University School of Medicine, Baltimore, 1937, aged 27, was found dead, June 11, in Stamford of a self-inflicted bullet wound

Edmund Peyton Lowe, New Orleans, Tulane University of Louisiana Medical Department, New Orleans 1885, aged 77, died, June 24, of myocarditis, angina pectoris and arteriosclerosis

Frank S Furman @ Lincoln, Neb., University of Nebraska College of Medicine, Omaha 1930, on the staff of the Bryan Memorial Hospital, aged 37, died, June 6, of sepsis and pneumonia

Benjamin Edel Helprin, Brooklyn, Long Island College Hospital, Brooklyn, 1903, served during the World War, aged 57, died, June 28, in the Jewish Hospital of morphine poisoning

Charles David Rawson, Des Moines, Iowa, Medical College of Ohio, Cincinnati 1880, member of the Iowa State Medical Society, aged 85, died, June 19, of lobar pneumonia

Karl Louis De Sombre, Fond du Lac, Wis., University of the City of New York Medical Department, 1889, aged 75, died, June 28, of myocarditis, arteriosclerosis and nephritis

Plato W Robinson, Osawatomie, Kan., Ensworth Medical College, St Joseph, Mo., 1897, served during the World War, aged 60, died, June 17, at Carbondale, of heart disease

Edwin Louis McAuliffe, Woodstock, Ill., Rush Medical College, Chicago 1882, aged 80, died, June 23, in the Michael Reese Hospital, Chicago, of carcinoma of the pancreas

Frederick Edward Marscheider, New York, Bellevue Hospital Medical College, New York, 1895, aged 63, died, June 10, in St Luke's Hospital, of chronic bronchitis

Alice A Stoddard McCullough, Rochester, N Y, New York Medical College and Hospital for Women, 1878, aged 81, died, June 1, of bronchopneumonia and arteriosclerosis

George Francis Roberts, Allison Park, Pa., Western Pennsylvania Medical College, Pittsburgh, 1902, aged 60, died, June 14, of coronary occlusion

Israel L McInnis, Edmonton, Alta., Canada, Manitoba Medical College, Winnipeg, 1892, aged 77, died, June 8, of hypostatic pneumonia and heart disease

Thomas Jackson Davis, La Center, Ky., Vanderbilt University School of Medicine, Nashville, Tenn., 1894, aged 71, died, June 7, of carcinoma of the colon

Charles Dake, Hot Springs National Park, Ark., University of Tennessee Medical Department, Nashville, 1881, aged 76, died, June 12, of arteriosclerosis

John Wyatt McClain, Pelham, Ga., University of Georgia Medical Department, Augusta, 1889, aged 69, died, June 10, of arteriosclerosis and diabetes mellitus

George J Eblen, Van Wert, Ohio, Eclectic Medical Institute, Cincinnati 1880, aged 83, died, June 2, in the Van Wert County Hospital, of pneumonia

Alexander F McDonald, Wickford, R I, Medico-Chirurgical College of Philadelphia, 1898, aged 71, died, June 7, of heart disease and pneumonia

James T Elder, Farmington, Ga., Georgia College of Eclectic Medicine and Surgery, Atlanta, 1887, aged 75, died, June 7, of bronchopneumonia

Wyatt Farmer Simpson, Hot Springs National Park, Ark., University of Arkansas School of Medicine, Little Rock, 1913, aged 54, died May 28

Frank B Craddock, Sheridan, Wyo., Barnes Medical College, St Louis, 1903, aged 76, died, June 5, in the Sheridan County Memorial Hospital

Frank Ageton Remde, Bottineau, N D, Rush Medical College Chicago 1933, aged 36, was shot and killed, June 17, by an intoxicated patient

Charles Baxter Harwood, Houston, Texas, Rush Medical College, Chicago, 1905, aged 63, died, June 6, of carcinoma of the face with metastasis

Laurie Longley Harrison, Halifax, N S, Canada, McGill University Faculty of Medicine, Montreal, Que., 1904, aged 57, died suddenly, June 30

John Elijah Underwood, Waveland, Ark. (licensed in Arkansas in 1903), aged 72, died, June 1, in a hospital at Russellville

Robert William Dress @ Tamaqua, Pa., Jefferson Medical College of Philadelphia, 1923, aged 38, died, June 7, of coronary sclerosis

Newbern Nuckolls Brown @ Bakersfield Calif., College of Physicians and Surgeons, Los Angeles, 1905, aged 54, died, May 30

John C Graham, Trinity, Ky., Kentucky School of Medicine, Louisville 1897, aged 69, died, June 2, of cerebral hemorrhage

George W Mayfield, Bruceville, Ind., Kentucky School of Medicine, Louisville, 1892, aged 79, died, June 15, of senility

John Jonas Kerr, Baltimore, Maryland Medical College, Baltimore, 1905, aged 55, died, June 9, of coronary thrombosis

James Atkin Sewell, Rockwood Tenn., College of Physicians and Surgeons, Baltimore 1879, aged 88, died, June 5

Alonzo Martin, Bellmore Ind., College of Physicians and Surgeons, Keokuk, Iowa 1878, aged 85, died June 14

William Clifford De Forest, Clarksburg W Va., Baltimore Medical College, 1896, aged 71, died, June 13

Ewing W Miracle, Loyall, Ky., Hospital College of Medicine, Louisville, 1898, aged 64, died, June 19

John B Huff, Taylorsville, Miss. (licensed in Mississippi in 1889), aged 71, died in June

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THESE WILL BE OMITTED ON REQUEST.

OXIDATION AND TOXIC EFFECTS OF ALCOHOL

To the Editor—1 A pamphlet issued by the National Distillers Products Corporation New York says that from 90 to 96 per cent of the alcohol taken is oxidized in the body. Is this statement true? If not what percentage is oxidized? 2 In a lecture on alcohol which I attended the speaker stated that alcoholic beverages according to one observer have produced albuminuria. 3 If this is true what is it due to and what change does this substance undergo on aging?

MD Massachusetts

ANSWER—1 The statement concerning the amount of alcohol oxidized is correctly quoted from Atwater and Benedict (*Nat Acad Sci* 8 231, 1902). However Voeltz and Baudrevel claim that as much as 12 per cent of the ingested alcohol may escape oxidation if the amount taken is large, for example 3 cc per kilogram of body weight (*Emerson Alcohol and Man* p 8).

2 Alcohol itself does not produce albuminuria although this condition is commonly found during the acidosis of delirium tremens.

3 Almost any foreign substance may gain entrance into alcoholic beverages, producing deleterious effects. Also raw distilled liquors usually contain small amounts of aldehydes such as formaldehyde, acetaldehyde, butyl aldehyde and amyl aldehyde which by proper aging are oxidized to their corresponding acids. These acids combine with alcohol to produce esters which are relatively nonirritating and nontoxic. The aldehydes in raw liquors are probably responsible for some gastrointestinal irritation but there is no evidence of kidney damage (*Emerson Alcohol and Man*, pp 211 and 221).

TOXICITY OF MATERIALS USED IN LINING BEER CANS

To the Editor—I have a patient working for the American Can Company engaged in handling chemical preparations used in lining the beer cans. He is suffering from a marked degree of secondary anemia apparently a toxic type. The preparations used are known as LAC V21B and Methyl Ethyl Kuprin (MEK) solvents each having pronounced ethereal odors. I would appreciate knowing whether any industrial hazard exists and what measures are advised as a safeguard for health. Reference to articles or experts acquainted with the subject will be appreciated.

MD California

ANSWER—In the lacquer and solvent trade MEK commonly refers to methyl-ethyl-ketone and not to methyl-ethyl-kuprin. The latter is not known as a chemical term but may constitute a particular trade name. The toxicity of methyl-ethyl-ketone is kindred in nature and extent to that of dimethyl ketone, commonly known as acetone. From animal experiments it is concluded that acetone possesses acute narcotic action stronger than chloroform. The Bureau of Mines has reported experiments in which death took place when the concentration of acetone in the air reached 110 mg per liter. Other workers such as Flury and Zernik have exposed animals to much higher concentrations without fatal outcome and apparently with increasing tolerance. Recently a group of Russian investigators (*J Indust Hyg* 18 117 [Feb] 1936) reported that acetone is more toxic than methyl alcohol under certain specific conditions. However, it is to be doubted that either acetone or methyl-ethyl ketone is correspondingly as toxic for man. Acetone being a marked solvent for fats may lead to a dermatitis from defatting but as a general rule acetone is rather freely used in various industries without unusual precautionary measures and without known cases of intoxication. However MEK is probably somewhat more toxic than acetone. Commercial products possibly may contain impurities of a character to complicate intoxication possibilities.

LAC V21B is believed to be a vinylidene synthetic resin solution prepared for the American Can Company by Stoner and Mudge of Pittsburgh. The exact nature of the material as applied to beer cans is not known. The statements now following are somewhat speculative but may serve to indicate the order of toxicity. Vinyl resins chemically are polymers derived from vinyl acetate which in turn may be derived from acetylene. These resins are likely to be primarily dissolved in substances represented by the following possibilities: hexone (2 methyl 4 pentanone), cellosolve acetate, carbital acetate, N-butyl acetate, methyl cellosolve acetate, methyl acetate, ethyl acetoacetic ester,

also methyl, 2-ethyl hexyl acetate, butyraldehyde and numerous other compounds. After solution of the resin further thinning may be accomplished through the use of a wide range of diluents, including benzene, toluene, xylene, solvent naphtha, ketones, acetates and other esters, special petroleum fractions, hydrogenated naphthas and many others. Since the solvents and thinners used conceivably may vary from time to time under conditions of special needs, it is impossible precisely to appraise the extent of health hazard. In general, it may be recognized that some degree of hazard obtains, as the vapors of no solvents are entirely innocuous. In the absence of very harmful agents such as benzene, toluene, xylene, solvent naphtha, butyl alcohol, methyl alcohol and chlorinated solvents the general order of toxicity is low and apparently may be exemplified by the toxicity of ethylene glycol, which is believed to be limited to minor respiratory tract irritation, irritation of nasal passages and eyes as commonly applied. Reference should be made to the article cited and to Hamilton's 'Industrial Toxicology,' published by Harper & Brothers in 1934. It is believed that the Division of Industrial Hygiene of the United States Public Health Service or the Bureau of Mines may best be in position to supply additional information. A somewhat pertinent article entitled 'Response of Guinea-Pigs to Vinyl Chloride Gas' by F A Patty, W P Yant and C P Waite appeared in *Public Health Reports* (45 1963 [Aug 22] 1930).

PERIOD OF POTENCY IN MAN

To the Editor—What information can you impart concerning cases coming to the attention of the family physician wherein domestic felicity is beginning to be upset by men between the ages of 50 and 70 unable to perform the sex act to the satisfaction of their wives? These men apparently have considerable prostatic involvement but not sufficient to warrant surgical procedures. Can it be truthfully stated in the office to a wife making this complaint regarding impotence on the part of her husband that married life should have been fairly well carried out in this respect if a good sized family presents itself as evidence of a family duty being carried out faithfully and sufficiently for all reasonable demands? Are we to uphold the ideas that a husband to be really in love with his wife must during his entire life be a potent cave man? Please omit name and place.

MD Maine

ANSWER—The fact that a man has been able to impregnate his wife several times during their married life is absolutely no indication that his married life has been fairly carried out. It is a common experience that men who are suffering from rapid ejaculation, that is, that as soon as the penis has entered the vagina, ejaculation takes place are repeatedly impregnating their wives without the latter experiencing any orgasm or deriving any sexual pleasure at all from the coital act. These women are in a worse situation than single girls, because they are sexually excited and are left in an ungratified sexual condition which at times reacts severely on the nervous system.

While it is not necessary for a husband to be a cave man, a normal man ought to be able to indulge in coitus satisfactory to his wife and himself, beyond the age of 50. If not, his prostatic condition (as well as other functions) should be investigated, and if as is generally the case, a marked congestion of the prostate and prostatic urethra is found this should be treated not by operation but by gentle prostatic massage and instillations of weak silver nitrate solutions into the prostatic urethra. Of course there are other pathologic conditions leading to impotence in the male which should be diagnosed and properly treated.

OPERATIONS FOR BUNIONS

To the Editor—Is the operation on the foot for removal of an enlarged joint ever successful? What are the chances of getting a stiff joint and what are its dangers?

WARREN W ALGER MD Detroit

ANSWER—It is inferred that the inquiry refers to enlargement of the metatarsophalangeal joint of the great toe, usually called a bunion. However, hallux valgus may exist without a bunion. A bunion is merely a painful and inflamed bursa while hallux valgus is a valgus deformity of the joint and often exists without any pain. There are a number of different but quite successful and useful operations for bunions and none of them should leave a stiff joint.

Each type of operation has its definite place depending on the size of the enlarged joint and to a certain extent on the type of foot. For the more severe cases the Mayo operation consisting of excision of the head of the first metatarsal and turning in the bursal sac as a flap to make a new joint is satisfactory. The foot with a long first metatarsal and great toe is better suited for the Mayo operation than is the short broad foot with a short first metatarsal and short great toe. For the less severe cases other operations are advisable such as the Lapidus operation in which the inner side of the first

metatarsal is exposed and the projecting portion of the enlarged head is excised and the base of the metatarsal is fused to the cuneiform and the second metatarsal, thus preventing spreading of the first metatarsal inward and away from the second.

There are other operations in which the enlargement and marginal overgrowths about the inner side of the head are excised. In the McBride operation the adductor tendon insertion is transplanted from the base of the first phalanx of the great toe to the outer side of the head of the metatarsal bone, the action of the transplanted adductor muscle bringing the first metatarsal toward the second and thus preventing the spread between these two bones. When this spread exists the two sesamoid bones in the flexor tendons slip over into this interspace and at each step tend to increase the distance between the metatarsals.

In mild enlargements the wearing of shoes that will cause no pressure on the head of the first metatarsal often will give relief and prevent the development of a bunion. Hallux valgus need cause no discomfort even though quite a marked deformity is present. It is the wearing of shoes that causes the trouble. The rubbing of the foot against the shoe causes a bursa to develop over the head of the first metatarsal and as it becomes enlarged, thickened and inflamed the bunion is the result. If it were possible for people to go without shoes no such bursa would be produced and the hallux valgus would be of importance only because of its unsightliness.

HOUSE DUST ASTHMA AND ABDOMINAL DISTENTION

To the Editor—A woman aged 53 has had asthma for eight years. At the onset a sensitivity to house dust was noted. An antigen prepared from house dust appeared to aggravate the symptoms and was stopped. The early relief from epinephrine was replaced by reactions to it and ephedrine although giving some relief was also unpleasant. Five or six years ago she was given one-fourth grain (0.016 Gm.) of morphine sulfate and $\frac{1}{160}$ grain (0.4 mg.) of atropine sulfate for the attacks. They are now so frequent that she may take as many as four or five such tablets hypodermically daily. For the past year her abdomen has progressively enlarged. She is extremely nervous and cannot sit quiet for more than a few seconds. Her memory is impaired. Her weight is 95 pounds (43 Kg.) which is 30 pounds (13.6 Kg.) underweight. The pupils are dilated and equal but do not react to light or in accommodation. The lungs are at times full of wheezes and rales and at other times clear. The heart is in good condition. There is a postoperative hernia in the right lower quadrant at the site of an appendectomy scar. The superficial abdominal veins are dilated. There is marked tympany. A fluid wave can at times be found. Peristalsis has been noticed once. Borborygmus is marked. Her appetite is poor but the bowels are regular and described as watery and dark. There is occasional vomiting with relief. An x-ray plate of the abdomen showed generalized distention. A barium sulfate enema could not be carried out. Is this a case of chronic atropine poisoning causing a generalized ileus? The patient is receiving 1 cc. ampules of prostigmin twice daily. Can relief be expected? The atropine has been discontinued. Will morphine alone for the attacks help? What treatment might be given to relieve this chronic distention?

MD New York

ANSWER—If the aggravation of symptoms was actually due to injections of house dust, this must be considered an important factor in the condition. Under such circumstances proper elimination of house dust by covering the mattress and pillows with rubberized covers and eliminating completely overstuffed furniture from the room should be of benefit. In addition house dust injections should be of help if used in doses below those producing aggravation of symptoms. It is generally true that an antigen which can aggravate symptoms can produce relief if properly used in the right dosage. Since the patient was studied from an allergic point of view eight years ago it is advisable to restudy her if she can be relieved for a sufficient time so that no drugs are necessary. Many drugs will interfere with the skin reactions. In addition, however it is necessary to study the patient's general medical condition. The possibility of a gastro-intestinal malignant condition or of cirrhosis of the liver is suggested. Complete gastro-intestinal x-ray and stool examinations should be made. A more specific diagnosis of the cause of the abdominal distention is necessary before any effective treatment can be given for the condition.

It is not likely that either the atropine or the morphine used is responsible for the abdominal distention described as no note is made of other symptoms of atropine poisoning (tachycardia, marked drying up of the secretions). The use of morphine to relieve asthma is contraindicated for two reasons. First, there is a real danger of death from the use of morphine in asthma because of the depression of the respiratory center. When morphine is combined with atropine, this danger is greatly increased because of its synergistic action and the drying of the bronchial secretions, making them more tenacious and therefore more difficult to bring up. The other danger from the use of morphine in a chronic condition such as asthma is that

of addiction. The most important factor in giving relief in a case of this type is several nights of sufficient sleep. Chloral hydrate is frequently effective. After such rest is obtained, epinephrine solution subcutaneously used frequently (every two hours if necessary) in the minimum dose to produce relief will often work even in the face of previous failure.

CARDIAC ARRHYTHMIA AND INSURANCE

To the Editor—A man aged 29 was recently rejected for life insurance because of a cardiac arrhythmia. His past history is negative for all infectious diseases and symptoms of myocardial disease. Physical examination does not reveal evident foci of infection. There is no cardiac enlargement or murmurs. The pulse rate averages eighty beats per minute with about twenty-two premature contractions which always disappear with exercise only to return on rest. The blood pressure is 118 systolic 80 diastolic. Fluoroscopic examination of the chest is negative. An electrocardiogram reveals no structural disease and no other abnormalities except the ectopic beats. The Wassermann reaction is negative. Since he is entirely symptomless (except for the anxiety resulting from his rejection for insurance) is any treatment indicated and if so what? Is smoking contraindicated despite the fact that complete abstinence for months did not alter this condition? Would the condition have any bearing on his longevity? Would he be considered a bad risk if insured?

MD New Jersey

ANSWER—No treatment whatever is indicated in this case. With the examination as negative as it is, there is no reason for assuming an organic basis for the premature ventricular contractions. If absence from smoking for several months did not alter the condition, there is no reason for giving up smoking except that equally there is no reason for smoking. The premature ventricular contractions of themselves would not have any bearing on the longevity of the patient. It has been shown that the minute volume in these cases is not decreased, and if there are no organic changes responsible for the premature ventricular contractions there is no reason why he should not be considered a good life insurance risk.

DIABETES

To the Editor—Please give me a definition of diabetes mellitus. How many grams of dextrose in the form of a balanced diet must a patient successfully metabolize in twenty-four hours to be considered nondiabetic?

MD Louisiana

ANSWER—In a recent monograph on diabetes (Joslin, E. P. *The Treatment of Diabetes Mellitus*, Philadelphia: Lea & Febiger, 1935) the disease is defined as follows: "Diabetes is an hereditary disease, characterized by an increase of sugar in the blood and the excretion of sugar in the urine, it is dependent upon disease of the pancreas, particularly of its islands of Langerhans, which are functionally interrelated with other endocrine glands and the liver, the secretion of the islands of Langerhans, insulin, not only promotes the normal accumulation of glycogen in the liver, muscles and skin, and the combustion of glucose in the tissues, but also exerts a control upon the metabolism of protein and fat."

No exact number of grams of dextrose even with a balanced diet could be given to prove a patient nondiabetic. Too many other factors enter into the problem. The following statement, taken from page 249 of the last edition of the same monograph might furnish the information desired.

Test for Recovery—Glycosuria and hyperglycemia shall be absent, while the patient is without diabetic medication both before and an hour after a meal. This meal must contain at least two-fifths of the carbohydrate for the day. The carbohydrate for the twenty-four hours shall comprise at least two-thirds of the calories necessary to provide 30 calories per kilogram body weight. Better still, the carbohydrate tolerance shall be unimpaired as judged by a normal glycemic curve following the oral administration of 50 to 100 grams of glucose to the patient in the postabsorptive state.

Establishment of Recovery—A proved case of one or more months duration, which conforms to the test for recovery at the beginning and end of an interval of five or more years shall be considered cured."

As an introduction to the foregoing statements occurs this paragraph:

Curability of Diabetes and Criteria for Cures—It is yet too early to state that recovery from diabetes takes place. Just as a time limit is set before one speaks of recovery from cancer, so it should be in diabetes. But the problem in diabetes is not so easy as in cancer. A cure from cancer dates from the day of operation in a diabetic's story no such definite date is available. Quite arbitrarily, therefore the writer proposes the following standards to which cures from diabetes should conform and by which they should be classified:

URTICARIA AND PYURIA

To the Editor—A man aged 58 has had chronic urticaria for the past five years. Shortly before the hives made their appearance pus was found in his urine. This condition has persisted along with the hives. At times he has had chills and fever when urinary dyes such as pyridium (phenylazo-2,6-diaminopyridine monohydrochloride) were administered. The patient is a dynamic high pressure type of individual. Many urticarial lesions are present at all times in their various stages. His teeth reveal a moderate degree of pyorrhea; the tonsils have been removed and a general physical examination was otherwise essentially negative. The laboratory studies included blood count, the routine serologic test for syphilis and x-ray examinations of the chest and gallbladder, all of which revealed nothing of importance. A test meal revealed normal gastric acidity. Skin tests for hypersensitivity to foreign proteins were all negative. Urinalysis revealed the presence of pus from 200 to 300 cells per low power field in all examinations. The prostate is not enlarged but the smears also revealed the presence of pus. I have felt that the nervous element and the pyuria are the important factors in the production of the patient's urticaria. All the urinary antiseptics have been tried in an attempt to clear the genito-urinary tract. Elimination diets have been tried. The patient has received all the known forms of therapy and each time the result has been disappointing. I should like to have your comments on this case. Do you feel that a cystoscopic examination is indicated?

M D New Mexico

ANSWER—With regard to the appearance of such large quantities of pus in the urine of this patient a complete urologic investigation should be instituted. First of all an excretory urogram should be made and then a cystoscopic examination with catheterization of both ureters. The specimens from the kidneys as well as the one from the bladder should be stained for the ordinary infecting organisms and also for acid-fast organisms.

With regard to the urticaria and its relationship to the pus in the urine it is difficult to state whether or not there is any connection between the two conditions. There is a form of urticaria which is on an infectious basis, but this is an extremely rare condition.

MICROCEPHALY

To the Editor—I delivered a baby Dec 31 1935 with microcephaly. The fontanel closed soon after birth and the baby appears perfectly normal otherwise. She was the second child and was delivered as a vertex presentation without forceps. Both parents have negative Wassermann reactions, and there is no history of any importance in their families. The baby has been examined by two child specialists who advised that nothing can be done and that it is not an extreme case. To satisfy the parents I am writing for any possible suggestion that may be of benefit.

A P GUTTMAN M D Winnipeg Manito

ANSWER—In microcephalic infants it is usual for the fontanels and the sutures to be closed at birth or shortly thereafter. In these cases there is usually arrested development of the brain or it may be imperfectly formed in portions or degenerated. A condition of microgyria (abnormal smallness of the convolutions of the brain) is frequently observed. The mental power of these infants is defective; muscular rigidity is sometimes present, and convulsions may occur.

When the microcephalus is of only slight degree, spasticity does not occur and some mental development may take place. It is obvious that a patient with a small cranium containing a small brain with retarded growth is not amenable to treatment. Craniotomy has been tried though without benefit.

SHOULDER INJURY

To the Editor—Two months ago a man aged 53 was struck on the shoulder by a heavy bag. A subglenoid dislocation took place without fracture but the circumflex nerve was injured. The dislocation was replaced easily but there is no sign of nerve regeneration as yet. There is an area of numbness over the deltoid some muscle wasting and an inability to extend the arm from the body. What treatment would you advise and what is the prognosis? Please omit name.

M D Wisconsin

ANSWER—Before answering the question satisfactorily it would be necessary to determine the degree of fixation from pericapsular adhesions that now are present in the shoulder. A severe injury to the shoulder of a person more than 40 years of age commonly leads to a rather marked degree of limitation of humeral scapular motion. If such limitation of motion is present the adhesions should be broken up by manipulation under complete anesthesia. After this manipulation or if there is no limitation of motion this arm should be placed in the strap-hanger position (90 degrees abduction and 180 degrees external rotation) by means of a splint. This position relaxes tension on the nerves and the muscles which are necessary for abduction, external rotation and extension of the arm from the body.

The splint should be worn for at least six weeks but should be removed for an hour each day during which time heat and

massage may be employed and the arm gently moved through as much of a range of motion as is possible without occasioning severe pain.

Unless the clinical examination indicates a rupture or avulsion of the tendon of the supraspinatus muscle, open operation is not indicated. Better results and a greater degree of recovery following a crushing injury or partial avulsion of the nerves that supply the shoulder muscles will be obtained if the more conservative program is adhered to. Prognosis for a useful shoulder after three or four months may be considered a reasonable expectation.

WEIGHT REDUCTION

To the Editor—A man aged 42 whose height is 67 inches (170 cm) and weight 210 pounds (95 kg) reports that he must of necessity reduce his body weight to 172 pounds (78 kg) by July 1 in order to meet the physical requirements of the position he now holds. He has always enjoyed the best of health, his weight has remained around 200 pounds (91 kg) continuously for the past twenty years and his appetite is moderate. His position necessitates a moderate amount of physical exercise. Physical examination is negative; the blood sugar and basal metabolic rate are normal and the blood pressure is 122 systolic/80 diastolic. He does not present the picture of obesity but rather one of a well proportioned stocky muscular individual. Please comment on any possible dangers in the contemplated reduction in body weight and any medication that may be used to supplement diet and exercise.

M D Maryland

ANSWER—Authorities in nutrition and life insurance companies have taken the position that the best approach to an estimate of the ideal weight of the body is to permit a 10 per cent deviation from the weights given for height and age in the actuarial tables. In stocky persons the weight is considered satisfactory if it is 10 per cent over the figure in the actuarial tables.

In the case cited, the man being a "well proportioned stocky, muscular individual," 170 pounds (77 kg) might be considered as the ideal weight. Therefore it would be unwise for this person to reduce more than to 170 pounds but it should not be dangerous to effect this degree of reduction.

The treatment of obesity is ineffective unless the calories of the intake are lowered significantly below the requirement for the twenty-four hour metabolism. The rate of reduction will depend on how small the intake of calories is. Recently it has become the practice of many physicians to supplement low calorie diets with a vitamin concentrate and calcium phosphate. Detailed directions for such a procedure are given by Russell M. Wilder (*The Treatment of Obesity, Internat Clin* 4:1 [Dec] 1933).

PREMENSTRUAL ASTHMA

To the Editor—A patient is suffering from asthma. She is sensitive to many foods and to timothy. Her worse attacks and those most intractable to treatment however are present during the week preceding the menses. At this time the asthma increases in severity reaching a maximum on the day preceding or the first day of the catamenia. There have been two pregnancies. The first terminated in the birth of a son about nine years ago and was accompanied by complete relief from asthmatic attacks which returned within two weeks from the time the patient left the hospital in other words at the first postpartum menses. A second pregnancy during the past summer which terminated at the fourth month showed a similar state of affairs while it endured. What prospect of cure of these attacks (premenstrual) is held out by x-ray sterilization and what clinical background is there for such treatment?

M D Connecticut

ANSWER—Unfortunately, we know of no statistical inquiry on a sufficiently large number of patients to supply us with a good answer to the question. The problem is similar to that in cases of severe migraine especially when it comes premenstrually and disappears during pregnancy. From an unpublished investigation of a fairly large series of cases of this type of migraine it appeared that an artificial menopause brought relief to about a third of the patients. The impression was that relief was obtained more often by the older women who were about due for a menopause anyway.

Some physicians who have experimented with the induction of the menopause in patients with premenstrual asthma have not been encouraged by the results and unfortunately, in a number of the cases the condition was worse. In deciding what to do one must take into account at least two things: one the present age of the patient, and the other her nervous and psychic status. Asthmatic patients are commonly unstable and unstable women often have a stormy menopause. A stormy menopause is more likely to make asthma worse than to cure it.

Doubtless efforts have been made to give this woman relief by administration of an estrogenic preparation. Occasional patients have been helped in this way. An effort might be

made also to raise the nervous threshold before the menstrual period by prescribing rest and perhaps a little phenobarbital.

Probably in these cases three factors unite to produce the asthmatic attack: one perhaps a dust or other allergen, another, an increased irritability of the nervous system and third, perhaps some toxic internal secretion. One is reminded of the cases of asthma in which in the fall certain pollens plus some food such as wheat will unite to produce the bronchial spasm. At that time the removal of wheat from the diet will bring relief. At other times of the year, when pollen is absent, wheat can be eaten with impunity.

LOSS OF HEARING AFTER ELECTRIC SHOCK

To the Editor—A patient received a minor shock by coming in contact with an electric wire. There was no loss of consciousness. He claimed no injury except complete deafness of the left ear beginning immediately after the shock was sustained. Deafness of the right ear had been present long before as a result of chronic purulent otitis media. Examination of the left ear on the day following the injury revealed complete conduction deafness for Hartmann's tuning forks but all the forks were heard by bone conduction. The left ear drum was normal and there were no signs of labyrinthine involvement. The left eustachian tube was normal. There was no history of previous trouble with the left ear. The condition has remained unchanged during the past several months. Is it likely that the electric shock caused this condition?

M D West Virginia

ANSWER—It is possible that an electric shock of great intensity might involve the auditory nerve. Judging from the history in this case, in that there was "no loss of consciousness" and "merely a minor shock," it is difficult to make a definite statement. The fact also that there were no signs of labyrinthine involvement, and that bone conduction is still preserved, would incline one somewhat to the conclusion that no serious injury was sustained. It is possible, of course, that the bone conduction is perceived by way of the right ear, which has had a chronic purulent otitis media.

PIRETHRUM OINTMENT IN SCABIES

To the Editor—I am advised that pyrethrum ointment is effective in the treatment of scabies. Will you comment on the suggested use of the widely used fly and insect spray fluids said to consist of a light petroleum oil impregnated with pyrethrum extract in the treatment of scabies? Is there any danger in its use? It would seem to be readily available, inexpensive and an acceptable means of treating this often embarrassing infestation.

H S BUCKINGHAM, M D Berwick, Pa

ANSWER—Pyrethrum ointment, which is usually prepared by dissolving from 25 to 30 per cent of pyrethrum extract in liquid petrolatum and then incorporating this in an inert ointment base, has been used in the treatment of scabies. It is stated that the physician may encounter a sensitivity to pyrethrum in "no more than one case in six hundred."

The widely used fly and insect spray liquids usually consist of ground flowers from which the pyrethrum is extracted with a petroleum distillate. "To this distillate extract are added 'camphor-sassafrassy,' methyl salicylate and traces of other compounds, the result being a powerful insecticide, the strength of which is standardized by testing on insects. A similar extract of pyrethrum flowers made with a heavier petroleum distillate and di-ethyl phthalate is made to use as a cattle spray to repel flies" (Skin Hazards in American Industry, Pub Health Bull 215, Washington, D C, p 52).

Cases of dermatitis have been reported from contact with these insecticides. The sensitivity in some of the cases tested was to the Japanese insect flower from which the pyrethrum was extracted and to the petroleum distillate. In the report mentioned, twenty cases of dermatitis occurred during a period of two years in a factory employing about 100 people. This indicates a high degree of sensitivity as compared to the use of pyrethrum ointment and would make it dangerous for general use.

VISCOSITY OF BLOOD IN HYPERTENSIVE DISEASE

To the Editor—Is there an increase of viscosity of the blood in high blood pressure cases? Many authors assert that there is and some do not. I should like to know the latest thought on the subject.

CHARLES PER, ROEBI S M D Winona Minn

ANSWER—The general consensus is that in hypertensive arterial disease appreciable and significant increase in the viscosity of the blood does not occur. This statement applies to hypertensive arterial disease, but there are hypertensive states in which increased viscosity is presumed to be a factor. In the rare condition polycythemia vera hypertension is common and is considered to result from the increased friction offered the flow of blood. In one series of cases of arterial

hypertension this accounted for one case in 750. The hypertension associated with eclampsia and preeclampsia may be due in part to greater blood viscosity, although arterial spasm is responsible for the greater portion of the rise. In eclampsia the blood is highly concentrated and more viscous than normal. These two exceptions to the general rule however, must not be considered as being hypertensive arterial disease (so called essential hypertension).

FRIEDREICH S ATAXIA

To the Editor—Have you anything in your files on the treatment of Friedreich's ataxia? There is nothing given in textbooks unless there is something newer than textbooks possibly in exercises or therapy. If anything is available where? I have a patient here with this and the parents would at least like to try something if it has any possible merits.

ARTHUR J GRIOT, M D Chadron, Neb

ANSWER—This disease is chronic, it is familial, and it usually occurs in pairs in sisters or brothers. The prognosis for life is good and for cure is poor. The only treatment outside of symptomatic therapy that can be recommended is that for the ataxia. This is usually carried out by means of reeducation exercises, starting with simple maneuvers and gradually increasing to more complicated exercises. The amount of change that may take place in the ataxia will of course depend on the extent of the damage to the cerebellar and spinocerebellar tracts. Goldscheider in an article entitled "Anleitung zur Uebungsbehandlung der Ataxia" Leipzig, 1904 has collected and described the Frenkel exercises very clearly. One should not become too enthusiastic with regard to these exercises because they do not cure the disease. The parents should be informed of this point.

TUTOCAIN HYDROCHLORIDE IN SEASICKNESS

To the Editor—Will you kindly inform me of the use of tutocain in the external auditory canals (and ear drums) for the prophylaxis and treatment of seasickness? Some time ago an article appeared in *Time* magazine about its use with almost magical results and if such really is the case I should like to be in on it.

JOHN SEALY PEEK M D, Brownsville Texas

ANSWER—Tutocain hydrochloride is used to produce local anesthesia on mucous membranes. As the mechanism whose stimulation produces vertigo and seasickness consists of the semicircular canals and other structures of the vestibular mechanism in the inner ear, it is inconceivable how instillation of a solution of tutocain into the external auditory canal or against the drum membrane can in any way influence the static apparatus. From time to time miraculous measures are cited or medicaments proclaimed for use in the prevention or relief of seasickness. While it is true that sedatives taken internally may lessen the sensitivity of the vestibular mechanism to a certain degree, the greatest measure of relief as a rule is found in having the individual lie perfectly flat. Then with the rolling of the boat only the horizontal canals will be stimulated rather than the vertical, and it is the latter whose stimulation gives the greatest degree of vertigo. As stated before, the local application of tutocain or any similar drug to the external auditory canal would not be likely to have any beneficial effect.

COMPENSATION IN EYE INJURIES

To the Editor—I am writing to you for information concerning a compensation case. A man, aged 29 whose left eye is normal injured his right eye about a year ago and since that date a cataract has slowly developed. What improvement should I expect from an extraction and proper refraction of this eye? Also from an industrial standpoint is this operation advisable?

JAMES W FRAZIER M D Charleston, W Va

ANSWER—This brings up a much discussed question that has never been decided satisfactorily. From the ophthalmic standpoint, removal of the traumatic cataract is advisable for several reasons. 1 It provides a good reserve eye in case of accident to the other. 2 It permits of lateral vision beyond the field of the other eye, which vision, although not clear, is of use. 3 It prevents the amblyopia of disuse. In contrast to these advantages, there is the possibility of subsequent diplopia, a rather rare occurrence, but extremely unpleasant when it does happen. Of course, the two eyes cannot be used simultaneously, although work now under way is in the direction of providing a minimizing glass for the eye that has been operated on which will permit of the simultaneous use of an aphakic and a nonaphakic eye. From an industrial standpoint the operation is advisable. From a compensation standpoint the boards do not differentiate between an eye with a traumatic cataract and the same eye with the lens removed, regardless of the final vision.

TOXICITY OF SOLDERING PROCESS

To the Editor—During the last few weeks I have been seeing several patients with upper respiratory symptoms who have been working with a soldering sal that is manufactured by the L. B. Allen Manufacturing Company of Chicago. This particular preparation in soldering casts off fumes that are quite irritating in the nasal and respiratory passages. Will this preparation the contents of which I do not know cause any chronic condition from prolonged exposure? Also would there be any scientific way of eliminating its immediate irritation?

J W EBERT MD Everett Wash

ANSWER—This reply is without particular reference to any one product. Soldering is such a general term that its mere mention fails to reveal the type of operation that possibly may be involved. Soldering may be hard (brazing) or soft (usually with lead and tin), soldering may unite copper, lead, tin, zinc, iron or aluminum. In each instance different fluxes may be employed. The assumption is that the soldering leading to this query makes use of the customary lead and tin mixture. In this case the flux may be a liquid paste or salt. The salt in commonest use is zinc chloride. Zinc chloride fume may be produced but more likely the fume of hydrochloric acid is present. Such fume is irritating to the respiratory tract. Acute inflammatory disease may arise and is common among solderers. Near sighted persons working closely at hand soldering are especially apt to become involved. No specific chronic disease is known to arise—rather an endless series of repeated minor acute episodes. Conditions are now much better in this trade, owing to an increased extent of automatic soldering. Suction systems can be so constructed as to remove the irritant fume at the point of origin.

HEMIPLEGIA AFTER ELECTRIC SHOCK

To the Editor—A man aged 55 received 2,300 volts while repairing an electric transmission line. His face was burned and his forehead and ears became swollen and there was a discharge for several months. Six months later a right sided hemiplegia developed. From a legal standpoint what connection does this accident have directly or indirectly on this hemiplegia?

MD Indiana

ANSWER—The amount of injury caused by electric currents depends on the voltage and ohmic resistance, on the duration and extent of the contact, and also on the presence of clothing or gloves. The query does not state whether there was unconsciousness, slow pulse, vomiting convulsions or twitchings. In exposures to electric current, transient paralyses may follow the convulsions or appear in their absence. The paralytic signs may not be evident at once but develop gradually weeks or months after the accident. If one can show a causal relationship between the electrical exposure and the onset of cerebral symptoms at once or very soon after the accident, one may say that the hemiplegia was the result of multiple small hemorrhages and softenings in the brain superinduced by electricity.

TONSILLECTOMY IN SYPHILIS

To the Editor—What contraindication would there be if there is any at all to tonsillectomy in a girl aged 18 years who has been receiving arsenicals during two months for a positive Wassermann reaction? It has not been definitely determined whether infection was acquired or congenital. The general condition of the patient is very good.

MD South Carolina

ANSWER—For many years the consensus has been that no operation of the throat should be performed during the time the Wassermann reaction is positive. In an emergency, of course, an operation might be undertaken the patient carefully watched at that time, and treatment vigorously carried out. But a tonsillectomy is certainly no emergency, and therefore the operation should be done only if the Wassermann reaction is negative.

PNEUMOPERITONEUM

To the Editor—In pneumoperitoneum that is introduction of air inside the peritoneal cavity, how do we know that the tip of the needle is already free in the peritoneal cavity? Kindly give me information as to the manometer readings.

JOSE A MENDIOLA MD Pateros Philippine Islands

ANSWER—The simple method is to employ a syringe with a fine cannula, filled with physiologic solution of sodium chloride. The needle is cautiously inserted and at the same time pressure is made on the piston of the syringe. Prompt flow of the saline solution indicates that the needle has reached the abdominal cavity. With the patient turned on one side preferably the right, the site of puncture is chosen in the middle of the rectus muscle from 3 to 5 cm below the umbilicus. The bladder should be emptied just before the insertion

of the needle and the skin thoroughly cleansed with tincture of iodine. The needle is slowly advanced as far as the fascia, when very gentle pressure will ease it through the fascia and the peritoneum into the peritoneal cavity.

BOOKS ON ELECTROTHERAPY AND ELECTROCOAGULATION

To the Editor—What books do you recommend for (1) electrotherapy (2) showing methods of removal of warts by electrodesiccation (3) treatment of ulcer of the skin by electrocoagulation and (4) electrocoagulation of the tonsils.

E S COSTER MD Solomons Md

ANSWER—The following books are recommended to cover the points mentioned.

Kovacs Richard. *Electrotherapy and Light Therapy*. Philadelphia Lea & Febiger 1935 \$7.50 reviewed in THE JOURNAL Feb 8 1936 p 492.

Handbook of Physical Therapy. Chicago American Medical Association 1936 \$2.

Mock H E. *Principles and Practice of Physical Therapy*. Hagerstown Md W F Prior Company 1934 vol 3 \$35 reviewed in THE JOURNAL April 7 1934 p 118.

Andrews G C. *Diseases of the Skin*. Philadelphia W B Saunders Company 1930 \$12 for removal of warts by electrodesiccation p 879 and treatment of ulcer of the skin by electrocoagulation chapter 10 p 251.

TOLERANCE TO ETHER

To the Editor—A dental surgeon has asked me to test an asthmatic patient for ether before he attempts the extraction of many abscessed teeth. Is there any way of doing this except by starting an anesthesia? Is a person ever allergic to ether? This patient is slightly allergic to procaine hydrochloride.

MD Illinois

ANSWER—The best way of testing a person's tolerance for ether is to administer by inhalation a very small quantity diluted. Certain persons may not tolerate ether but they are not known to be allergic to it, for example, soldiers who have been gassed in warfare do not tolerate ether well but show no evidence of allergy to it. The fact that the patient is slightly allergic to procaine would not indicate that there would be a tendency to be allergic to ether.

CONTROL OF EFFECTS OF PERIVASCULAR INJECTION OF CALCIUM CHLORIDE

To the Editor—Kindly let me know what has been found most effective to control the pain and the sclerotic effect produced by the accidental perivascular injection of a 10 per cent solution of calcium chloride.

MD Los Angeles

ANSWER—Whenever an irritative intravenous injection, such as that of calcium chloride, is given, one should have at one's elbow a dish of sterile water, which might contain a small proportion (0.1 per cent) of procaine. Should perivascular injection occur one should inject immediately and through the same needle enough of this fluid to distend the tissue liberally so as to dilute the noxious solution as much as possible. It is of course advisable, before doing this to aspirate as much of the paravenously deposited fluid as one can.

BLOOD TYPING

To the Editor—1 In what type or group of direct blood matching is the probability of error most commonly encountered? 2 In the event that a small spot of blood approximately one-fourth inch in diameter was found on a piece of cotton or silk and rayon material and such a spot had been on this garment for a period of ten to twelve days and then the material had been placed among dirty clothes and then exposed to some sunlight and heat of normal temperature in a residence with some dampness usually found in a basement of such residence what is the probability of error in typing this blood and is there more probability of error in typing I II III or IV Moss classifications? 3 Is there any possible way of determining the type of blood on a piece of cloth that has been washed in water the red stain remaining?

V L CHAMBERS MD Huntington W Va

ANSWER—1 In the hands of competent investigators there should be no error in blood typing at all. The most frequent mistake is to assign incorrectly a blood to group AB owing to failure to recognize pseudo-agglutination. On the other hand, blood of group AB, particularly the subgroup A B may be taken for group B by overlooking weak A reactions.

2 Under the conditions described, the determination of the blood group may be difficult or even impossible. However a mistake should not be made because the absence of any positive reaction would not warrant a conclusion. In other words unless a clear cut result is obtained no opinion can be offered.

3 The determination of the blood group will probably not be feasible in such material.

EFFECTS OF TOBACCO ON CIRCULATION

To the Editor—Would tobacco be a possible etiologic factor in occasional numbness of the distal parts of both upper and lower extremities, coming on as an exaggeration to a similar numbness caused by cramped positions in healthy individuals? Does tobacco contribute to impairment of the vestibulomotor system causing periodic dizziness noted particularly while in the act of smoking? Does it cause labyrinthitis? (It is assumed that patients complaining of these symptoms are what would be considered excessive smokers)

M D, Ohio

ANSWER—The act of smoking tobacco causes diminution of the circulation to the extremities and might in certain hypersensitive individuals be responsible for the symptoms of numbness of the acral parts. It should not, however, be considered an etiologic factor until all other possibilities have been surveyed. Many persons who smoke have noted a sensation of dizziness and unsteadiness of gait while smoking. Excessive smoking might stimulate the labyrinths but it is not certain that it might produce definite organic changes, although amblyopia from tobacco smoking is well known.

JOINT PAINS IN SERUM SICKNESS

To the Editor—In THE JOURNAL, Nov 28, 1936 on page 1830 you published a letter concerning atrophic arthritis contracted through serum disease. In your answer you made the statement that joint pains have been known to exist for quite some time following serum sickness. Will you kindly let me know by letter what your authorities are for that statement and for what lengths of time joint pains have been known to continue.

M D New York

ANSWER—The statement with reference to the length of time which joint pains may persist following serum disease was confusing. A careful search of the literature shows that they usually last but a few days and rarely as long as three weeks. In an occasional case the joint pains, without swelling, occurring during a serum reaction have persisted longer.

PRECIPITIN SERUM FOR TESTING FOR HUMAN BLOOD

To the Editor—I am writing you for some information. Police officers submitted several bits of flesh and bone marrow to me for examination. To make possible identity as to whether bits of flesh were of human origin or not, I purchased human precipitin serum which was used in the test. The results were not satisfactory. Can human precipitin serum be purchased to be used for determining the identity of human blood? If you would make suggestions on how this examination should be handled I would be grateful.

HARRY FALCONER, TECHNICIAN, SIOUX FALLS, S D

ANSWER—Precipitin serum for testing for human blood can be purchased. The potency of such serum must be determined beforehand in every case in which it is used. Directions for the preparation of precipitin serum are given in textbooks on immunology, see also Hektoen, Ludvig. The Precipitin Test for Blood, THE JOURNAL, May 4, 1918, p 1273, and Biologic Tests for Medicolegal Purposes, NEW ENGLAND J MED 199 120 (July 19) 1928.

DESENSITIZING TO MOSQUITO BITES

To the Editor—Do you know of any material that can be given orally or by injection which will desensitize persons to the undue effects of bites by mosquitoes? I am referring to the toxic manifestations of the bite itself.

ELMORE R BAILEY, M D, Lakewood Ohio

ANSWER—There have been many attempts to desensitize man to the ill effects due to bites of the mosquito and in a high percentage of these tests the results have been entirely negative. There are no successful preparations available, for either oral or hypodermic use, which will diminish the intensity of reaction following the bite. Most persons seem to acquire considerable resistance after frequent bites, and reactions are usually less severe late in the mosquito season than early.

CYSTITIS WITH IMPOTENCE

To the Editor—With reference to the question sent in by a physician from Illinois entitled Cystitis with Impotence—Addiction to Hypnotics (THE JOURNAL August 14 p 527) I wish to take exception to the answer given to the doctor's inquiry regarding the first patient (cystitis with impotence). In the first place nowhere in the answer do you suggest that an attempt be made to make a definite diagnosis in other words a complete cystoscopic examination. Here is a patient 53 years of age with about 1 1/2 ounces of residual urine. This may easily indicate a middle lobe enlargement of the prostate or at least a median bar. I believe a very good way to get any drug into disrepute is to recommend its promiscuous use such as has been done here with ammonium mandelate without careful investigation of the patient's genito-urinary tract.

JAMES H BORRELL, M D, Buffalo.

Medical Examinations and Licensure

COMING EXAMINATIONS

STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in THE JOURNAL September 4 page 814.

NATIONAL BOARD OF MEDICAL EXAMINERS

NATIONAL BOARD OF MEDICAL EXAMINERS Parts I and II Sept 13 15 Ex Sec Mr Everett S Elwood 225 S 15th St Philadelphia

SPECIAL BOARDS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY Written examination for Group B applicants will be held in various cities throughout the country in April. Oral examination for Group A and B applicants will be held at San Francisco in June. Sec Dr C Guy Lane 416 Marlboro St Boston.

AMERICAN BOARD OF INTERNAL MEDICINE Written examination will be held in different centers of the United States and Canada Oct 18. Chairman Dr Walter L Biering 406 Sixth Ave, Rm 1210 Des Moines Iowa.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY Written examinations and review of case histories for Group B candidates will be held in various cities of the United States and Canada Nov 6 and Feb 6. Application must be filed at least sixty days prior to these dates. General oral clinical and pathological examinations for all candidates (Groups A and B) will be conducted in San Francisco June 13 14. Application for admission to Group A examinations must be on file before April 1. Sec Dr Paul Titus 1015 Highland Bldg Pittsburgh (6).

AMERICAN BOARD OF OPHTHALMOLOGY Chicago Oct 9 and San Francisco June 13. All applications and case reports, in duplicate, must be filed at least sixty days before the date of examination. Sec Dr John Green 3720 Washington Blvd St Louis Mo.

AMERICAN BOARD OF ORTHOPAEDIC SURGERY Los Angeles Jan 14 15. Sec Dr Fremont A Chandler 6 N Michigan Ave Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY Chicago Oct 8 9. Sec Dr W P Wherry 1500 Medical Arts Bldg Omaha.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY New York Dec 28 (tentative). Sec Dr Walter Freeman, 1028 Connecticut Ave, N W Washington D C.

AMERICAN BOARD OF SURGERY Part I (written) Oct 20. Sec Dr J Stewart Rodman 225 S 15th St Philadelphia.

Louisiana June Report

Dr Roy B Harrison, secretary, Louisiana State Board of Medical Examiners, reports the written examination held at New Orleans, June 3-5, 1937. The examination covered 12 subjects and included 100 questions. An average of 75 per cent was required to pass. One hundred and forty nine candidates were examined, 148 of whom passed and one failed. Ten physicians were licensed by reciprocity. The following schools were represented:

Book Notices

The Fundamentals of Electrocardiographic Interpretation By J. Bailey Carter M.D. Clinical Instructor Department of Medicine Rush Medical College the University of Chicago With a foreword by Horatio Burt Williams M.D. Dalton Professor of Physiology College of Physicians and Surgeons Columbia University New York Cloth Price \$4.50 Pp 326 with 251 illustrations Springfield Illinois & Baltimore Charles C. Thomas 1937

This new book on clinical electrocardiography has been prepared for the beginner in the subject. Its arrangement is good and its text is clear and simple. The case histories in chapter XXXIII, the glossary and the bibliography of recent contributions to electrocardiographic literature arranged according to subject (for example, alternation, angina pectoris, diphtheria, low voltage, nicotine and T wave) should be especially useful. The book begins with a statement of the value of the electrocardiogram in clinical practice, goes on to discuss the principles and technique of electrocardiography, and presents the normal waves, or complexes, and the intervals between them, in the first section of the volume, comprising thirty-five pages. The second section, comprising nearly a hundred pages, deals with the individual wave changes or abnormalities, axis deviation and ventricular preponderance and the various arrhythmias, including disturbances of conduction of all kinds. A third part of the book of some sixty pages discusses the electrocardiographic observations in various clinical conditions, beginning with coronary occlusion in chapter XXII and including a chapter on chest leads. The book closes with a chapter on the clinical value of electrocardiography, twenty-five brief case histories with illustrative electrocardiograms, an appendix on certain technical aspects of electrocardiography, a glossary, and a bibliography of seventy-five pages.

The weakest part of the book is its illustrations, in which it should be strongest. There seem to be far too many. One hundred excellent, well selected characteristic electrocardiograms, including some of those already in the book, would be preferable to the bulk of the present 240, a good many of which are distinctly mediocre or practically duplicates, and a few open to question as to interpretation. With fewer illustrations there would doubtless be the added advantage of a lower price for the book. Incident probably to the multiplicity of illustrations, a few errors have crept in, for example, figure 143 is reversed from left to right.

The author follows the classic opinions throughout most of the book, incidentally holding to the old view concerning the axis deviation of bundle branch block and premature beats. He makes too much, however, of very slight slurring of the QRS waves, as in figures 43, 74 and 176, which most workers in the field would now consider within the range of normal and not evidence of myocardial damage. Also he makes too much of the so-called Q wave in lead 3, which is a not uncommon occurrence in the case of obese but otherwise normal adults. One might take exception to a few statements such as that "thrombosis is the commonest cause of interference with the coronary circulation," page 129 (undoubtedly atherosclerosis with narrowing of the coronary artery lumen holds that role long before thrombosis takes place), and regret the omission in chapter XXIII of the contribution of Thomas Lewis and of Frank Wilson to the study of chest leads between the early days of electrocardiography and the routine introduction of the chest leads in 1932. For the most part, however, one may attest to the soundness of the text, which in its conciseness and clearness should be helpful to the beginner in electrocardiography.

Manuel de biochimie Par Pierre Thomas de l'Institut Pasteur professeur de chimie biologique à la Faculté de médecine de Cluj. Cloth Price 180 francs Pp 978 with 51 illustrations Paris Masson & Cie 1936

This book is intended for physicians, biologists and those for whom biochemistry is 'an indispensable science'. The introductory chapter gives some of the modern views on atomic and molecular structure, valence and isotopes without the development of the fundamental facts in supporting them and without emphasis on their biologic significance. The chapter on the colloidal state has practically no application to biology. The author develops the idea of the building up of molecules of high

molecular weight, such as proteins, polysaccharides and isoprene polymers, and a consideration of their x-ray structures. One wonders what this treatment can mean without first developing the organic chemistry of the simpler units of these colloids. The same criticism may be made of the too early presentation of special chapters on adsorption, surface tension, viscosity, osmosis, Donnan equilibrium, catalysis, cell permeability, enzymes and enzyme action. A series of excellent chapters cover the chemistry of amino acids and proteins, phospholipins, cerebrosides, carotenoids, sterols, fats and carbohydrates, and the distribution and function of inorganic elements in tissues and body fluids. The third part of eight chapters is devoted to the synthesis of tissue constituents and to their utilization. Here is a good treatment of the synthesis of carbohydrates and proteins in plants. There are separate chapters on the formed elements of the blood, the blood plasma, the vitamins, the hormones, digestion, muscle chemistry, the nervous system, the skin and skeleton, the reproductive organs, excretory products in animals and plants, with special emphasis on glucosides, terpenes, tannins and alkaloids. On the whole, the subject matter is presented clearly. The least satisfactory chapters are on vitamins, hormones and digestion. Each chapter is followed by instructions for a limited number of preparations and of qualitative and quantitative experiments. In most cases these instructions are given too briefly and uncritically to be of specific value. The author does not cite the specific references, but at the close of most chapters he gives a list of general works or monographs. These recommendations do not appear to be the best for critical consideration. The book is well indexed.

New and Nonofficial Remedies 1937 Containing Descriptions of the Articles Which Stand Accepted by the Council on Pharmacy and Chemistry of the American Medical Association on January 1 1937. Cloth Price \$1.50 Pp 557 Chicago American Medical Association 1937

The substantial row formed on the library shelf by the successive volumes of *New and Nonofficial Remedies* represents a valuable service to the medical profession for more than thirty years. *New and Nonofficial Remedies* is being used by various purchasing agencies, hospital superintendents and others as a guide in authorizing purchases of nonofficial drugs. Somewhat paradoxically, a great many brands of official preparations are listed as "acceptable" in *New and Nonofficial Remedies*. These have been considered by the Council at the request of manufacturers who desire the added prestige of Council acceptance for their products. Heretofore such brands, when marketed under the official names, have been included by name in the "List of Articles and Brands Accepted by the Council but Not Described in N. N. R." Such accepted brands when marketed under a name other than the official one have been described in the body of the book. As a new departure the Council has this year transferred to the body of the book all accepted official products of which there is a brand marketed under a proprietary name. A striking example of this is found in the various brands of Solution of Posterior Pituitary. For years a well known brand of this preparation has been accepted by the Council as marketed under the name Pituitrin.

The following new drugs have been added in the 1937 edition: Kephrene Hydrochloride, another vasoconstrictor resembling Epinephrine; Botulinus Antitoxin, an antitoxic serum prepared from the toxin of *Clostridium botulinum* for prophylaxis and treatment of botulism; Tetanus Toxoid, Alum Precipitated, another alum precipitated toxoid; Oleum Percomorphum, a fish liver oil preparation of high potency in vitamins A and D. There are some noteworthy changes in classification. The various vasoconstrictors, Benzedrine, Ephedrine, Epinephrine and Neo-Synephrin, have been grouped together as phenylalkylamine derivatives under the heading "Epinephrine and Related Preparations." This terminology is in keeping with the Council's policy of avoiding therapeutically suggestive names. Another similar change is the abandonment of the classification "Medicinal Foods" and substitution of a chapter titled "Carbohydrate Foods Chiefly Dextrose." The classification "Vitamin Foods" had been set up as an independent chapter under the title "Vitamins and Vitamin Preparations for Therapeutic and Prophylactic Use" in the previous edition. The consideration of other classes of food preparations was long ago transferred to the Council on Foods. The chapter

"Organs of Animals," which has heretofore included only endocrine preparations, has been expanded by transfers to this heading of the chapters Liver and Stomach Preparations, and Insulin

Physicians who wish to know why a given proprietary is not described in New and Nonofficial Remedies will find the "Bibliographical Index to Proprietary and Unofficial Articles not Included in N N R" of much value. In this section (in the back of the book) are given references to published articles dealing with preparations that have not been accepted. These include references to the Reports of the Council, to Reports of the A M A Chemical Laboratory and to articles that have appeared in *THE JOURNAL*.

Out of the Test Tube By Harry N. Holmes Ph.D. Second edition. Cloth. Price \$3. Pp. 301 with 102 illustrations. New York: Emerson Books, Inc., 1937.

No lesser adjective than "fascinating" describes this book adequately. Greeting his readers as modern Caesars, who enjoy the comforts of modern civilization by virtue of chemistry, from the soap in their morning baths to the motor cars and the fuel by which they are whisked to work, the author proceeds to show how chemistry is at the basis of everything we use. With chapter titles he woos the reader to look just a few pages further no matter how late the hour. "With Fire Man Rose Above the Beasts" is the story of oxygen, "The Importance of Nothing at All" deals with vacuums and the behavior of gases, "Language and Tools" is his approach to chemical symbols, weights and measures, "The Lightest Substance Known" is, of course hydrogen, and "The Elixir of Life," water. The chapters devoted to "atom smashing" bring ionization and allied phenomena within the comprehension, at least in a general way, of the reader whose chemistry is far behind him or who never had any. Numerous chapters are devoted to the chemistry of the objects of our everyday life—motor cars, steel and gasoline, aluminum, silks and cellulose, high explosives, insect poisons, dyestuffs and what has come out of their chemistry, sugars, fats, vitamins and minerals essential in the diet, bodily secretions, especially hormones, minerals and world power, and lastly a list of Nobel prize winners in chemistry. The author has an eye for that which will appeal to the average reader. He has a breezy style, with a bit of humor here and an incisive observation there, which leaves no dull page. For a better understanding of chemistry and what it means to us in our everyday life, as a contribution to general information, and for a delightful few hours of reading, this book cannot be too heartily recommended. Even the structural symbols of the carbon compounds are presented in a manner to stimulate curiosity. The book should be useful to teachers or to any one who desires a bird's-eye view of chemistry today.

Studies on the Bacterial Flora of the Respiratory Tract in Acute and Chronic Bronchitis, Bronchial Asthma and Lung Gangrene By Sverre Dich-Henriksen from the Bacteriological Laboratory of the Norwegian Army. Skrifter utgitt av Det Norske Videnskaps Akademi i Oslo I. Mat. Naturf. Klasse 1936. No. 11. Paper. Price 18 kroner. Pp. 241, with 14 illustrations. Oslo: Jacob Dybwad 1937.

The author of this monograph has attempted to study the occurrence and significance of bacteria in certain pathologic conditions of the respiratory tract. The observations were made during the years 1933 to 1936 in the bacteriologic laboratory of the Norwegian army. While there have been excellent reports on special phases of the bacteriology of the respiratory tract, none have comprehensively evaluated the entire bacterial flora of the tract in relatively common ailments such as bronchitis and asthma.

The work is reported under three major divisions. First, the technic and methods are discussed. In this connection the author presents an account of his attempts to isolate gram-negative anaerobes by selective bacteriostasis with dyes. In thirty specimens of sputum the author was able to isolate fifteen strains of *Fusiformis* by cultivating the specimens in broth containing a piece of sterile raw potato and varying amounts of brilliant green or crystal violet. The second part of the monograph is devoted to the bacterial flora of the sputum in acute bronchitis, fetid infections of the bronchi and lungs, chronic bronchitis and bronchial asthma. The author discusses the bacterial flora of the respiratory tract in normal conditions

and in the acutely infected state. Similar work reported in medical literature is reviewed and critically surveyed.

Of sixty-eight cases of acute bronchitis studied, the largest number of cases fell in a group in which one or two pathogenic organisms predominated and the normal saprophytic flora was displaced. The most important causal factors were *Haemophilus influenzae*, the pneumococcus and the hemolytic streptococcus. These bacterial species were found to be the most frequent cause of acute bronchitis. The demonstration of antibodies against these organisms in a few of the cases seems to strengthen the author's belief of the etiologic relationship. In a few specimens, intestinal bacteria were found and the author explains their presence as embolic from infections in the gastrointestinal tract.

A chapter is devoted to fetid infections of the lungs and bronchi. The number of cases reported is small. Spirochetes seemed to have a minor role and the author cites the experimental evidence that fetid infections may be produced by injecting material that contains no spirochetes. The specific causation was not determined by this study. The occurrence and significance of bacteria in chronic bronchitis and asthma is next discussed. A short account of each case is given at the end of the monograph.

In addition to the bacteriologic investigations of the sputum, the author presents supplementary studies on serology, allergy and experimental work which are pertinent to the investigation. He concludes that *Haemophilus influenzae*, *Diplococcus pneumoniae* and *Streptococcus haemolyticus* are the most frequent causes of acute bronchitis and assigns an important role to *Haemophilus influenzae* as a primary factor in predisposing to fetid infections of the lung. Three different types of bacterial flora were demonstrated in asthma and chronic bronchitis. The pertinent literature, while not exhaustively reviewed, is well handled.

Carcinoma of the Female Genital Organs By M. C. Mallinowsky and E. Quater. Translated from the Russian by A. S. Schwartzmann. A. B. M. D. Cloth. Price \$5. Pp. 255 with 50 illustrations. Boston: Bruce Humphries Inc. Publishers 1936.

This Russian volume, which presumably presents the views of the present Russian leaders in a special branch of medicine, has been read with interest. The *Cumulative Index Medicus* has been scanned over a period of six or seven years in an effort to identify the eleven authors who have contributed to the work, with failure to secure any enlightenment as to their hospital positions or previous researches and publications. It would seem that the translator has missed an opportunity in not furnishing this kind of information in an introduction, however short. He or the publishers also should have given the date of publication of the original Russian edition. The practical as well as the scientific value of the eleven monographs would be greatly enhanced if they had been accompanied by an index and by accurate documentation. While there is frequent reference throughout the entire book, by name and sometimes by location to various experts, many of them German, there are practically no bibliographic references to enable the reader to refer to the originals. The printing is well done but the illustrations are mediocre, three are taken from Thomas S. Cullen's monograph on Cancer of the Uterus, written many years ago. There is much repetition, a common defect in books written by multiple authors, and while the style varies from author to author, it is, in general, involved. This may be, perhaps, a necessary consequence of translation. The general impression made on the reader is that, in this particular branch, Soviet medicine is well advanced and that there is also adequate information as to foreign work.

In addition to dealing with the usual forms of gynecologic cancer, there is a chapter devoted to mammary carcinoma. The sections dealing with the general etiology of cancer, with the especial symptomatology and diagnosis of cancer of the various organs, is well covered. In chapter V, on metastatic cancer of the ovary, Dr. Thomas J. Pajarski thoroughly reviews the literature and incorporates some original work on the lymphatics of the abdomen which throws some light on the reason for the ovary being such a common focus of metastatic malignancy. From the point of view of treatment, the sections dealing with the surgical procedures in uterine and mammary

cancers are much more thoroughly done than the corresponding sections on ray treatment. Ray therapy seems to be based mainly on the methods of Wintz and Dessauer, and radium therapy on the procedures of Lahm. The American reader will find little new information as to either theory or practice. It is impossible, within a volume of this size, to present the subject completely so that a student of medicine, or a general practitioner, could read it and secure a working knowledge of how to deal with these conditions in practice, nor does it go into sufficient detail to be of any great value to the specialist.

Perhaps the most interesting chapter of all is the last, dealing with the question of disability. The author speaks of medical valuation commissions. Apparently there is a corps of doctors whose duty it is to estimate the disability of patients and to decide as to the amount of pension they should have, and the duration of the pension. These doctors, in contrast to those practicing in the hospitals, the physicians-clinicians, are called physicians-experts. It is frankly stated that medical examination, which he terms "valuation," should be placed under the control of the working masses that they have constructed new foundations in the Soviet Union, and that the problem with these patients, as well as with all others, is to restore them to the capacity for effectual work and to insure that they are not a burden on those who are not sick and who can work. The author seems extremely proud of the social insurance laws of his country and mentions the yearly outlay in this direction as being enormously greater than that of any other country. This outlay seems small, indeed, when compared with the public and private charitable outlay in the United States of America at the present time.

The Biochemistry of the Lipids. By Henry B. Bull, Ph.D. Assistant Professor of Physiological Chemistry, Northwestern University Medical School, Chicago. Cloth. Price \$2.75. Pp. 189 with 63 illustrations. New York: John Wiley & Sons, Inc. London: Chapman & Hall. Limited 1937.

This is a revision and extension of the mimeographed edition that appeared under the same title in 1935. Numerous typographic errors and omissions have been eliminated. The material has been rearranged and extended so that the physiologic aspects are discussed in connection with the chemistry of each type of lipid. Much use is made of interpretations and presentation of data from x-ray analyses and of recent work on surface tension phenomena, various colloidal phenomena, iso-electric ranges and melting points. In this manner the author treats the lipins in the following order: fatty acids, soaps, alcohols, waxes and hydrocarbons, the sterols and related compounds, fats and oils, the phospholipids, cerebroside, carbohydrate esters of the higher fatty acids, and emulsions. The work is well done and excellently presented for advanced students in biochemistry. The compilation of the recent observations on emulsions, buffer action, pH , antioxidants and unsaturation is especially valuable. It seems rather odd to consider fatty acids first and then to delay the consideration of fats and oils until after the discussion of soaps, alcohols, waxes, hydrocarbons and sterols. Although the treatment of phospholipins is satisfactory in most respects, it is surprising to find that the rather excellent work of Klenk on the structure of sphingosin is not referred to. In fact, the author assigns two different formulas to sphingosin in connection with sphingomyelin and cerebroside respectively.

Cytologie du liquide céphalo rachidien normal chez l'homme. Monographie critique et pratique. Par H. Jessen. Paper. Price 40 francs. Pp. 168 with illustrations. Paris: Masson & Cie 1936.

In this well written monograph the author discusses the morphology, physiologic significance and methods of counting the cells in the cerebrospinal fluid. To the small and large mononuclear cells normally considered to be present in the spinal fluid, Jessen adds polygonal cells, which exist in various numbers, often up to 5,026 per cubic millimeter. These cells were not previously identified because they were considered to be products of degeneration. The author believes that the cerebrospinal fluid is principally a secretion of the choroid plexus and that the cells are probably of histiogenic origin. The normal cell count is up to 5 per cubic millimeter but there is a constitutional variation in the number of cells found. Some people have consistently low cell counts (from 0.1 to 0.2 per

cubic millimeter) while others may have from 4 to 6 cells per cubic millimeter. The literature is thoroughly covered and there is an extensive bibliography of more than 500 references which covers all languages.

Hautdesinfektionsprobleme. Von Jørgen Ernst. Paper. Price 10 kroner. Pp. 174. Copenhagen: Levin & Munksgaard 1937.

As the problems of disinfection of the skin are always interesting to surgeons and bacteriologists, this new book is timely. An expansion of the author's prize-winning dissertation in clinical medicine at the University of Copenhagen in 1935, the volume contains the reports of the results of 1,729 cultures from the skin of the hands and arms of interns, nursing sisters, physicians and patients before and after the application of various disinfectants in the obstetric service of the government's hospital at Copenhagen. In addition to a general introduction, it includes ninety-six tables (one for each person examined) and a bibliography. There are short chapters on the localization of bacteria in the skin and the bactericidal (self-sterilizing) power of the skin, methods for the collection of bacteria from the skin, the question of chemical neutralization of disinfectants, the methods and procedures used by the author, the results and conclusions, and a final summary.

To collect the bacteria from the skin, the author or subject wiped the surface of the hands or upper arm with a piece of moist sterile gauze. This was then shaken in 30 cc of sterile salt solution. From this suspension 1 cc was pipetted into melted nutrient agar, to which was added 0.4 per cent dextrose and 5 per cent horse blood. Plates were poured and incubated at 37°C. The colonies were counted and the organisms identified. The predominant bacteria in the cultures were staphylococci and *Bacillus subtilis*. Streptococci were rarely found in uninfected skin. Cultures were made daily or at short intervals, usually during a month's observation of each subject. By following this schedule the author could observe the effects of repeated washings and frequent applications of disinfecting solutions. Numbers of bacteria decreased considerably at first and occasionally increased toward the end of the month. In cases in which the bacterial flora increased there were usually fissures, superficial infections or scaliness of the skin. These small lesions were attributed to the injurious effects of disinfectants on the epidermis.

The chief disinfectants tested were 70 and 90 per cent alcohol, alcoholic soap solutions, a 0.1 per cent solution of mercury bichloride and an aqueous solution of iodine and potassium iodide in the proportion of 1:2:1,000. As most of the disinfectant could be removed from the hands by brief washing in running water, the author found that it was unnecessary for the bacteriologic purposes to neutralize the mercurial with ammonium sulfide and the iodine compound with sodium thiosulfate.

His results showed that mercury bichloride held first place among the substances tested by him as skin disinfectants. It could not be used constantly for a long time, however, because it produced erythemas and scaliness of the skin. The dilute iodine-potassium iodide solution was remarkably effective in reducing the number of bacteria in the superficial layer of the skin. Its only disadvantage was that it discolored the hands, turning them brown. The old dogma that 70 per cent alcohol is more bactericidal than 90 per cent alcohol was demolished by the author, as he found that the more concentrated was invariably more effective than the lower concentrated.

His quantitative method permitted him to observe that during a given period the bacterial flora of a person's hands change as the result of extrinsic factors and also through the operation of individual factors, some of which may be hormonal as well as infectious in nature. The extrinsic factors, producing "hetero-infection" of the hands, are such activities as playing tennis, gardening, and handling of contaminated material. The self-sterilizing power of the skin is attributed by the author to acids produced by glands and cells in the epidermis. It can be abolished by the application of alkali.

The care with which this study was made and the coherent results summarized in the tables produce a favorable impression. The author has not attempted to investigate a number of problems of disinfection of the skin and has little to contribute to the knowledge of the actual localization of bacteria in the skin and the relationship of indigenous cutaneous micro-

organisms to the occurrence of surgical wound infection. In the absence of studies on these subjects the book is not a general treatise. It is, however, a contribution of both theoretical and practical importance.

Bacteriology of Specific Communicable Diseases. Handbook of Public Health Bacteriology. General Information Regarding Epidemiology, Collection and Shipment of Specimens and Bacteriologic Serologic and Chemical Procedures 1937. Edited by M. S. Marshall. Department of Public Health, City and County of San Francisco, California. J. C. Gelger, Director. Paper. Pp. 141. San Francisco. J. W. Stacey, Inc. 1937.

This manual could well serve as a standard for every progressive city or state health department. It is not only a most useful handbook of condensed general information on routine public health work but an epitome of public health laboratory methods. It coordinates the work of the epidemiologist, sanitary inspector, medical man and laboratory technician. A concise practical pocket manual such as this will undoubtedly do much for the successful prosecution of public health work. The information is precisely and clearly stated. The first twelve pages include a list of reportable diseases in California, a table of clinical specimens for laboratory examinations, and explicit instructions on the handling of specimens. The largest part of the manual is devoted to the bacteriology and serology of the communicable infections. A brief consideration of the bacteriology of shell-fish, milk, water and sewage follows. The final chapters discuss chemical procedures performed by the public health chemist. The appendix contains useful information on suggestions for diagnostic methods in addition to the usual tests performed, a compilation of the laboratory animals most useful for diagnostic inoculations, their care, methods for bleeding, sites for inoculation and other useful data. Drs. Giger and Marshall and the competent committee who collaborated with them deserve commendation for the manner in which they were able to make available such essential public health information.

The International Medical Annual. A Year Book of Treatment and Practitioner's Index. Edited by H. Letheby. Tidy, M.A., M.D., F.R.C.P., and A. Rendle Short, M.D., B.S., B.Sc. Fifty-fifth Year 1937. Cloth. Price \$6. Pp. 665 with 167 illustrations. Baltimore. William Wood & Company. 1937.

In this book the more important medical contributions of the year 1936 are discussed in the form of short essays written by a rather large group of contributors. In the introduction the editors call attention to selected subjects of unusual interest, among which are the psychiatric examination of van der Lubbe of the Reichstag fire, the problem of "punch drunk" in professional pugilists, acute and chronic alcoholism, snakes and snake venom, cerebrospinal surgery and sulfanilamide. Naturally the space available for each subject is limited. Hence some subjects are little more than abstracts of current literature, while others form in themselves more or less complete discussions. The fine print makes continued reading hard on the eyes of most persons. A number of illustrations are included which might, perhaps, have been better selected in some instances. While not in any sense completely covering the contributions made in 1936, it does take up the most important advances. It is perhaps questionable whether books of this nature should be published annually or whether they and their possessors would not both gain by rather more extended treatment at less frequent intervals.

Man in a Chemical World. The Service of Chemical Industry. By A. Cressy Morrison. Cloth. Price \$3. Pp. 292 with illustrations. New York & London. Charles Scribner's Sons. 1937.

This is a common sense presentation of chemical factors underlying most articles and activities in our complex modern world. Dates, formulas and technical terms do not burden the reader, though essential terminology is not avoided. No extravagant claims are made for chemistry, failures and unexplored fields are described without allowing unique historical data to overshadow their present economic and social significance. The emphasis is on the modern world so marvelous yet seemingly commonplace to those who do not understand the forces creating it. This book will undoubtedly be welcomed by the intelligent inquiring layman. The illustrations are excellent.

Surgical Pathology of the Thyroid Gland. By Arthur E. Hertzler, M.D., Surgeon to the Agnes Hertzler Memorial Hospital, Hulsehead, Kansas. Cloth. Price \$5. Pp. 298 with 238 illustrations. Philadelphia. Moorehead & London. J. B. Lippincott Company. 1936.

In this monograph the author discusses the clinical and surgical aspects of various types of thyroid disturbances and has illustrated them by reproductions of photographs of patients and of the gross specimens. The various pathologic conditions of the thyroid gland are shown in photomicrographs. The reader, therefore, receives a complete picture of the clinical and pathologic status of the gland. Some pathologists might disagree with the author's classification of the pathologic changes in the thyroid, but the book nevertheless acts as a working basis for the surgeon, the pathologist and the internist.

Ber'luth Ha zibur. Derakim uem'tza'sh Shmur neged mahaloith miltad begoith. [Public Health Ways and Means of Prevention of Infectious Diseases.] By A. J. Levy, M.D., Dr. P.H., Ph.D., Director of Health Education, Straus Health Center, Jerusalem, Palestine. Fabricoid. Price \$1.50. Pp. 287 with 66 illustrations. Tel Aviv, Palestine. Achlefer. 1935.

Sanitariuth. Madrich Hishmirat tzorke hammazon uhammaskeh ulehat kanat fene e hayim nohim umavrilim babbalith ubahutz. [Sanitation. A Manual for the Care of Food and Drink and for Instituting Healthy Sanitary Conditions Within and Outside the Home.] By A. J. Levy, M.D., Dr. P.H., Ph.D., Director of Health Education, Straus Health Center, Jerusalem, Palestine. Fabricoid. Price \$1.50. Pp. 303 with 76 illustrations. Tel Aviv, Palestine. 'Achlefer. 1936.

Ezrah Rishonah. Sefer shimmushi lekoi adam. [First Aid. A Manual for Every Individual.] By A. J. Levy, M.D., Dr. P.H., Ph.D., Director of Health Education, Straus Health Center, Jerusalem, Palestine. With the collaboration of W. Nissel, M.D., and A. Simon, M.D. Fabricoid. Price \$1.50. Pp. 354 with 114 illustrations. Jerusalem, Palestine. Reuben Mass Publisher. 1936.

The author has undertaken the task of writing a series of textbooks on public health for the Palestinian population. He is well qualified to write these books, as he himself is a Palestinian who knows the habits of the people, he has in addition received his training both in medicine and in public health in American universities, and he is actively engaged in health center and health educational work. The first three volumes have already appeared, one on general hygiene, one on sanitation and a third one on first aid. All three books are written in a popular style, understandable by any one who knows the Hebrew language. They are illustrated profusely and contain some historical references. The books embody the latest health information and have already proved their great value to the Hebrew reading public.

Die Drüsen mit innerer Sekretion. Ihre physiologische und therapeutische Bedeutung. Mit einem Vorwort von Dozent Dr. Wilhelm Raab. Autorisierte Übersetzung und Erweiterung des Werkes "Glandular Physiology and Therapy." A Symposium Prepared Under the Auspices of the Council on Pharmacy and Chemistry of the American Medical Association. Von Dr. med. Adolf Nichtenhauser und Dr. med. Kurt Stern. Cloth. Pp. 423 with illustrations. Vienna & Leipzig. Aesculap Verlag. 1937.

This translation of *Glandular Physiology and Therapy* is identical with the American edition except for the section by Zondek on the chromatophorotropic principle of the pituitary, which has been revised and considerably enlarged. The translators, Drs. Adolf Nichtenhauser and Kurt Stern of Vienna, and the publishers are to be congratulated on the faithful rendition into German. The number of pages has been reduced one fifth by use of a larger page. Typography, illustrations and binding are all excellent. This edition of the symposium by renowned endocrinologists, which has already received wide acclaim in the English version, should be of great value to German-speaking physicians.

Diseases of the Nose, Throat and Ear. A Handbook for Students and Practitioners. By I. Simson Hall, M.B., Ch.B., F.R.C.P.F., Surgeon to the Royal Infirmary, Edinburgh (Department for Diseases of Nose, Throat and Ear). Cloth. Price \$4. Pp. 423, with 56 illustrations. Baltimore. William Wood & Company. 1937.

This is a handbook for students and general practitioners. Precisely and clearly it discusses the chief diseases of the ear, nose and throat. There is some discussion of operative procedures although not too much nor in too great detail which is proper for a book of this character. The illustrations are clear, and many of them seem to be new.

Contributions to the Microscopic Anatomy of the Pancreas By Paul Langerhans [Berlin 1869] Reprint of the German Original with an English Translation and an Introductory Essay By H Morrison MD Boards Price \$1 Pp 39 with 3 illustrations Baltimore Johns Hopkins Press 1937

Dr Morrison has rendered a great service to all interested in the history of medicine, and particularly to those who are concerned with instruction in the history of diabetes mellitus, by reprinting the German original of "Contributions to the Microscopic Anatomy of the Pancreas," by Paul Langerhans, and adding an excellent English translation of the article. In the well written and interesting introductory essay, a short account of the personal and scientific history of the German investigator is given. Langerhans, it is pointed out, was the son of a physician and began his important researches while still a student. Indeed, it was this fact which focused the author's attention on Langerhans. It is not appreciated by many students of the history of diabetes that Langerhans, in a rather short research career, was able to make several other significant contributions in addition to the discovery of the cells that were named "islets of Langerhans" by the French histologist Laguesse. There is no doubt, however, as Dr Morrison says, that Langerhans will be remembered chiefly because he detected that the structures in the pancreas that now bear his name possessed characteristics distinguishing them from the cells of the acinous tissue.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Medical Practice Acts Revocation of Physician's License for Failure to Report Venereal Disease—The physician appellant was convicted of violating a Nevada statute requiring physicians having knowledge that a prostitute is infected with a venereal disease to report that fact immediately to the chief of police. Thereafter proceedings were instituted before the state board of medical examiners to revoke the physician's license under a complaint charging him with (1) wilful disobedience of the law, and (2) conviction of an offense involving moral turpitude. The license was revoked, the second judicial district court, Washoe County, upheld the revocation, and the physician appealed to the Supreme Court of Nevada.

The physician contended that the word "law" as used in the section of the medical practice act authorizing the revocation of a license for "wilful disobedience of the law" was limited in its meaning to laws included in the act creating the state board of health. With this contention, the Supreme Court disagreed. Wilful disobedience of a law requiring immediate report by a physician of a prostitute afflicted with a contagious or infectious venereal disease, said the court, comes within the meaning of "wilful disobedience of the law" as those words are used in the medical practice act. The word "law" in this connection does not refer exclusively to the act creating the state board of health. The physician further contended that the offense of which he was convicted was not one involving moral turpitude. Whether the misdemeanor was an offense involving moral turpitude, the court said, depends on the circumstances under which it was committed. It is easily conceivable, the court pointed out, that a physician of the most ethical type, knowing a prostitute to be afflicted with such a disease, and being about to report the case immediately to the police authorities, might have his attention distracted before actually doing so, by reason of some emergency, and then forget the matter for several days. The fact that he unintentionally overlooked reporting the case to the police authorities would not be a defense to a prosecution under the law requiring him to report, because the mere failure to notify the police authorities constitutes the offense, yet no moral turpitude would be involved in such a case. After reviewing the record, the court was of the opinion that, while there was substantial evidence to support the findings of the board of medical examiners, there was some doubt as to whether the physician's failure immediately to report the prostitute to the police authori-

ties was an intentional violation of the law and as to whether that failure involved moral turpitude. In *State Board of Dental Examiners v. Saville*, 90 Colo 177, 8 P (2d) 693, 82 A L R 1176, it was held that the power to revoke permanently includes the power to suspend. Under all the circumstances of the present case, the court thought that the revocation of the physician's license should have been temporary rather than permanent. Feeling that the demands of justice had already been met in this case, the physician's license having been revoked Feb 3 1936 the court ordered that the revocation of the license should terminate on the filing of the opinion by the court and that the physician be permitted to resume practice from and after Feb 5, 1937.—*In re Reno (Nev)*, 64 P (2d) 1036

Workmen's Compensation Acts Blindness in Relation to Trauma and Syphilis, Medical Books in Evidence—The claimant, while at work cleaning the inside of a metal tank with an electric brush, complained to a fellow worker that something had got into his left eye. Shortly afterward the claimant reported to the plant surgeon who found some pieces of foreign matter in the eye which he apparently removed. The claimant however, continued to insist that there was still something in his eye and during the next several months he received treatment from various physicians but obtained no relief. Eventually, he became totally blind in his left eye. Vision in his right was reduced to less than one tenth of normal vision and the condition could not be corrected by lenses. During the course of treatment for his eye condition it was discovered that the claimant had syphilis and he underwent treatment for that disease. In a proceeding under the workmen's compensation act of Connecticut, the commissioner awarded the claimant compensation and the employer appealed to the superior court which remanded the case to the commissioner for the taking of further evidence. The claimant thereupon appealed to the Supreme Court of Errors of Connecticut.

The commissioner concluded that an injury which the claimant received to his left eye precipitated an optic neuritis in that eye and that atrophy of the optic nerve developed, resulting in total blindness in that eye that sympathetically the right eye was affected by the injury to the left, so that the net results of the injury was that the claimant was industrially blind in both eyes. The employer contended that the claimant's condition was not due to trauma but to syphilis. Whether or not the claimant's blindness was due to the trauma or to syphilis, said the Supreme Court of Errors was a medical question on which the witnesses called by the two parties were diametrically in opposition. Two physicians testifying for the claimant expressed the opinion that loss of sight which the claimant was suffering was due to the injury received while working in the tank. The medical testimony for the company was that the condition was wholly due to syphilis or to the treatment therefor. In the conflict of testimony as to the cause of the claimant's disability, the court said, it was the province of the commissioner to determine the matter and with his conclusion the court felt disinclined to interfere.

In the course of the hearing before the commissioner a medical expert on behalf of the claimant was asked how he accounted for the 90 per cent loss of vision in the claimant's right eye by reason of the injury to the left eye. The witness stated that he could not answer the question from personal experience but read to the commissioner a statement concerning the matter from a medical book. The employer contended that it was error for the commissioner to receive the statement in evidence. This contention the court said, overlooks the nature of the hearing before the commissioner. The law provides that the commissioner shall not be bound by the ordinary common law or statutory rules of evidence or procedure and is therefore permitted great latitude in the admission of evidence. The employer further contended that an award of compensation to the claimant was not permissible because the workmen's compensation act provides that in case of an accidental injury a disability or death due to the acceleration or aggravation of syphilis does not constitute a compensable injury. Under this provision the court said, where the effect of the injury is to accelerate or aggravate the constitutional disease, no recovery can be had. The provision, however, was

not intended to prevent compensation in all cases. Compensation is not made to depend on the condition of health of the employee or on his freedom from liability to injury through a constitutional disease or latent tendency. If the injury is the cause of the disability, it is compensable even though such an injury might not have caused the disability if occurring to a healthy employee or even an average employee. In the present case the ultimate conclusion of the commissioner was that the injury which the claimant received because of his condition affected the optic nerve in such a manner as to result in loss of sight of both eyes. As the record supported this conclusion, the court said, the disability was compensable.

The cause was remanded to the superior court, with directions to enter judgment for the claimant—*Nicotra v Bigelow, Sanford Carpet Co (Conn)*, 189 A 603

Workmen's Compensation Acts Disfigurement Not a Compensable Disability—The claimant's face was badly scarred by acid, resulting in considerable disfigurement. He was otherwise injured and instituted proceedings under the workmen's compensation act of New Jersey. The question as to whether or not disfigurement constituted a compensable disability eventually was presented to the supreme court of New Jersey.

A reading of the several sections of the workmen's compensation act, said the court, clearly indicates a legislative purpose to provide compensation for disability which disqualifies an employee from doing work in whole or in part. In *De Zeng Standard Co v Pressey*, 86 N J Law 469, 92 A 278 (affirmed in 96 A 1102) the court said:

The disability intended thereby (the act) is a disability due to loss of a member or part of a member or of a function rather than to mere loss of earning power.

In that case it was claimed that if there was injury but no loss of actual wages there was no loss of earning power, and that this precluded an award. The court, however, refused to take this view, declaring that it was disability alone that counted, whether loss of physical parts or loss of function. In the present case the court said that the disfigurement and scars on the claimant's face may well deter employment and thereby lessen his earning power, but they in no wise impair his ability to work. If disfigurement, standing alone, is to be made the basis of compensation, it must be done by the legislature and not by an extension of the act by judicial construction. If and when such legislation shall be deemed desirable, the court said, the legislature can determine what types of disfigurement, marks and scars, and on what portion of the face, head or body, shall be considered, and within what limits and bounds awards of compensation shall be made—*Everhardt v Newark Cleaning & Dyeing Co, (N J)*, 189 A 926

Workmen's Compensation Acts Student Nurse an Employee Within Meaning of Act—The claimant, a student nurse at the defendant hospital, apparently sustained an injury, the nature of which does not appear in the record. In affirming an award of the industrial accident board granting her compensation, the supreme court of New York, appellate division, third department, held that, while the claimant's remuneration consisted solely of room, maintenance, education, and training, she was an employee of the hospital within the meaning of the workmen's compensation act—*Nelson v St Francis Hospital (N Y)*, 202 N Y S 552

Medical Practice Act Enforcement by Quo Warranto, Burden of Proof—The state of Alabama, on relation of the solicitor of the ninth judicial circuit, instituted proceedings in the nature of quo warranto against the appellant, charging him with intruding himself into the profession of treating or offering to treat diseases of human beings. The trial court gave judgment against the appellant, who thereupon appealed to the court of appeals of Alabama.

The burden rested on the state said the court, to offer evidence to sustain the material allegations of the complaint and until such evidence was produced the appellant was under no duty to undertake to disprove the charges against him. Only two witnesses were examined by the state. The appellant offered no testimony. A practicing physician testified that he

was called to attend a patient and saw the appellant there and that he, the appellant, rubbed the patient's arms and legs. The other witness testified that he told the appellant that he had a pain in his leg and that the appellant rubbed it for him. In the opinion of the appellate court, this evidence did not entitle the state to a verdict, for there was a total lack of any proof tending to show that the appellant committed any of the acts charged in the complaint. The evidence in its strongest phase against the appellant, the court said, merely showed that on the occasions mentioned he merely rubbed the extremities of the two persons who were suffering from pain. In *Thompson v State*, 228 Ala 231, 153 So 470, the Supreme Court of Alabama said:

The treatment as set out in the opinion of the Court of Appeals was massages by the defendant of two persons, one of whom had a pain in her shoulder and the other a pain in the neck, and this being so the state failed to show that the defendant treated them for a disease.

We find no discussion of the word 'disease' as used in a criminal statute but many of the leading courts in defining the word 'disease' hold that it means more than a mere temporary pain or disorder.

Relying on the foregoing decision of the Supreme Court of Alabama, the court in the present case held that the verdict and the judgment based on it were impregnated with error and could not be sustained. The appellant was therefore discharged from further custody—*Ferguson v State ex rel Bailey (Ala)*, 172 So 350

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Sex Hormones and Cancer—From the data that Murray obtained from a study of 189 parabiotic pairs of mice, it seems that the introduction of the male hormones into the blood stream of the female causes an upset in her sexual cycle. The ovaries are stimulated to a precocious and prolonged production of follicles which degenerate within the gland, with the result that no luteal tissue is formed. Since none of these females developed mammary tumors, it seems reasonable to assume that the proliferation and change to malignancy in the mammary glands may be due, in some measure, to the luteal fraction of the ovarian hormone. On this hypothesis, the observed difference in cancer incidence between the breeding and the virgin females may be explained as being due to the prolonged luteal phase of pregnancy. It is also supported by the observation of Lacassagne, who found a correlation between the rapidity of normal estrous cycles and the incidence of cancer in mice.

Menopausal Age in Women with Cancer of the Breast—Olch collected 342 instances of cancer of the breast in women first coming to medical attention when they were more than 50 years old. These cases were unselected except that women who had had previous pelvic operations were excluded. There were 54.7 per cent who were still menstruating at the time of observation or who had passed through the menopause after the age of 50. That is, almost five times as many women in this group had a delayed menopausal age as compared to a series of normal women. This difference is too striking to be disregarded and coupled with past clinical and the more recent experimental knowledge, forces the author to the conclusion that delayed or prolonged menstruation is a factor to be considered in the etiology of this disease in older women.

Study of Peptic Activity by Means of Double Histamine Test—Rivers and Vanzant performed the double histamine test in sixty-six cases. A large number of the patients had peptic ulcer. From the results obtained, it is evident that the argument that the secretion of pepsin is not stimulated by histamine but that preformed pepsin is merely washed out breaks down because the shortness of the interval (one hour) between the two injections precludes the possibility of pepsin accumulating in the tubules in large quantities. The curves show that the secretion of pepsin reaches its height in the first twenty minutes after injection and then falls rather abruptly to a low level. Following the second injection of histamine, an almost identical curve was observed except that slightly higher values for pepsin were obtained in the first ten minutes after the first injection than were obtained in the corresponding period after the second injection. This difference may well be due to a washing out of preformed pepsin by the first injection.

Passive Transfer Antibody—For the technique developed by Lippard and Schmidt for titration of the passive transfer antibody, blood is obtained from patients with allergic disorders, the serum is separated and stored in sterile rubber-capped vials. Concentrated antigen solutions of known nitrogen concentration, prepared within six months, are freshly diluted when mixtures are to be made. The stock solution is diluted so that 1 cc contains 0.15 mg of total nitrogen. Progressive dilutions of the stock solution are prepared (1, 2, 1.5, 1, 10, 1, 20, 1, 50, 1, 100 and 1, 1,000). The diluent is physiologic solution of sodium chloride containing merthiolate in a concentration of 1:2,000. For the preparation of antigen-antibody mixtures 0.4 cc of undiluted serum is placed in each of seven vials, 0.1 cc of one of the antigen dilutions previously mentioned is added to each vial. The final dilution of merthiolate in the mixtures is 1:10,000. One-tenth cubic centimeter of each mixture is injected intracutaneously at intervals of approximately 5 cm into the arms of three recipients who are in good health and have no history of allergic disorders. When the antigen concerned is a food, it is eliminated from the recipients' diets until the subsequent injection. Secondary injection

tions of antigen are administered from one to three days after the injection of the antigen-antibody mixtures. As a preliminary test, to exclude the possibility of natural sensitivity, recipients are tested endermally with 0.02 cc of a strong concentration of the antigen (containing 0.3 mg of nitrogen per cubic centimeter). If no significant local reaction appears, the same solution is injected intramuscularly into the external aspect of the thigh. The sites previously sensitized with serum-antigen mixtures are then observed for wheals, which may appear from twenty minutes to two hours later. The dimensions of the reactions are recorded. The titer of the serum is based on the antigen concentration of the mixture at the site above the first wheal. The technic has been found useful in the study of fluctuations of the passive transfer antibody content of human serums in terms of antigen equivalence. Experiments concerning several factors involved in the technic, such as the standardization of intramuscular injections, the stability of antigen-antibody mixtures and the specificity of neutralization, are described. The method has demonstrated variations in the titer of the passive transfer antibody in serums of persons hypersensitive to a variety of antigens.

Value of Fever Therapy in Arthritides—Simmons points out that, of nine cases of acute rheumatic fever with active endocarditis, six became inactive in an average of twenty-four days, following an average of five fever treatments. Three cases of acute rheumatic fever with active endocarditis and complicated by chorea became inactive in an average of forty-six days, following an average of nine fever treatments. This is a marked improvement over any other type of therapy and justifies further investigation. Of twenty-three cases of gonorrheal arthritis, 82 per cent were cured or markedly improved after an average of 26.4 hours of fever maintained between 106 and 107 F. A minimum of at least twenty-five hours of fever at this elevation is necessary before this therapy is concluded to be a failure. Artificial fever therapy is a valuable adjuvant, along with dietary, supportive and orthopedic measures, in the treatment of atrophic arthritis. This combination of treatment was of benefit in 78 per cent of the thirty-six patients treated. Hypertrophic arthritis is benefited by artificial fever therapy only in those cases in which there is a superimposed traumatic and infectious element. In any type of arthritis with or without an infectious element, heat is a justifiable therapeutic measure. Other means of producing febrile reactions are not so efficiently controlled nor so safe as mechanically induced fever therapy. The beneficial effects of fever therapy in the arthritides, with the possible exception of

gonorrheal arthritis, are in all probability not solely bactericidal but rather the result of the beneficial effects of vasodilatation and increased immunologic response.

Importance of Soft Tissue Lesions in Arthritis—Kling believes that the usual cursory examination of the joints and periarticular structures in arthritis has resulted in an overvaluation of x-ray signs. Routine roentgenograms, however, give details only of bone structure. Shadows of the soft tissues are, at best, poorly registered. Therefore they are usually disregarded and the diagnosis is based solely on the changes in bony articular structures. The danger of such misinterpretation is realized if one considers that the finding of spurs is accepted as evidence for the presence of osteoarthritis (hypertrophic arthritis). Degeneration of cartilage and osteophytes at the articular surfaces are present in more than 80 per cent of persons more than 40 years of age. Clinical symptoms, however, develop in not more than from 5 to 10 per cent. Indeed, spurs are seen in most roentgenograms of persons past middle age who have never experienced trouble in their joints. It will be a great stimulus to develop advanced methods for registering the soft tissues. A beginning was made in this direction by the inflation of air or other gases or by the injection of contrast mediums into the joint cavity. These methods, under favorable circumstances, show changes in the soft tissues, such as tears in the cartilages or hypertrophy of the synovial membrane. Unlike changes in bone, lesions of the soft tissue are almost invariably associated with clinical symptoms. The great effort should be expended to advance the knowledge of the structure and behavior of the soft tissues in health and disease.

Retrobulbar Neuritis in Pellagra—Fine and Lachman have observed three patients suffering from pellagra who had impaired vision due to retrobulbar neuritis. In the first of these the retrobulbar neuritis was diagnosed several weeks before signs of pellagra appeared. In each case the presence of skin lesions led to the correct diagnosis. With the present state of knowledge of pellagra, one can only speculate about the relationship of the pellagrous syndrome to the visual disturbances. The etiology of the disease is still unsettled. Since vitamin B or G, was separated from the antineuritic factor B₁, it has become more and more apparent that even G is a complex of various factors the number and nature of which are not at all understood. The history in these cases is usually that of chronic alcoholism over many years with the appearance of pellagra-like symptoms after a spree lasting several weeks. It has been suggested that the important factor in these cases is undernutrition and damage to the alimentary tract from the alcohol, interfering with absorption. In considering the ocular disturbance associated with pellagra, the problem of the role of alcohol becomes more significant in view of the relative frequency of so-called tobacco-alcohol amblyopia. The association of tobacco with ethyl alcohol in producing injury to the visual fibers is a constant one. There has been an increasing tendency to regard alcohol as an exciting factor in tobacco amblyopia. Recently the role of chronic alcoholism in peripheral neuritis has been questioned. It does not seem improbable that a relationship such as exists between vitamin B₁ deficiency and the peripheral nervous system may also exist between vitamin B (G) deficiency and the central nervous system, of which the optic nerve is a part and that in each case the alcoholism plays only an indirect part. Such a quantitative relationship would offer an explanation of the fact that some alcoholic

addicts never suffer from amblyopia, while other relatively moderate drinkers suffer serious insult to the visual fibers. The question arises whether many cases of "alcohol and tobacco" amblyopia are not complicated by a deficiency of vitamin G

Seasonal Variations in Number of Platelets—Tocantins, by obtaining counts of the platelets and erythrocytes from twenty-eight white male medical students, observed that the number of platelets in arterial and venous blood from the upper extremity in man is significantly higher in the winter than in the spring, there are no significant differences between counts on cutaneous blood in the two seasons. In the winter the number of platelets in arterial blood is significantly higher than in venous blood, it is also significantly higher in venous than in cutaneous blood. In the spring there are no statistically significant differences between the means of platelet counts on blood from the three sources. There are no significant differences between the erythrocyte counts in the two seasons.

Saliva Cell Count in Myelogenous Leukemia—Allen and Dickey agree with Isaacs' conception of the effects of irradiation on chronic myelogenous leukemia (that in health a fairly constant relationship exists between the cells in the saliva and those in the blood and that in aleukemic leukemia as the leukocytes of the blood decrease in number the saliva count mounts) and urge frequent, detailed microscopic studies of the blood and saliva by those who treat myelogenous leukemia. Ten cases of chronic myelogenous leukemia are cited and a detailed consideration of their response to irradiation as depicted in graphs of blood and saliva counts is given. The major effect of irradiation on the blood is maturation of the myelocyte to the polymorphonuclear stage and division and reproduction of primitive myeloblasts and myeloblasts, as described by Isaacs. Irradiation under certain circumstances and special dosage may cause death of some of the abnormal blood cells. A little evidence which points toward an irradiation effect on the blood stream-gastro-intestinal threshold of leukopenesis is presented.

Radiation Treatment of Hyperthyroidism—Harris reports on the 350 patients that were given radiation therapy for toxic goiter at the University Hospital. Of this number only 244 could be used for statistical study. The women outnumbered the men about four to one. The majority of the patients were in the third, fourth or fifth decade of life. The duration of symptoms ranged from a few weeks to two years or more. The greatest number had been ill less than six months. The patient whose major symptom is nervousness, who has a small soft goiter and who has been ill six months or less has the best prognosis for relief by irradiation. All children with thyrotoxicosis should be given irradiation before surgical intervention is considered. Adequate irradiation of the thyroid in this disease is followed sufficiently often by satisfactory permanent remission to justify a carefully controlled trial. If definite improvement does not appear within three months, or if a marked exacerbation of the disease appears at any time, irradiation should be stopped and preparation for thyroidectomy begun. By such a course the thyroid can be saved and this is important to the adolescent whose endocrines are in the process of adjustment for adult life. Serious visceral changes can be prevented by a careful selection of patients and

by careful observation and check of the status of the disease while treatment is being given. A temporary exacerbation of the symptoms of thyrotoxicosis can be expected for from twenty-four to seventy-two hours after the first few treatments. This reaction is not serious and ordinarily subsides with rest and sedatives. In the occasional patient there is a slight to mild cutaneous reaction in the area treated. This is never more than a first degree reaction and soon disappears. The possibility of alopecia developing while the patient is under treatment must be kept in mind. Not infrequently this is a symptom of the disease and is never the result of irradiation if ordinary care is taken to protect the hair with lead rubber. A release card, which mentions the possibility of alopecia, should be signed by the patient or responsible relative. There is also the possibility of depressing the thyroid activity to the point at which myxedema develops. This can be readily controlled by thyroid medication. The size of the goiter is influenced little if any by irradiation. With the present selection of cases, excellent results are being obtained, as evidenced by the 90 per cent of cases improved during the years 1932 and 1933. The latter cases have not been followed long enough for definite conclusions to be drawn. Some of the good results during the latter period are probably due to a better recognition of the type of case amenable to irradiation. Postoperative recurrences are treated without selection.

Protective Influence of Adrenal Hormones Against Tuberculosis—After administering adrenal products to tuber-
culous patients who suffered greatly with malaise and lack of
vigor—some with toxemia, others without, and noting an
improvement in their vigor, a lessening of their fatigue and an
apparent beneficial effect on the tuberculous process, the
Pottengers carried out experiments on guinea-pigs to test

whether extracts made from the adrenal containing adrenal
cortex extract would exert any effect on tuberculosis either in
the susceptibility to infection or in the character of the lesion.
The longevity and the extent and nature of the disease found
at necropsy in animals treated with cortical extract are com-
pared with untreated controls and animals treated with other
substances. Of twenty-four untreated animals inoculated with
100 \pm 10 tubercle bacilli obtained from fresh human sputums
and five inoculated but treated with insulin, all became infected.
Twelve of forty-three inoculated animals (28 per cent) that
received cortical extract for periods varying from ten days
to the entire life of the animals showed at necropsy no evidence
of tuberculous infection. It was further found that infection,
when present, differed from the infection in untreated animals
in that it was milder and less extensive.

Theobromine Calcium Gluconate—Because of the known
tendency of theophylline preparations to cause gastric irritation
as a result of their prolonged use in cardiovascular disease,
Ziskin studied the effects of theobromine calcium gluconate in
fifty-two cases. Among these were twelve cases of hyperten-
sion, eleven cases of hypertension with cardiac decompensation
seventeen cases of coronary disease with angina pectoris and
twelve cases of coronary disease with cardiac decompensation.
Thirty-two were bed patients and twenty were ambulant. Many
of these patients had been taking theophylline with ethylene
diamine before being started on theobromine calcium gluconate.
Other drugs, such as digitalis, were used when necessary.
Theobromine calcium gluconate was given in doses of 0.32 Gm.
three times daily. This dose was later increased in some
patients to 0.65 Gm. three times daily. There was not a single
instance of nausea or gastric irritation in any patient from the
use of this preparation. Some of the patients have been taking
this drug continuously now for a period of nine months. Favor-
able results were noted in the majority of the patients in
relieving symptoms of congestive failure, angina and dyspnea.

and in some cases the results were very striking. In comparing the effects of aminophylline with theobromine calcium gluconate on the relief of cardiac symptoms, more favorable results were noted with the use of the latter. Eight of the fifty-two patients reported greater relief of pain when taking theobromine calcium gluconate. Twelve patients, who were taking the theobromine preparation and then changed to aminophylline, asked to be put back on theobromine calcium gluconate, stating that they received greater relief from their symptoms when taking this preparation.

Essential Dietary Factor in Mammalian Liver—Halliday and Evans performed experiments in an attempt to confirm the results of Elvehjem and his co-workers regarding the new essential dietary factor found in mammalian liver. Their results appear to indicate that the alcohol-ether precipitation procedure carries down vitamin B₆, since the precipitate is highly effective in preventing and curing severe dermatitis. They seemed to obtain a separation of flavine and vitamin B₆ by this method, the flavine passing into the supernatant liquid. Their results do not demonstrate a new factor essential in addition to vitamins B (B₁), flavine, B₆, and "B" as postulated by the other workers. However, until or unless results obtained in one laboratory can be duplicated in another, it is difficult to draw absolute conclusions. The difference in results may be due to biologic variations in the experimental animals. If such is the case, it will be difficult for one laboratory to confirm results obtained in another.

Passive Vascular Exercise in Diabetes—Edelen calls attention to the harmful effect of heat in the form of hot water bottles, hot packs, electric pads or cradles with electric lights. Accompanying the impaired circulation there is an impaired sensory mechanism and before one realizes it irreparable harm has been done to a toe or foot, with the formation of blebs or blisters. Heat also increases the metabolism of tissues up an extremity in which there is already a deficient circulation, and this leads to harmful results. It is in this instance that the use of passive vascular exercise is valuable, for with increase in cellular metabolism caused by heat passive vascular exercise therapy will bring about the needed increase in blood supply. The use of heat in combination with the exercise overcome vasospasm. It is a vital aid in developing collaterals and hastens the demarcation of spreading gangrene and is quite a factor in converting moist gangrene to dry gangrene. The best results from passive vascular exercises are obtained in patients with involvement of major arterial pathways and the least benefit is obtained in persons with extensive sclerosis of the arterioles of the feet and toes. In diabetic patients the so-called arteriolar bed is fairly good and passive vascular exercise valuable in restoring a circulatory balance. Thus mechanical means of reducing environmental pressure will not obviate surgical intervention but it will tend to more conservative surgical procedures, aid in demarcation of gangrene and promote healing.

Syncope as Result of Circulatory Disorders—Ten years ago Herrmann began a study of the causes of sudden disability as determined in the emergency service of La Charite in New Orleans. The result of this study, covering the five years 1926 to 1930 inclusive, indicates that medical conditions and particularly cardiovascular diseases play an important part in the production of unconscious states. In the study of any patient in coma or recovering from a syncope seizure a swift general survey is in order, followed by neurologic and cardiovascular examinations. In the general survey the patient's color should be noted, with particular reference as to whether there is a rapidly increasing pallor or flushing or cyanosis or beads of perspiration about the face. A search should be made for evidences of trauma, scalp lacerations, bruises, depressions or fractures of the skull and attempts should be made to determine whether the trauma was administered before or after the faint. Odors such as the aroma of alcoholic beverages, acetone or other poison should be investigated. The character of the respiration should be noted. The neurologic examination should consider the eyelid reflex, of defense closure, the tonus

or flaccidity of the extremities, the tonus reflex of the neck and the involuntary reflex thumb extension and opposition on finger flexion (Mayer-Stiefler). The signs of greatest significance in the cardiovascular examination are usually to be found in the study of the heart action and blood pressure. A disturbed cardiac mechanism may result in a rapid or slow heart rate or a transient total absence of the heart beat. Auscultation may reveal the presence of murmurs of an acute or chronic valvulitis. The blood pressure in instances of cerebral vascular accident may be high or may be alternating, but usually temporary or permanent hypotension is to be found. Local circulatory disturbances involving the cerebral arteries dominate the group and attest the importance of blood pressure, eye-ground and neurologic examinations.

Buerger's Theory Applied to Treatment of Secondary Anemia—Almour selected seven patients with secondary anemia and has treated them with a combination of the hematopoietic drugs. In the application of Buerger's principle to the treatment of secondary anemia there is available iron which serves as a hemoglobin builder, copper, which acts to stimulate erythrocytic formation, liver, which contains the intrinsic factor, vitamin B as the extrinsic factor, and calcium, which acts on bone and cell permeability. Thus, when combining all these, a multiplicity effect should result because of the different pharmacologic points of attack. A preparation containing liver extract 24 grains, iron albuminate 166 grains, calcium gluconate 1.2 grains, two Sherman units of vitamin B, and ten units of vitamin G was selected. The combined small doses, in preference to large doses of a single ingredient, should, according to Buerger's theory, produce the desired effect. In the patients observed the symptoms of lassitude, fatigue, loss of appetite, and the like cleared up after two weeks of therapy. The rise in hemoglobin was prompt, and in some instances an increase of 10 per cent was recorded after two weeks. The increase in red cells was not as marked. However, after one

month most patients showed counts of approximately 4,500,000 red cells. Two cases, while other than secondary anemia, are also included because they serve to confirm Hesse's method of using iron as a red cell stimulant and copper as a detoxifying agent to thyroxine.

Miliary Calcifications in the Spleen—In the last three years Berman has observed eighteen cases of miliary calcification in the spleen, discovered accidentally during the course of X-ray examinations of the chest and abdomen. Three cases showed a quiescent adult type of pulmonary tuberculosis. One patient, a girl 13 years of age, presented multiple calcified Ghon's tubercles in the right lung. Of these four, only one gave a clinical history of tuberculosis (urogenital). Another patient, 28 years of age, had a normal chest roentgenogram and the etiology of the splenic calcifications here is doubtful. The patient's age favors tuberculosis, but the absence of pathologic changes in the lung favors phleboliths. Two other cases are also doubtful but probably represent phleboliths. The remaining cases gave no clinical history of tuberculosis. In four, roentgenograms of the chest showed no pathologic signs, six exhibited calcified Ghon's tubercles. Three came to necropsy, including two which showed calcified primary tuberculous lesions in the lungs. Histologic study of all three showed the calcifications to be phleboliths. This intimates strongly that the mere presence of a Ghon's tubercle does not indicate the tuberculous nature of miliary splenic calcifications.

X-Ray Therapy in Amenorrhea—Friedman and Seligman treated nine consecutive cases of amenorrhea due to endocrinopathies with small doses of radiation and regular menstruation was reestablished in all. Endocrinologic stigmas other than the amenorrhea were not influenced by the treatment. The

dosage used in the treatment of the pituitary region was approximately as follows from 200 to 250 roentgens at the sella turcica. The factors were 200 kilovolts, 0.5 mm of copper plus 1 mm of aluminum, 40 cm focus skin distance, and 200 roentgens to each of two lateral fields and one anterior field. The dosage used in the ovarian irradiation was kept below 100 roentgens at the ovaries and administered through three or four pelvic fields, usually two anterior and two posterior pelvic ports. Regardless of the mode of action, evidence is fast accumulating that x-ray therapy to the pituitary gland and/or ovaries causes a return of the normal menstrual cycle. In some persons the menses are reestablished for a time and a second course of irradiation has to be given.

Antiscorbutic Properties of Salt of Iron and Cevitamic Acid—Pijoan limits his communication to a discussion of a salt of reduced iron and the levorotatory form of cevitamic acid which has proved itself nontoxic when administered intravenously to either experimental or human subjects and has been used in his clinic for the treatment of secondary anemias. This salt was found to have a highly antiscorbutic property when given intravenously daily, over a period of six days to a patient with severe scurvy. A daily dose of 250 mg was sufficient to bring the plasma cevitamic acid level from 0.02 to 12 mg per hundred cubic centimeters and the withdrawal of marked scorbutic symptoms. This salt not only is successful in bringing ferrous iron into the treatment of secondary anemias but has valuable antiscorbutic properties in which single daily doses produce prolonged and increased plasma cevitamic acid values.

Nuclear Jaundice in Neonatal (Umbilical) Sepsis with Jaundice A. Biemond and S. Van Crevel—p. 173

Health of Preschool Children—Henderson examined 1,530 preschool children to determine at what age physical defects appeared. Of 1,014 children less than 2 years of age, 526 (51 per cent) had physical defects other than constipation and disorders due to faulty methods of feeding, and of the 516 children over this age 362 (70 per cent) had one or more bodily defects. The fifteen most obvious disorders were digestive (104), congenital heart disease (nine), skin disease (145), hernia (fifty-two), orthopedic defects (thirty-six), defects of the nervous system (fifty-five) diseases of the eye (100), rickets (thirteen), enlarged tonsils and adenoids (345), otorrhea (sixty-one), palpable cervical glands (428), carious teeth (245) respiratory diseases (255), anemia (forty-nine) and malnutrition (ninety-five). There were fourteen other defects (thrush, harelip, goiter and the like) that were self evident. The author believes that to state, without qualification, that 60 per cent of the 1,530 children examined had physical defects would be to give a grossly distorted picture of the health of the preschool child. If it is agreed that unusual palpability of neck glands is not necessarily and in fact rarely is a sign of disease and that simple enlargement of the tonsils has no adverse effect on the child's health, only a minority of preschool children will be found to have physical defects other than carious teeth. But a substantial minority (166 per cent) have had or still have attacks of bronchitis, which in more than 50 per cent of cases followed an infective condition of the nasopharynx, or respiratory tract of some other member of the family. Malnutrition was a problem of importance, but a problem of much greater importance was that 30 per cent of 1,214 families whose economic state was specially investigated had incomes insufficient in amount to buy the food stated by the Nutrition Committee of the British Medical Association to be the minimum essential for health. Carious teeth became a problem only after the age of 2 years, but then it became a serious one and one that increased with age. Though an increasing and more regular attendance at the infant welfare centers will help to improve and foster the health—and thereby the happiness—of the preschool child, it is still felt that no great advance in the standard of health of the citizen of tomorrow can be expected until the problem of adequate feeding of all the children in the community is scientifically and thoroughly managed.

Effect of Boiling on Nutritive Value of Milk—In deciding whether or not sterilization alters the biologic value of milk, Graham and Morris gave two children aged 10½ and 7½ years a diet that supplied about 50 per cent of the caloric value of the diet and 70 per cent of the total protein in the form of milk. The caloric intake as well as that of protein, minerals and fat was ample. James S. was given boiled milk for three periods of seven days and raw milk for two such intervals. The reverse was true of Peter T. With James S. the retentions of phosphorus, nitrogen and fat showed no significant variations during the whole period of observation. Calcium retention showed a slight increase during the last two weeks on boiled milk. With Peter T., however, the change from raw to boiled and boiled to raw milk produced in each case a great increase in the retention of calcium and phosphorus, owing to a great decrease in fecal output. This increased retention was only apparent, as it was counterbalanced by the increased fecal output during the succeeding week. When the raw milk results are taken together and compared with the figures obtained during the two weeks on boiled milk, it is clear that the retention of calcium oxide and phosphate during the consumption of boiled milk is only slightly lower

than when raw milk was taken. It would appear that the change from raw to boiled milk and vice versa led to temporary periods of constipation. This is an observation which requires to be emphasized in the performance of retention experiments. It is generally held that a period of a week is sufficient for the determination of retention. These observations indicate that in some cases a fortnight may be necessary in order to prevent a temporary alteration producing a fallacious result. The results recorded here indicate that there is no evidence that over short periods the boiling of milk impairs either its absorption or its utilization, when there is an ample supply of proximate principles and minerals and when the caloric intake is adequate. It still remains possible that, over long periods or/and when the intake is no more than sufficient, the sterilization of milk might make a difference to the retention of essential substances.

Chronic Monocytic Leukemia—Smith believes that, accepting monocytic leukemia as a separate disease, a chronic form, as with the other leukemias, might be expected to occur, and the features of his case seem to warrant its recognition as an example of a chronic leukemia of monocytic type. The spleen, which weighed 1,531 Gm and was 24 cm long, was much larger than has been previously described in monocytic leukemia. The size of the spleen implies chronicity. The diagnosis rested between chronic lymphatic, myeloid and monocytic leukemia. The absence of nucleoli from most of the primitive cells, together with the fact that the nucleus was often divided into two or three parts, is quite unlike the picture of either myeloblasts or lymphoblasts, except for the absence of granules they were similar to cells drawn and described by Doan and Wiseman (1934) as premonocytes in a case of monocytic leukemia with a long history, ending in death from intercurrent disease. Two features in the case are worthy of comment. 1 The fact that active erythropoiesis was going on in the bone marrow, and the corresponding absence of any anemia in spite of a leukocytosis of 500,000 per cubic millimeter. A progressive anemia is almost the rule in leukemia of this degree. 2 The spleen was densely infiltrated with monocytes and primitive cells, the latter being more plentiful than in the bone marrow, suggesting that the monocytes were being produced chiefly in the spleen. Death occurred from nephritis.

Diphtheria Immunization in Nursing Staff—Anderson discusses the results of 198 nurses who came under an immunization scheme in which, without a previous Schick test all received injections of toxoid antitoxin floccules or alum-precipitated toxoid and all were completely protected from diphtheria. The nursing staff of a large fever hospital, admitting annually between 800 and 900 cases of diphtheria, is constantly and closely exposed to the disease. To eradicate the

infection completely, a more stringent method of control is necessary than would suffice for the ordinary population. In these circumstances it is not wise to be content with the immunization of the susceptible but it is necessary to ensure that resistance is increased by immunizing the whole staff. Apart from the obvious advantage of using two injections instead of three, alum-precipitated toxoid is no more efficient in the immunizing of adults than toxoid antitoxin floccules.

Cretinism in London—Lewis and his assistants examined seventy-nine patients who had been treated for cretinism. Detailed psychologic tests showed that it is possible for cretins to become mentally normal. The occurrence of other psychologic features, including traits of personality commonly called "obsessional," was established. Comparison of the patient's present intellectual level with treatment received indicated that promptness and continuity of thyroid administration were not alone decisive in determining whether or to what extent the child would remain backward. A few who had normal intelligence quotients had had inadequate treatment, a few with low intelligence quotients had been treated regularly from the time their symptoms appeared. In the majority, however, there was a rough correspondence between adequacy of treatment and intellectual level attained. The other factors which influence psychologic attainment were apparently the stage of development at which symptoms of thyroid deficiency appeared, the degree of this deficiency, the hereditary endowment of the child (as it might be inferred from the intellectual level and other specific features in his family), any cerebral damage either at birth or in infancy and the environmental influences (including special education). Problems of development, as assessed in the somatic and the psychologic spheres, also presented themselves in the inquiry and are discussed.

Unusual Illness with Eosinophilia—Thomson and his co-workers describe three cases of obscure illness. All the patients had eosinophilia. The first had symptoms of irritability of the colon and mild fever for some weeks. The second had prolonged and more severe fever with symptoms of an acute abdominal crisis and signs of a right subphrenic abscess for which a laparotomy was done, the liver was found to be grossly enlarged and infiltrated with granulomas which microscopically showed the changes heretofore regarded as characteristic of infection with *Bacterium tularensis*. The third had an attack of what appeared to be simple catarrhal jaundice. All three patients had been shooting rabbits in southwestern Ireland at the end of September 1936 and for ten days were in intimate contact. The first two patients had been shooting together in the same area for more than two months previously. There is no evidence of any epidemic plague among the rabbits but the local cats were dying in unusual numbers at the time. The first two patients gave negative agglutinations to *Bac*

terium tularensis and negative skin tests for trichinosis. Careful search for parasites was negative. The possible existence in the British Isles of infection with *Bacterium tularensis* or some allied organism is suggested.

Formol Toxoids in Prophylaxis of Gas Gangrene—Penfold and Tolhurst find that formol toxoids of *Bacillus welchii* which have been rendered atoxic for mice in intraperitoneal quantities of 1 cc produce effective immunity in animals when given in from four to eight large injections. Suspensions of alum precipitates of similar formol toxoids given in two small injections a month apart are excellent immunizing agents in animals. Both active and passive immunity have been demonstrated. The purpose of their research was to determine whether the prophylaxis of gas gangrene in man by the use of formol toxoid was a feasible proposition or not. Their animal experiments suggest that it is, and at an early date they hope to apply it experimentally in man. If the experiments should prove successful, the indications for the use of the prophylactic would probably be in the army, particularly for contingents fighting in Europe, where the highly manured soil is frequently a source of infection, in women before the commencement of their childbearing life or in women about to have abortion induced for any legitimate indication, and for persons who take the risk of serious accidents, such as from farm machinery, motor racing and the like. The use of serum therapeutically in such persons may induce serum sensitivity, with its attendant risks, which could be avoided by the carrying out of active immunization.

Radiologic Interpretation of Obscure Pulmonary Lesions—During the past year the medical unit at Preston Hall has investigated some obscure pulmonary lesions by means of tomography. McDougall asserts that the value of tomography over the usual roentgenographic methods is that sections—anteroposterior and lateral—may be taken at any depth of the chest in such a way that it is possible to analyze the various strata of the lung substance at given depths and thereby to eliminate much of the confusion which frequently appears on ordinary roentgenograms owing to the superimposition of shadows of varying density. The author explains some of the advantages of tomography by the description of two cases which have recently come under treatment. In both cases latent cavities have been brought to light. In the first case extensive cavity formation unsuspected in the anteroposterior roentgenograms was shown in the dorsal section of the lungs, and in the second case a patent cavity following thoracoplasty has been accurately localized with a view to complete closure at an early date. It was for this particular type of case that tomography was considered in its earliest days to be most

useful, but it is now abundantly clear that sectional analysis of the chest in cases of pulmonary tuberculosis reveals many secrets which are not given by ordinary flat roentgenograms, however excellent the technic. The information which has been supplied in cases of incomplete artificial pneumothorax and in all cases of cavity formation is invaluable. Postmortem verification of x-ray appearances is most important and in one case in particular tomography during life reproduced with fidelity the pathologic appearances found at necropsy.

Communicable Diseases in China—Hsu and Ke analyze material presented by an investigation covering nineteen communicable and parasitic diseases. The data were collected from 204 hospitals in various provinces. Among 29,468 cases reported for the year 1935, 16,829 were outpatients and 12,639 were inpatients. The numbers of inpatients suffering from ancylostomiasis, cerebrospinal meningitis, fasciolopsiasis, kala-azar, typhoid and typhus were much larger than those for outpatients with these diseases. Among the nineteen diseases, malaria had the greatest incidence of all, 50.2 per cent of the total. The men patients having schistosomiasis were ten times as numerous as the women.

Lead Poisoning and Sources of Intoxication—In the last two years, Yang and his associates encountered thirteen cases of lead poisoning. In searching for the source of intoxication they found that, among the uneducated and occasionally the educated suffering from serious illness, many resort to religious aids, some of which are related to charms and amulets. As practiced when a person is ill a taoist priest, after having performed certain religious ceremonies, takes up a pen and writes on a piece of yellow paper a series of charms and amulets, which after burning into ash is partaken of by the patient in a cup of water. An experiment was conducted in which the smoke from a certain type of opium pipe having a holder coated with pewter was sucked through water in which a stream of hydrogen sulfide was passing. After the fume had passed through for three minutes, the water appeared definitely grayish. Small pieces of the coating material were scraped from the mouth piece and subjected to chemical analysis. In this particular pipe the pewter contained 21 per cent of lead. Persons using this kind of pipe may be poisoned either through the fumes or through the ingestion of lead from the mouth piece. There are two such cases in the present series. It was also found that the commonly used wine pot made of pewter contains lead in large quantities, varying from 32 to 72.8 per cent. In the Chinese way of warming rice wine before drinking, the pot containing wine is placed in hot water. It was found that in as short a time as fifteen minutes from 0.0155 to 0.0054 Gm of metallic lead went into solution per hundred cubic centimeters of wine. There was one case in which the history indicates that the intoxication must have been either from the ingestion of lead particles or from inhaling dust in a smelting foundry.

Treatment of Leprosy with Tellurium—Marchoux and Chorine report experiments on the treatment of leprosy. Among the various substances that were tried at their laboratory, tellurium was found to be the most effective. In this report they describe experiments on rats with metallic tellurium and its mineral salts in oil suspension or in solution of dextrose. In summarizing their observations, they state that metallic tellurium or its mineral salts arrest the further development of leprosy. In the treated animals, the micro-organisms either ceased to multiply or did so very slowly, while in the untreated rats the development remained active. The metal is deposited on the waxy membrane of the bacilli, but it is doubtless the interior milieu of the host cell which is more active than this deposit in inhibiting the further multiplication of the parasitic elements. Between April 1936 and June 1937, rats weighing about 100 Gm tolerated weekly injections of 2, 4, 5, 6 and 10 mg of sodium tellurate, that is, a total of 24 Gm per kilogram of body weight. From the first injections the animals gave off a strong odor of garlic, the eyes of the white rats became black and the skin took on a gray color. In the treatment of human leprosy the authors observed pigmentation of the skin and discoloration of the eyes. The cutaneous lesions were set off in black on a slightly grayish skin. An injection of 0.25 Gm every five days was well tolerated. Under the influence of the tellurium the pains disappear, the lepromas decrease and the general condition improves. All these improvements become manifest during the month following the beginning of the treatment.

Action of Sex Hormones on the Prostate—Champy and his associates point out that the introduction of large amounts of estrogen produces in normal male animals, young or old, a sort of adenomatous hypertrophy of the prostate. This action cannot be a direct one, for, if the same amount of estrogen is administered to castrated animals there is no modification of this type. The estrogen probably acts on the hypophysis and the testes. After citing other experimental observations, the authors point out that the experimental hypertrophy of the prostate which is produced by estrogen and that which develops in men are caused by the same condition in the testis and its internal secretions. Further, the authors give their attention to the therapeutic use of testis hormone in hypertrophy of the prostate, pointing out that the favorable effect on the dysuria often precedes the diminution of the adenoma. The authors think that this is due to a mucoid edema around the vessels of the verumontanum, an edema that is normal to adult animals, is missing in castrates and is diminished in aged animals. In discussing the relationship between the reappearance of this edema and the cessation of the dysuria, the authors point out that the retention of the urine in hypertrophy of the prostate is not merely a mechanical problem, that is, the retention is not simply caused by the enlargement of the prostate, for in case of an extremely large prostate evacuation of the bladder may not be hindered, while complete retention may exist in the presence of a slight hypertrophy. Resection of only the median lobe of the prostate often reestablishes normal vesical evacuation, owing to the fact that in this resection fibers are severed which represent the posterior commissure of the urethrovaginal sphincter. Since the rupture of the muscle counteracts the dysuria, it is reasoned that its relaxation should accomplish a similar result. The edema that is elicited by testis hormone effects such a relaxation and the authors think that this explains the prompt effect of testis hormone on the dysuria in hypertrophy of the prostate.

- *Simultaneous Punctures of Hematopoietic Centers in Chronic Erythroblastic Splenomegaly of Adults P Emile Weil and Suzanne Perles—p 53
- Congenital Hemopathies with Erythroblastosis M Lelong—p 59
- Pleural and General Eosinophilia in a Case of Pleurisy with Eosinophils P Harvier and J Mallarme—p 67

Punctures of Hematopoietic Centers in Erythroblastic Splenomegaly—The condition designated by Emile Weil and Perles as chronic splenomegaly with erythroblastosis of adults includes not only a part of the erythrocythemas, the erythro-leukemias and several myelogenic subleukemias but also certain splenic anemias, the megakaryocytic splenomegalies and an important part of Banti's disease. This synthesis is the result of splenic punctures, for in furnishing identical pictures in all these cases, it was demonstrated that a splenogram exists which is characterized by a more or less pronounced myelocytosis and a considerable erythroblastosis, which in the circulating blood may be manifest or not. The authors describe their observations in splenic, hepatic and sternal punctures. From the combination of these punctures in ten cases of typical or latent erythroblastosis, the authors arrived at conclusions which are of theoretical and practical interest. The combination of punctures and the puncture of the spleen in particular permit the recognition not only of erythroblastosis in the blood but also of the cryptic forms, even in the absence of circulating erythroblasts. In discussing the treatment, the authors point out that irradiation modifies the volume of the spleen only slightly and diminishes only the accompanying myelomatosis. Some patients observe an improvement in their general condition, but many do not feel better, on the contrary, they complain of increasing fatigue and anemia. For this reason it is advisable to employ radiation therapy only under strict hematologic control. But without hoping to obtain results as satisfactory as in myelogenic leukemia, the treatment may be begun with irradiations, and splenectomy can be resorted to secondarily. In several, even severe, cases splenectomy produced favorable results and did not act as in myelogenic leukemia, in which removal of the spleen had fatal consequences. The involvement of the liver in the morbid process does not contraindicate a surgical intervention, but, if the sternal puncture reveals even a slight cellular proliferation, surgical treatment is inadvisable.

- Organizing Principle and Problem of Cancer J Jolly—p 1083
- *Death from Intrahepatic Hemorrhage in Cancer of Liver M Loeper—p 1085
- Tularemia in Czechoslovakia J Drbohlav—p 1086

Intrahepatic Hemorrhage in Cancer of Liver—According to Loeper, in patients with cancer of the liver the general condition is often comparatively favorable for long periods. Even if the neoplasm is rather large, the patient is not only practically free from symptoms but even the chemical examinations produce practically normal results. Death comes slowly. However, occasionally it is rapid, sudden and surprising because it occurs without apparent reason. A digestive intoxication may provoke a mild diarrhea and vomiting and death may follow in thirty-six hours. After citing earlier reports on the termination of hepatic cancer, the author describes several cases of rapid and sudden deaths after hepatic cancer, which are not caused by hematemesis, by toxic hepatitis or by a terminal infection but by unrecognized intrahepatic hemorrhage. The first patient whose history is reported had a giant lymphadenoma of the liver, but despite the enormous size of the liver the general condition was comparatively favorable. One morning he complained of a violent epigastric pain, which persisted for five or six hours and then suddenly became exacerbated. Nausea developed and angina pectoris, and within five hours the patient died. The necropsy revealed an enormous lymphadenoma, the interior of which contained hemorrhagic foci, and in the adjacent parenchyma there were veritable lakes of blood. Death was apparently caused by this hemorrhage. Following the description of another case, the author points out that this mode of termination by hepatic hemorrhage is not sufficiently thought

of The treatment is of course purely palliative in these cases In the summary the author states that cancer of the liver may terminate rapidly (1) by the sudden aggravation of the inanition, which is produced by the dyspeptic coma, (2) by rapid secondary cancerization, (3) by an external hemorrhage, hematemesis or melena and (4) by intraparenchymatous hemorrhage In the latter cases, the rupture of a vascularized nucleus produces an effusion in the surrounding parenchyma and separates the trabeculae and even the capsule This accident is indicated by a sudden hepatic pain and is rapidly followed by death

*Prognostic Value of Slowing of Radial Pulse During and After Blood Transfusion for Hemorrhage M Fourestier—p 1113
Bilateral Renal Tuberculosis Marion—p 1118

Prognostic Value of Radial Pulse in Blood Transfusion—Fourestier demonstrates the importance and the necessity of the slowing down of the radial pulse during and after a transfusion that is given as a substitution in case of hemorrhage He shows that studying the frequency of the pulse before, during and after the transfusion permits the estimation of the quantity of injected blood, regulation of the rhythm of the intervention and the anticipation to a certain extent, of the patient's reactions after transfusion In case of a transfusion for substitution or replacement (in case of hemorrhage) the pulse which was at first accelerated must slow down during and after the transfusion If it does not do this the reason is that either the transfusion was not sufficient, the hemorrhage continues, or a state of shock exists, and it is necessary to try to arrest the hemorrhage by other means than even a massive transfusion The site of the injection can sometimes explain the absence of the influence of the transfusion on the slowing down of the pulse Transfusions in the veins of the lower extremities that are made late in profuse hemorrhages are often without apparent immediate action on the cardiac rhythm

Male Hormones in Urine of Men and Women—Dingemans and his collaborators studied the amount of male hormone in the urine of men and women of different age groups The male, like the female hormones, are eliminated in the urine in two different forms The methods of determination formerly employed disclosed only the free form of the male hormone. However, a large portion of the hormone is eliminated in the combined form Thus the formerly detected quantities of from 4 to 6 units of male hormone per liter of urine are much too low By heating with acid, the hormone can be freed from the combination and thus becomes demonstrable The authors do not describe the details of their method of extraction The hormones were tested by determining the growth of the combs of capons after injection of the hormone preparations The stated units are international units The authors summarize their observations as follows 1 The urine of healthy, sexually mature men contains from 40 to 50 units 2 The urine of healthy women contains approximately the same quantity of male hormone as does that of men (on the average from 30 to 60 units) 3 After the sexual function has ceased, even during advanced senility and after castration the urine still contains male sex hormone to be sure, the quantities of the hormones are considerably less than in younger persons 4 Boys and girls eliminate male hormone, but here too the quantities are smaller 5 Pregnancy urine also contains male hormone 6 It is improbable that the eliminated hormone originates in the ingested food

*Early Diagnosis of Acute Anterior Poliomyelitis R De Mattia—p 640
Old and New Treatments Humoral Mechanism of Bleeding U Roncelli—p 641

Leukemia with Early Myelosis and Remission—Penati states that there is a type of acute leukemia which evolves in two different periods with an interval of remission which lasts for from two to eight months The early period is that of acute or subacute myelosis or acute leukemia with grave hyperchromic anemia, a decreased number of blood platelets and leukocytes, agranulocytosis and the presence of a great number of immature cells in the blood During remission the clinical recovery is complete The hemogram is normal or there is slight agranulocytosis After remission, acute leukemia develops According to the author, this type of acute leukemia offers two problems for discussion The first problem is that of the relation between leukemia and the dysfunction of the hematopoietic system It points out the relation of leukemia to certain blood diseases (agranulocytosis, aleukia and panmyelophthisis) which originate in a dysfunction of the hematopoietic system The second problem is that of the possible reversibility of histopathologic changes in leukemia In connection with it, it is interesting to ascertain the reason for the recurrence after the remission According to the author the evolution of this type of leukemia is due to the fact that the threshold of the hematopoietic system is normal during the early period of the disease but is lowered as the disease progresses and is the lowest after remission The author recommends that (1) one have in mind a diagnosis of acute leukemia in acute and subacute myelosis (agranulocytosis, aleukia and panmyelophthisis), (2) if the clinical and blood conditions improve one should have the patient under medical observation for six or eight months for a possible recurrence, and (3) a biopsy of bone marrow obtained by puncture of the sternum should be done in all the cases in which recurrence takes place

Early Diagnosis of Acute Anterior Poliomyelitis—De Mattia emphasizes the importance of the diagnosis of acute anterior poliomyelitis early in the preparalytic period It is made by the following symptoms muscular pain that is more intense at the zones of union of the muscles and tendons, hyperesthesia of the skin on the involved muscles, disappearance or diminution of the reflexes, hypomotility of the muscles of the nucha (Deshayes' sign) and meningism The pain is of a lancinating type It shows the development of vascularitis and neuritis early in the evolution of acute anterior poliomyelitis and indicates the advisability of performing an examination of the cerebrospinal fluid obtained by lumbar puncture The cerebrospinal fluid in poliomyelitis is eliminated under normal or slightly increased pressure It is clear free from septic material and, after standing, produces no sediment and shows slight pleocytosis and increase of dextrose and albumin A doubt as to the differential diagnosis between lymphocytic meningitis and acute anterior poliomyelitis is no excuse for delaying the antiserum treatment, which has to be administered as soon as the first nervous symptoms appear Sometimes the administration of antiserum is followed by the appearance of paralysis of certain groups of muscles The paravsis is transient and confirms the diagnosis of acute anterior poliomyelitis in the given case

Conservative Surgical Treatment of Bilateral Reno-Ureteral Calculosis and Local Glycerin Treatment of Pelvic Ureteral Calculosis Results in Cases G di Maio—p 20

Tumor with Myeloplaxes of Tendon Sheaths—According to Santero, tumors with myeloplaxes of tendons and of tendon sheaths are made up of dystrophic tissues originating in local inflammation and trauma The clinical diagnosis is that of probability The differential diagnosis is made from

other types of benign tumors. The slow and benignant evolution of tumors with myeloplaxes differentiates them from sarcoma. The tumors, on microscopic examination, seem to be made up of giant cells of myeloplaxic type with a large number of nuclei, equally distributed in the cell, leaving the cellular periphery free from nuclei. The treatment consists in early surgical removal of the tumors and surrounding tissues. The patient must be observed for possible recurrences and the operation is repeated if there are any. Two cases of tumors of myeloplaxes of the tendon sheaths of the fingers are reported. There was an inflammatory factor in addition to industrial trauma in each case. Up to the present, two and four years since removal of the tumor, it has not recurred.

Systematic Administration of Intravenous Vaccines in Treatment of Typhoid A. Piraino—p. 1483

Pluriresistant Syphilis—Fivoli advises resorting to pyretotherapy in association with bismuth preparations in syphilis that is resistant to arsphenamine, bismuth preparations and mercury. The treatment consists of eight injections of streptobacillary vaccine (dmelcos) given at intervals of four days. During the intervals fifteen intravenous injections of 3 cc of a 10 per cent oil emulsion of bismuth are given at the rate of two each week. On completion of the treatment the patient is clinically cured, as is verified by the complete disappearance of the lesions of genital organs and oral mucosa and by the negative results of the Wassermann test. The crisis of the blood and nutritional and general condition of the patient are greatly improved by the treatment, which is harmless and well tolerated. One case is reported.

*Motor Functions of Ureter in Course of Pregnancy G. Cordaro—p. 92

Motor Functions of Ureter in Course of Pregnancy—According to Cordaro, the motor functions of the ureter during pregnancy are normal up to the fifth month, when they are retarded up to complete atony. Near the ninth month of pregnancy, the ureters become normal and continue to be normal during the puerperium. The age of the women and the number of children they have previously have no influence on the functional behavior of the ureters during pregnancy. The temporary atony of the ureters is due to the predominance of substances from the corpus luteum over prehypophyseal and follicular substances during this phase of pregnancy. The temporary inhibition of ureteral functions causes no injury to the kidney. However, if during the period of ureteral atony a local infection takes place, pyelitis develops. The functional torpor of the ureters in pyelitis continues all through the last three months of pregnancy and slowly regresses late in the puerperium.

*Etiology, Differential Diagnosis and Therapy of Pylorospasm and Pylorostenosis H. Knauer—p. 78

Roentgenogram of Sella in Premature Births K. Gefferth—p. 87

Treatment of Acrodynia in Children E. Mayerhofer—p. 94

Etiology, Differential Diagnosis and Therapy of Pylorospasm—Knauer points out that, because the stimulus threshold of the center of vomiting is rather low in nurslings and small children every infection not only a cerebral one, may be accompanied by vomiting. Moreover, such attacks may be followed by habitual vomiting. However, if vomiting appears during the first few weeks of life and is especially massive and explosive, pylorospasm or pylorostenosis is usually thought of. After pointing out that this condition is comparatively frequent, the author shows that two different terms for the same or at

least extremely similar disease entities indicate that the etiology of the condition has not been completely explained as yet. Some apply the term hypertrophic pylorostenosis, while others adhere to the term pylorospasm, some assume an abnormal narrowness of the mucosa, others see the cause of the symptoms in a primary, tumor-like muscular hypertrophy, and still others assume a primary stenosis followed by secondary muscular hypotrophy. Still other theories have been advanced and it is possible that the different theories are justified, for the reason that the anatomic foundation may not be the same in all cases. The author also cites cases in which the symptoms of pylorospasm are of purely nervous origin. In such cases the vomiting usually ceases as soon as the children are hospitalized, but it often recurs when the children are returned to the nervous parents. The author thinks that various factors concur in order to produce the condition, which he designates as "pylorospasm in simultaneous hypertrophic pylorostenosis." He gives several case histories which illustrate the justification of designating the condition as he does. He says that for years he was an advocate of the conservative method of treatment, but in view of the fact that of the large number of conservative measures which have been recommended none produce satisfactory results, he now advises surgical treatment for the pylorospasm with hypertrophic stenosis. Of course he does not recommend an immediate operation for every patient who is hospitalized with the diagnosis of pylorospasm. However, if after several days of observation the vomiting does not cease and other symptoms of pylorospasm are present, the operation should be performed for it is not advisable to postpone it for weeks until the child has become extremely weak. It is of course essential that the operation for hypertrophic pylorostenosis be done only by experienced surgeons, the after treatment should if possible be conducted in the pediatric clinic.

Chemotherapy and Specific Therapy of Tuberculosis H. Siegmund—p. 605

Specific Treatment of Tuberculosis W. Pfannenstiel—p. 655

Tuberculous Infection and the Endocrines—Schedtler was induced to study this problem by Schroeder's observation that the function of the thyroid plays an important part in the course of tuberculosis. That author observed that, in patients with hyperthyroidism, tuberculosis usually takes a rather mild course, whereas in myxedema an accompanying tuberculosis often has an especially unfavorable character. On the basis of these observations, which were supported by others, it has been suggested that thyroxine be used in the treatment of tuberculosis. The author investigated these problems in animal experiments but was unable to obtain uniform results in rabbits and guinea-pigs. On the whole he gained the impression that the animals which had been subjected to thyroidectomy succumbed to the tuberculous infection more slowly than the controls. Moreover, the administration of thyroxine exerted an unfavorable effect in that it activated the tuberculous process. In his studies on a large number of patients, the author found the combination of anomalies of the thyroid function with tuberculosis neither especially rare nor extraordinarily frequent but just about as would be expected. Thus he came to the conclusion that the thyroid function is not especially important for the course of the tuberculous process. Nevertheless, in case of the concurrence of tuberculosis with thyroid disturbances, the two disorders may influence each other. He does not think that thyroxine can be generally recommended as a therapeutic agent for tuberculosis. Further he discusses the influence of the gonadal function on tuberculous infections. In this connection he cites the unfavorable effects exerted on the tuberculous process during the time of puberty, the first period of married life, menstruation, pregnancy and especially during the time immediately after the birth of a child. Experiments have

proved that castration has a weakening effect on the tuberculous process and so it is suggested by the author that temporary castration (perhaps by means of roentgen rays) might exert a favorable influence on some cases of tuberculosis. Regarding the role of the pancreas in tuberculous infections, he says that it is generally believed that diabetes mellitus often favors the development of tuberculosis and that the tuberculosis in diabetic patients is usually rather severe. However, there is no evidence that tuberculosis predisposes to diabetes mellitus and so it may be concluded that the reduced resistance to tuberculosis on the part of diabetic patients demonstrates only that the resistance of these patients is generally low. The knowledge about the relation between the thymus and tuberculous infections is still limited, but the author directs attention to Schroeder's investigations, which proved that tubercle bacilli may be rendered apathogenic in thymus extracts. Other excretory organs seem to exert no noticeable influence on the general tuberculous infection.

General Tuberculous Infection as Allergic Disease—Schulz says that it is well known that allergy develops with tuberculous infections. This fact as well as the allergic processes in tertiary phthisis are not discussed here, but the author tries to find replies to the following questions: 1. Is there a tuberculous hyperallergy? 2. Under what conditions does it develop? 3. What are its clinical aspects? He defines hyperergy as an increased reaction and hyperallergy as an increased, changed reaction, that is, a pathologic one, an increased sensitivity to toxin. In tuberculosis the hyperallergic process is demonstrated most clearly when the intracutaneous vaccination with extremely small quantities of tuberculin is followed by a severe inflammatory or even necrotic reaction in the involved portion of the skin. It should be understood that such reactions can take place also in other organs which are not as easily accessible for observation as is the skin. Regarding the conditions under which tuberculous hyperallergy develops, the author is of the opinion that it can develop only if the tuberculous antigen reaches the blood stream slowly and successively by way of the lymphatic passages. In this manner the organism is again and again in a state of irritation, which results in sensitization and finally in hyperallergy. In discussing the clinical aspects of tuberculous hyperallergy, the author differentiates two phases. During the first phase the general sensitization of the organism develops. The second phase develops either as the result of the accumulation of antigens or because the body has been weakened and the consequent reduction in the antibody formation results in a great excess of antigens. After showing that the tuberculous hyperallergy may become manifest in pulmonary processes and also in other organs such as the stomach and gallbladder, the author discusses the therapy. Efforts should be made to bring the hypersensitized organism again into a normal reactivity by means of desensitization with tuberculin.

Blood Creatinine and Urine Creatinine as Measure of Glomerular Filtration W. von Morawski, S. Grzycki and W. Guca—p. 989

Antiketogenic Action of Dextrose—Markees describes his investigations on the "antiketogenic" action of dextrose. He attempted to answer the question "Can the administration of dextrose simultaneously with or before the intake of fat (in fasting persons) prevent the formation of acetone bodies from the food fats?" He found that the administration of dextrose does not prevent the formation of acetone bodies but accelerates and improves the utilization and removal of the formed acetone bodies in the organism, that is, it prevents a spontaneous hyperketonemia. The alimentary ketogenesis, however, is preserved, as was demonstrated by the epinephrine intercep-

tion method. The author points out that these observations are a new proof of the close connection between fat and carbohydrate metabolism.

Rapid Method for Estimation of Uremia—Popper and his associates assert that mild disturbances in the renal function produce an increase in the creatinine content even if the rest nitrogen is still unchanged. In the more severe forms of renal insufficiency, in which the rest nitrogen is increased, the increase in creatinine is much more pronounced. Whereas rest nitrogen rarely increases to more than ten times the normal value, the creatinine content may increase to forty times the normal content. Thus the creatinine content is an extremely sensitive indicator of renal insufficiency and the determination of the creatinine content deserves the preference over the determination of the rest nitrogen. Jaffe's color reaction, which was used by Folm and the principle of which is used also in the reaction here described, can be done rapidly and with simple means. It permits the demonstration of an increase in the creatinine content of the blood. Since the creatinine content of the whole blood and the plasma do not differ greatly, the test can be made on the whole blood. The required reagents are saturated picric acid and a 10 per cent sodium hydroxide solution. Approximately 2 cc of blood is withdrawn from the vein and put into a test tube that contains approximately 8 cc of saturated aqueous picric acid. After the blood and picric acid have been thoroughly mixed, the mixture is heated over the Bunsen burner until the color changes from yellowish red to brownish red. Then filtration is done and after the not always clear filtrate is cooled under the water tap, 1 drop of the sodium hydroxide solution is added for each cubic centimeter of filtrate. The authors remark that the quantitative ratios do not have to be absolutely exact. Following the addition of the sodium hydroxide, the light yellow color of the picric acid changes to dark yellow if the creatinine content is normal, for in such cases the concentration of the creatinine is too slight to produce a noticeable red coloration. If the creatinine content of the blood is slightly increased, a reddish color develops in the course of about five minutes. In case of greater increase in creatinine, the red coloration becomes more intense. With this simple test it is possible to determine in a few minutes the degree of renal insufficiency as well as the presence of an incipient or a fully developed uremia. The authors give a tabular report of fifty cases in which they demonstrate that the creatinine values (as determined with the described test) correspond with the rest nitrogen values.

Injurious Effects of Iodine Caused by Use of Tooth Pastes Which Contain Iodine W. K. Frankel—p. 1137

Acidity in Gastritis and Bacterial Flora—Mahlo reviews the literature on the bacterial flora in the stomach and finds some contradictory statements for whereas some insist that the gastric juice has a disinfecting power, others deny this. The author himself thinks that, in gastritis, in which the hydrochloric acid conditions are normal, bacteria from various sources may be found. There are bacteria which originate in the oral cavity, some which originate in the small intestine, some which thrive in the phase surface epithelium/mucus and some killed bacteria that are protected against digestion by mucus. The predominance of the one or the other factor will explain the different bacterial aspects in the presence of normal acidity. Moreover, even if the great bactericidal power of the gastric juice has been established, this does not prove that in stomachs with gastric changes the same conditions prevail over the entire epithelial surface, on the contrary, it must be assumed and it is indicated by the bacteria in the mucus that the bacterial colonies thrive in certain regions, that is, probably at the sites of severest inflammation. In answer to the question whether a gastritis in which the mucus contains large bacterial

colonies differs from other gastritides the author states that there are no definite clinical differences. Only a microscopic examination of the mucus permits a diagnosis. In discussing the therapy the author points out that watching the elimination of reducing substances in the urine is of great help. In case of gastritides with subacidity, measures should be taken to remedy this subacidity. If this is done, the bacteria will be killed and the gastritis improved. However, in gastritis with normal or hyperacidity a silver protein preparation not only kills the bacteria but also exerts a favorable effect on the inflammatory process. The author admits that the use of silver preparations involves the danger of argyrosis and so he recommends oxygen in the nascent state, which he produces by giving magnesium superoxide together with katalase (peroxidase). This medication destroys the bacterial colonies in a few days.

Transfusion of Conserved Blood E Domanig—p 1067

Pathogenesis of Herpes Zoster in Lymphatic Leukemia—Schemker gives a detailed description of a case of herpes zoster gangraenosus in which a lymphatic leukemia was discovered as the basic disorder. From the clinical point of view the case is noteworthy because of the formation of large pemphigus-like blisters with a hemorrhagic base and a tendency to hemorrhages. This symptom does not occur in the ordinary idiopathic herpes zoster and might be explained by the tendency to hemorrhages, which exists in leukemia. The case had a fatal outcome. The necropsy is described and particularly the microscopic aspects of the brain and spinal cord. Relations of leukemia to herpes zoster are suggested by the pathologic changes on the roots and spinal ganglions of the upper dorsal region. The root bundles contained dense leukemic infiltrations. The same infiltrations, although in a milder degree, were found also in the region of the spinal ganglions. The author suggests that these leukemic infiltrations on the spinal roots and ganglions may have elicited a disturbance in the trophovasomotor innervation and thus may have produced a favorable ground for the development of the herpes zoster.

Normal Human Serum in Multiple Sclerosis—Stransky based his therapeutic experiments with normal human serum on the hypothesis that multiple sclerosis is an infectious process. He admits that the infectious nature has not been proved as yet but thinks that it is nevertheless possible. He assumes that the blood of persons who remain free from it might contain humoral protective substances against the virus of multiple sclerosis and decided to try the serum of such persons in the treatment of patients with multiple sclerosis. In view of the fact that multiple sclerosis usually develops in the period between puberty and the middle years of life and only rarely in persons over 50 years of age, he decided to try serum of persons over 50 years of age who had never shown signs of multiple sclerosis. The serum of such persons was put through the necessary process to insure its sterility and was put into ampules of 10 cc each. It was injected into the gluteal muscle of patients with multiple sclerosis. The single doses never exceeded twice 10 cc in one day. The intervals between the injections were usually two days, rarely one day. In a few cases more than two days elapsed between the injections. The author cites several cases of multiple sclerosis in which this treatment produced favorable results. The quantity of serum that is required for an effect and the duration of the effect

seem to vary in different cases. The author shows that this treatment will require further investigation. He suggests that larger quantities of serum or even direct blood transfusion could be tried.

Action of Extract of Bacillus Pyocyaneus—Adler points out that as early as 1888 it was observed that *Bacillus pyocyaneus* and its metabolic products prevent infections with anthrax. He reviews subsequent bactericidal experiments with extracts of *Bacillus pyocyaneus* and shows that they produced contradictory results. The ineffectiveness of some preparations and certain defects, such as the unpleasant odor, caused many physicians to abandon the therapeutic use of the pyocyaneus extracts. The action of the former pyocyaneus preparations was due to their content in dyestuffs and in fatty acids. Both components have a bactericidal effect, but since there are pyocyaneus preparations that have no bactericidal effect, there must be a third, as yet unknown, factor. At the serotherapeutic institute of Vienna, efforts were made to eliminate the defects of the earlier preparations. The new pyocyaneus extract is produced from several strains, some of which contain dyestuffs and some of which do not. Alcoholic extracts are prepared from forty-eight hour agar cultures and, after several purifications, they are condensed by evaporation. The residue is dissolved in water and unsaturated fatty acids are added. By avoiding bouillon cultures, the offensive odors are readily removable. The final preparation is free from killed bacteria and from disinfecting substances. Bactericidal experiments with the new preparation gave satisfactory results. The preparation was found helpful in tonsillitis, nasal diphtherias and certain forms of rhinitis.

Magnesium Sulfate in Treatment of Eclampsia—Stroganov and Davidovich report the results of magnesium sulfate therapy in 201 cases of eclampsia. The treatment was carried out in the following manner. The patient was placed in a darkened room and kept at absolute rest. Soon after an eclamptic attack or after the admission, the patient was given from 0.015 to 0.02 Gm of morphine hydrochloride and an examination made under light chloroform anesthesia. Half an hour later, 40 cc. of a 15 per cent solution of magnesium sulfate (6 Gm) was introduced under the skin. Morphine was repeated one and one-half hours later and magnesium sulfate three and one-half hours later in a dose of 6 Gm if there was another attack, or of 4 Gm when no further attack took place. If labor did not terminate, 4 Gm of magnesium sulfate was injected eight hours later. Full doses (6 Gm), not to exceed 24 Gm in twenty-four hours, were given if the attacks recurred. Patients admitted to the clinic after six or more attacks were treated by means of blood letting and puncture of the amniotic bag. Of the 201 patients, six died. Of 212 children born, 167 were dismissed living from the clinic (78.8 per cent). There were thirty stillbirths and fifteen deaths after delivery, altogether forty-five, or 21.2 per cent. Attacks were terminated in 136 (67.7 per cent) after one injection of magnesium sulfate. Sixty-nine patients went on to a spontaneous delivery, while 132 were operated on. The authors conclude that magnesium sulfate is a potent agent in the treatment of eclampsia. They are, however, unable to say whether it is more useful than chloral hydrate. Among the disadvantages of the drug the authors point out its toxicity, which they feel was counteracted in their cases by the administration of morphine, the tendency to the development of abscesses at the site of injection and a tendency to the development of psychoses. The latter occurred in 2 per cent of their cases, while with the use of chloral hydrate the incidence was 1 per cent.

THE VALUE OF SPECIALIZATION IN MEDICINE

CHAIRMAN'S ADDRESS

LOUIS A. BUIE, M.D.
ROCHESTER, MINN.

In past ages the majority of physicians remained in a middle state, being neither very capable nor yet entirely inefficient, neither very altruistic nor very vicious, but living each day in peaceful mediocrity, accepting current opinions without skepticism or desire for proof, exciting no interest or envy, causing no wonder, just maintaining their position on a level with their generation and innocuously conforming to the intellectual and scientific standards of the period and country in which they lived. Their guiding principle was a blind and unhesitating credulity, but they were so tenacious of the opinions which they imbibed that whatever first occupied their understanding was likely to mold much that followed. Constantly proceeding under the guidance of contemporary opinion, they created nothing new but merely ambled along in dull and monotonous uniformity, performing their duties according to current standards.

Such acquiescence inevitably engenders apathy, and such a cold spirit of routine acts on men like a blight, blunting their faculties and withering their powers. Under such conditions there is a sensible decay in that vigor of character and in that diversity and audacity both of conception and of execution which paves the way to achievement. Despite adverse circumstances, however, history has proved that mankind possesses more virtue than vice and that good actions, if not more abundant, are more productive of permanent effects than bad ones. If it were otherwise, the very preponderance of evil would doubtless have destroyed us long ago and there would not by this time have been left even a single individual to lament the degeneracy of his species.

Thus we have not succumbed to evil methods but have benefited by the influence of those really great spirits whose works are among the glories of medical science. Their discoveries have come down as eternal truths which have survived the shock of empire and outlived the struggles of rival creeds. Their influence shall reach the most distant posterity and after the lapse of centuries shall produce more effect than at the moment of their promulgation.

Knowledge is not an inert or passive principle. It must be sought before it can be won. It is the product of great labor and of great sacrifice, and men who are perfectly content with their intellectual allotment will

not incur this labor. For centuries civilization struggled along attended largely by men without science—men who practiced methods of healing based solely on empiricism. They possessed little knowledge and had little desire for it. At length, however, reason began to display its power and to disperse the mists by which it was surrounded. Even the most casual observer, witnessing the progress of science through the ages, becomes impressed with the undeniable truth that the significant part of genius is work and that the achievements of our predecessors have been due to endless labor and concentrated effort in specialized fields.

It was Andreas Vesalius, for example, a profound and energetic student, who during the sixteenth century freed the study of anatomy from the many prejudices which had surrounded it because of the theological concept of the sanctity of the human body and its ultimate resurrection. It was he who paved the way for such peerless students as Miguel Servetus, who discovered that the blood in the pulmonary circulation passes into the heart after being mixed with the air in the lungs and who was burned at the stake by order of Calvin because of a "theological quibble." The teachings of Vesalius were sustained by his contemporaries Fallopius, Sylvius and Eustachius and were rendered accessible to surgeons by Ambroise Pare, who reintroduced the use of the ligature in amputations, made the first exarticulation of the elbow joint, described fracture of the neck of the femur, first suggested syphilis as a cause of aneurysm, and by his description made podalic version practicable.

In the seventeenth century the name of William Harvey of course stands out as the greatest of that period, and although the circulation of the blood might have been previously inferred by Servetus, guessed at by Galen or witnessed by any wounded slave, it was Harvey who studied all preëxisting theories and who by anatomic dissection and experiment proved the muscular action of the heart and its effects on the motion of the blood. With the aid of the microscope, which he invented, Leeuwenhoek first described the spermatozoa (1674) and gave the first complete account of the red blood corpuscles. He discovered the striped character of voluntary muscle and made other discoveries in the microscopic field. Capillary anastomosis between the arteries and veins, which was the only phase of the circulation that remained obscure to Harvey, was observed by Malpighi (1660), and this tireless student has become known as the founder of histology.

The seventeenth century also produced Descartes, who was responsible for the first European textbook on physiology, Sylvius, who "did for Harvey's ideas what Pare had done for those of Vesalius", Glisson, the anatomist, physiologist and pathologist, who first gave a classic description of infantile rickets, first described the capsule of the liver investing the portal vein and first employed suspension in the treatment of spinal

Eighty-Eighth Annual Session of the American Medical Association
Atlantic City, N. J., June 10, 1937.

deformities, and Thomas Sydenham, who gave a new interpretation of internal medicine

The eighteenth century gave us the master physiologist Albrecht von Haller, Lavoisier, who discovered the true nature of the interchange of gases in the lungs, the great anatomist and surgeon Antonio Scarpa, William Hunter, the obstetrician, and his younger brother, the great John Hunter, whose contributions to the science of medicine are too numerous and well known to require review. In this period too we find Leopold Auenbrugger, who discovered and verified by post-mortem study the value of immediate percussion of the chest in diagnosis, Morgagni, who in his seventy-ninth year published the true foundation of modern pathologic anatomy, Gaspar Casal, a Spanish physician who in 1735 first described pellagra, Edward Jenner, who successfully introduced preventive inoculation in 1798, and Benjamin Franklin, who invented bifocal lenses in 1784, later invented a flexible catheter, and who treated nervous diseases by electricity.

The nineteenth century produced Laennec, who invented the stethoscope, Pierre Bretonneau, who performed the first successful tracheotomy in a case of croup and who located and described the typhoid lesions in Peyer's patches, Philippe Ricord of Baltimore, who was the greatest authority on venereal diseases after John Hunter, and Robert James Graves, Richard Bright, Thomas Addison, Thomas Hodgkin, James Parkinson, Carl Rokitsansky, Oliver Wendell Holmes, Sir Charles Bell, Johannes Muller and the physiologist William Beaumont. In our own country future generations will revere the names of Ephraim McDowell and James Marion Sims, in England, those of Lord Lister, Thomas Henry Huxley and Sir William Turner, in Switzerland, Wilhelm His, in Russia, Metchnikoff and Ivan Pavlov, in Germany, Rudolf Virchow, Cohnheim and Koch, and in France the great Louis Pasteur. The work of Long, Wells and Morton is too well known to require repetition here.

In the year 1851 Hermann von Helmholtz invented the ophthalmoscope. In 1852 Henry J. Bigelow performed the first excision of the hip joint, and in 1873 Theodor Billroth made the first complete excision of the larynx. In the same year Koch found the spirillum of Asiatic cholera, and in 1879 Hansen discovered the bacillus of leprosy. In 1880 Karl Joseph Eberth discovered *Bacillus typhosus*, Koch isolated the bacillus of tuberculosis, and Alphonse Laveran identified the parasites of malaria in the red blood cells. In 1882 Friedrich Löffler discovered the bacteria of erysipelas in swine and the cause of glanders and, with Edwin Klebs, found the bacillus of diphtheria. The cause of tetanus was discovered by Arthur Nicolaier in 1884, and in 1883 Fränkel isolated the pneumococcus. X-rays were discovered by Wilhelm Konrad Roentgen in 1895, and radium was discovered by the Curies in 1898. Sir Ronald Ross in 1897 discovered Laveran plasmodia in the wall of the stomach of *Anopheles* mosquitoes which had fed on blood of malarial patients. In 1901 the work of Walter Reed, Carroll and the martyr Lazear established *Stegomyia fasciata* as the transmitting agent in yellow fever.

In 1905 Fritz Schaudinn discovered *Spirochaeta pallida*. This was followed in 1906 by August von Wassermann's diagnostic test of syphilis, which he affirmed could never have been discovered had not Paul Ehrlich previously propounded the theory that the living protoplasmic molecule consists of a stable nucleus and unstable peripheral side chains, or chemoreceptors,

which enable it to combine chemically with food substances and neutralize toxins or other poisons by throwing out detached side chains into the blood. Ehrlich's arsphenamine appeared in 1910.

Our present generation witnesses the work of Flexner, Banting, Frei, Schick, Rosenau, the Dicks and others, and many have had opportunity to learn first hand from Osler, DaCosta, Janeway, Billings, Kelly and Welch. According to Garrison, the Mayos have made improvements in visceral surgery, and their genius for method and system has made listerian surgery a reliable science.

Thus we observe that, in medicine, materials have been collected which present a rich and imposing appearance, and what has characterized those eminent scientists who have been responsible for these immortal bequests and given them their real superiority is that fine and delicate perception which is due partly to experience, partly to their inherent aptitude in discovering analogies and differences which ordinary observers are unable to detect, but, most of all, to their ceaseless labor. The more sensibility and genius they possessed, the more they attached to themselves ideas that elevated them, and their doctrines have become our law. They displayed a boldness of inquiry, a recklessness in the pursuit of truth and a disregard of traditional opinion that entitles them to the highest praise. Their accomplishments have been only a part of that vast movement by which the human intellect, with infinite difficulty, has vindicated its own right and slowly emancipated itself from inveterate prejudices which long impeded its action.

From the foregoing historical review, it will be observed that specialism is not new. "I will not cut persons laboring under the stone but will leave this to be done by men who are practitioners of this work." In this language Hippocrates expressed his sentiments regarding specialization, and it is known that long before his time there were those who limited their work to various phases of medicine. It was probably not until the beginning of the nineteenth century, however, that specialization began to assume definite form. In 1804 the Royal Ophthalmic Hospital was founded in London, and in 1814 the Royal Hospital for Diseases of the Chest. A hospital for the practice of obstetrics was established in Boston in 1830.

In our own generation we are witnessing a new development in specialization. With the advance of medical science it becomes more and more evident that no single individual is capable of caring for all the ills to which the human body is heir. The general practitioner, the surgeon, the internist and the specialist himself seek assistance from those who by limiting their attention to a certain phase of medicine have become skilful in its management. Thus "group practice" has been evolved, and it appears that a difficult problem is more likely to reach solution in the hands of several physicians interested in various phases of that problem than if one physician attempts the task. For example, a patient with gastric distress may meet the internist, the gastro-enterologist, the radiologist and often the surgeon during the course of his examination. Such specialism may be carried to what is at present considered by some to be an undesirable extreme. For example, in the field of gastro-enterology there are men who specialize in the treatment of duodenal or gastric jejunal ulcer, esophageal diseases, gastric disorders, diseases of the gallbladder, amebic dysentery, ulcerative colitis and other conditions. Then there is the physician who has the temerity to deal only with the problems of

those who suffer from functional disorders of the gastro-intestinal tract. Abuses have developed, but probably every new truth that has been propounded has for a time caused mischief. Progress depends on change, and it is only by practicing uncustomary things that one can discover whether they are worthy. It is also likely that most opinions held by the majority were once limited to the minority. In fact, if the opinions of the majority had always prevailed, Christianity would have passed into oblivion at the time of the Crucifixion.

There is therefore no room or reason for discouragement as we face our task. It is probable that our generation has seen the beginning of a period which will be known as the age of specialization. We are fortunate in that, in the main, our destiny is in the hands of the Council on Medical Education and Hospitals of the American Medical Association and the Advisory Council for Medical Specialties. These bodies have performed signal service, and the fact that the latter is now composed of representatives of twelve separate specialties, with individual boards that determine the fitness of applicants seeking certification, indicates the progress which has been made. Under their guidance we may expect that there will soon be none who will be admitted to specialty practice without suitable qualifications based on fundamental training in medicine and surgery and final study and experience in the special field. The fact that under adverse circumstances such advance has been made is proof of the integrity of the scheme as well as of the commendable zeal of its protagonists. This justifies the belief that their aims will ultimately be achieved.

TREATMENT OF THROMBOSIS OF THE LATERAL SINUS

WITHOUT LIGATION OF THE INTERNAL
JUGULAR VEIN

MATTHEW S. ERSNER, M.D.
AND
DAVID MYERS, M.D.
PHILADELPHIA

The treatment of phlebitis and thrombosis of the lateral sinus has attracted discussion in otologic circles for many years. That it is still a moot subject is evidenced by the voluminous literature and the varying opinions expressed by the many leaders of our specialty. It is only by exchange of ideas and comparison of methods employed that the treatment of this dangerous complication will some day be settled to the satisfaction of all.

The precedents established by the early pioneers, Zaufal, Lane and Ballance, and others, have served to predicate for many years the mode of attack. That the ideal in therapy has not been achieved by the ligation of the internal jugular vein, or its resection, is easily ascertained by the high mortality rate various authors report.

Krepusca (quoted by Rott¹) reported 295 cases of involvement of the lateral sinus. The mortality was higher for patients who were subjected to ligation than for those who were not. In a total of 132 cases of

ligation seventy-four deaths occurred, or a mortality of 56 per cent, and in 163 cases of nonligation there were twenty-five deaths, or a mortality of 15 per cent. Later authors reported a lower mortality in the treatment of sinus thrombosis and phlebitis with newer modes of therapy, as in a series of cases reported by Coates, Ersner and Persky,² in which the mortality was only 14 per cent.

If ligation of the internal jugular vein is such a life-saving procedure and, as stated, shuts off the major portion of the cranial circulation from the general system, why is it that after the ligation many patients are still so very ill, that the period of hospitalization continues to average from six to seven weeks, that sepsis continues for many days after the operative procedure and that metastasis is so frequent after ligation? Meltzer³ showed that metastasis occurred four times as often after ligation as before it. Of thirty patients treated at the Massachusetts Eye and Ear Infirmary, twenty-six actually had metastasis after ligation.

In the past the treatment of thrombosis of the lateral sinus followed the hard and fast rules set down by the early pioneers. The internal jugular vein was ligated by some surgeons as the first step in the procedure and by others after the attack on the sigmoid, some followed the plan of Alexander, by exteriorizing the vein, after its section.

More recently, various surgeons e. g., Mygind, Rott and Dixon, advocated nonligation of the internal jugular vein. Thus there are two schools of thought.

Recently, in speaking on this subject before the Ear, Nose and Throat Section of the Pennsylvania State Medical Society in October 1935, we⁴ described our procedure as follows:

In the course of our experience with many of these cases, we have formulated the following flexible rules to help guide us. The lateral sinus is always first to be attacked. If an occluding thrombus is found that can easily be removed and free bleeding is obtained from both ends, then the lateral sinus is merely blocked by packing and nothing is done to the internal jugular vein.

If after incision of the lateral sinus phlebitis is found without a thrombosis, the sinus is obliterated and no treatment is given to the jugular vein. If a thrombus is found in which bleeding from the lower end cannot be obtained, we are then confronted with several problems. In mild cases without local signs in the neck the thrombus is not disturbed nor is the jugular vein ligated. In a case with severe septicemic symptoms, presenting local physical signs in the neck indicating an extension of the thrombotic process downward, the internal jugular vein was always ligated.

At present we are not concerned with producing free bleeding at the time of the surgical attack on the lateral sinus when an occluding thrombus is present. In such cases we do not attempt thrombectomy, nor do we remove the diseased sinus wall. We merely incise the lateral sinus and institute drainage.

Our reasons for these changes in therapy are based on clinical anatomic and physiologic facts which we shall attempt to enumerate. The anatomy of the cranial venous sinuses is well known. We shall mention only several important features that are germane to this dis-

cussion and will include a description of the areas drained by the lateral sinus and a description of the collateral circulation

The intracranial structures drained by the lateral sinus have recently been well described by Nielsen and Courville,⁵ from whose article the following sentence is quoted "The countless number of tributaries from every portion of the cranial cavity and its contents which flow into the lateral sinus are factors which must be remembered, since these traverse the subarachnoid and subdural spaces and potentially expose these spaces to infection when the lateral sinus becomes infected"

Connecting the cranial venous sinuses with the systemic circulation are the emissary veins, the mastoid, parietal, occipital and condyloid. In addition, the sinuses communicate with the superficial circulation through the vertebral veins, the ophthalmic veins, the middle meningeal veins, the pterygoid plexus, the basilar plexus and the carotid plexus

This hasty review will serve to illustrate the intercommunication of the dural venous sinuses with the general and intracranial circulation and the pathways through which infection may spread despite ligation and obliteration of venous structures

Our next consideration is the essential physiology, as well as the pathologic physiology, of the lateral sinus

The essential physiology is well summarized by Nielsen and Courville⁵

The lateral sinus carries the greatest portion of venous blood from the intracranial spaces through the jugular bulb into the jugular vein. Since these channels and their afferent veins are without valves the venous outflow is quite direct. The flow, however, is under negative rather than positive pressure in the system. The venous blood is pumped out of the skull by the action of the heart rather than evacuated by the force of gravity alone. The flow is also slowed by the numerous bends, twists and angulations in the course of the venous channels. It is also interfered with by the trabeculations which run across the lumens of the larger sinuses. In the case of the superior longitudinal sinus, the blood has to ascend when the body is in the erect position and also against the inflow from the superior cerebral veins

The lack of actual valvular obstruction makes it possible for the blood current to be entirely reversed within the system under certain conditions. As a result of coughing, straining or vomiting, the current may be temporarily reversed an alteration which is favored particularly by the presence of the inferior anastomotic veins which permit the backing up of the blood from the region of the genu directly to the dorsolateral surface of the cerebral hemisphere

In case of complete obstruction by pressure from a thrombus, reversal of the current may be responsible for retrograde thrombophlebitic changes, which may account for many of the distant complications of infection of the lateral sinus. This view is held by many. Dixon⁶ stated that extension of the thrombus is always retrograde and that ligation is therefore an unnecessary and illogical procedure. Stone and Berger,⁷ in a study of primary thrombosis of the internal jugular vein due to suppurative processes in the neck, observed that the extension of the thrombophlebitis is toward the periphery, i. e., toward the skull, or retrograde

Since the extension of the infection is retrograde rather than downward, it is evident that ligation of the

jugular vein is superfluous, because such ligation does not completely eliminate collateral circulation or prevent retrograde infection. The protective element is the thrombus, whether it is retrograde in the lateral sinus or its tributaries, not the ligation or the thrombectomy, because the final outcome of thrombectomy and ligation of the jugular vein is a thrombus which in itself may become retrograde

The basis of thrombus formation is the response of the endothelial tissue of the vein to an irritant—mechanical, bacterial or toxic. Other factors operative are slowing of the circulation and deposition of fibrin. The thrombus may form as the result of direct extension through the venules, as with hemorrhage in the mastoid, or by pressure of infectious material, as with perisinuous abscess. The latter type of formation often occurs with coalescent mastoiditis

A thrombus is therefore a physiologic protective mechanism having a pathologic basis for its formation and is nature's response to any or all of the factors enumerated. We have therefore come to regard it with a friendly attitude, because it is nature's response to a potential danger, and it is an important protective element in the line of defense. Rott¹ stated "Thrombosis is a protective mechanism, nature's method of preventing the spread of infection"

Kopetsky⁸ said "Thrombosis per se is regarded as a defensive mechanism, nature's effort to circumscribe our infection entering the blood stream through the wall of a vein"

Boyd⁹ stated that "the thrombus is beneficial as the thrombotic process which occludes the vessel usually succeeds in keeping ahead of the liquefaction process which renders the clot so dangerous, so that there may be a considerable area of liquefied clot in the vessel, a veritable abscess, which is, nevertheless, securely shut off from the general circulation by the thrombus"

On the other hand, we have observed that in the fatal cases of lateral sinus phlebitis, with septicemia, there was no attempt at thrombus formation

One must therefore reappraise the thrombus from a protective physiologic standpoint rather than consider it a pathologic foreign body. One must emphasize that the thrombus is nature's method of protecting the individual. When the thrombus is incompletely formed, septicemia, bacteremia and emboli are the result

TREATMENT

In view of the fact that the thrombus is considered a protective agent, the treatment should be expectant, with careful observation before the vein is attacked surgically. Many cases of phlebitis or thrombosis subside under conservative treatment. It is a well known fact that a thrombosed but uninfected lateral sinus does very little if any harm. Day¹⁰ reported six cases of spontaneous cure of unrecognized thrombosis of the lateral sinus accidentally discovered during operation

Richards¹¹ stated "There are the numerous cases of symptomless thrombosis discovered by chance during a mastoid operation, indicating that at times at least nature is quite capable of walling off an infection in the vein without any help from the surgeon. On this

fortuitous help, of course, one could never safely rely, but it indicates that thrombosis in and of itself does not necessarily lead to septicemia."

We shall divide our treatment of lateral sinus involvement into the medical and the surgical phase

Medical—The medical treatment is primarily concerned with the septic symptoms that the patient manifests. The transfusion of whole blood is probably one of the most important single modes of therapy we can mention. Transfusions of whole blood are given daily or on alternate days. The amount of blood administered is small. To children we give from 15 to 2 cc per pound (0.5 Kg.) of body weight. The transfusion should be guided by the temperature and by frequent hemograms. Small and frequently repeated transfusions act to stimulate formation of antibodies.

In addition to transfusions of whole blood, whenever practicable or available immunotransfusions, specific or nonspecific,¹² may be used. These also are given in small amounts and at frequent intervals.

The use of specific serum when available should be instituted. Dick's antiscarlatinal serum has been a useful adjuvant in some cases.¹³ Forced feedings, tonics and ultraviolet irradiation are of value. Symptomatic treatment is given as indicated.

Chemotherapy During the past year the use of sulfanilamide (para-amino-benzene-sulfonamide) has attracted considerable attention. Since most cases of thrombosis of the lateral sinus are of streptococcal origin, this drug should be of great value. The literature is full of glowing reports concerning its use.

The use of quinine dihydrochloride in the presence of chills, given in frequent doses until the patient complains of tinnitus aurium, occasionally yields beneficial results.

In the presence of generalized septicemia, a fixed abscess, specific or nonspecific, may aid in clearing the organisms from the blood stream. The nonspecific abscess may be produced by the injection of an irritating substance such as turpentine. The specific abscess is induced by injecting attenuated organisms obtained from the host.

Surgical Treatment—The first step in the surgical attack is to eradicate the focus or the source of the infection. (a) If symptoms suggesting sepsis are present in cases of otitic infection, immediate mastoidectomy should be performed and the lateral sinus exposed for further study and observation. In the meantime, expectant treatment is instituted. (b) If septic symptoms indicative of involvement of the lateral sinus occur after mastoidectomy, then the mastoid should be revised and the sinus exposed for inspection. In many instances we are unable to judge the contents of the vessel from its external appearance. It therefore becomes necessary to inspect the interior of the vessel. Our procedure in all instances is not to ligate the internal jugular vein as a preliminary step. The sinus is packed above and below and is then incised. If free bleeding is obtained from both ends of the sinus we repack in order to control the bleeding.

We feel that by packing we produce a "man made" thrombus which seems to limit the infection. This accomplishes what nature failed to do if the vein is

obliterated above the point of infection, the packing will produce the thrombus, and if this new thrombus is sterile, recovery follows.

Incomplete or mural thrombosis is treated in similar manner as phlebitis. The vein is occluded by packing, and the patient is treated expectantly. In cases of complete thrombosis without bleeding after incision of the sinus, we do not attempt to remove the thrombus or produce free bleeding. We insert a piece of rubber tissue or iodoform gauze as a drain and then proceed with the supportive treatment. It is not essential to remove the thrombus or to excise the wall of the sinus, because when this is done the sinus must be obliterated. Healing depends on the formation of another thrombus (man made), which may or may not be sterile. It must be remembered that the act of thrombectomy may destroy the protective barrier that nature has introduced. In the past we have observed many cases in which we were unable to dislodge the thrombus from the lower end of the lateral sinus and produce free bleeding. Rather than subject our patients to a difficult operation on the jugular bulb, we allowed the thrombus to remain and did not ligate the internal jugular vein. The patients made uneventful recoveries. It was this observation that led us to feel that when the thrombus is firmly fixed no benefit can accrue from its removal.

If on incision of the lateral sinus an abscess is observed, we insert drainage. This procedure was recently recommended by Maxwell.¹⁴ Three such cases were encountered by my associates Drs. Ball and Mitchell during the past few months. In each of these cases an abscess had perforated through the anterior wall of the lateral sinus. The only surgical therapy instituted was incision and drainage supplemented by supportive treatment. All the patients made an uneventful recovery. If the septic symptoms continue and physical signs evidence involvement of the internal jugular vein, then the vein is exposed and incised and drainage is instituted. We do not ligate, resect or exteriorize.

By following the surgical principles as outlined, we promote drainage, which after all is the primary surgical dictum. But we avoid meddlesome surgical intervention that might break up protective barriers. Sixteen cases were treated without ligation of the internal jugular vein, as follows: (a) four cases of central liquefaction of the thrombus, (b) three cases of phlebitis, (c) four cases of complete thrombosis of the jugular end of the sinus, (d) one case of mural thrombosis and (e) four cases of complete thrombosis in which no bleeding occurred from either end.

CONCLUSIONS

- 1 Thrombosis is a protective process.
- 2 Ligation of the internal jugular vein is not a panacea in the treatment of infection of the lateral sinus.
- 3 Ligation of the internal jugular vein does not prevent metastasis, embolism or septicemia.
- 4 Treatment of infection of the lateral sinus is primarily medical and partially surgical.
- 5 The surgical principle is the institution of drainage and the avoidance of over manipulation.
- 6 Thrombectomy is not indicated when the thrombus is firmly fixed.

7 The internal jugular vein should not be ligated when infection is present, but drainage should be instituted by means of incision

8 Ligation is not the crux of the situation

9 Recovery depends on the resistance of the host and its protective elements, according to our experience the thrombus is one of the mechanisms in the line of defense

1915 Spruce Street

ABSTRACT OF DISCUSSION

DR H MARSHALL TAYLOR, Jacksonville, Fla The treatment of lateral sinus thrombosis has developed more divergent opinions and animated discussions in the past than any other subject in otology. The authors tell us that two schools have arisen. One opposes the ligation of the internal jugular vein while the other school advocates ligation. The two schools seem to agree on other phases of treatment, that is, as to complete mastoidectomy, inspection of and attack on the sinus, transfusions of whole or immunized blood and chemotherapy. Infection of the lateral sinus is potentially a serious condition to deal with, owing principally to the number of tributaries of the vein and the intercommunication of the dural venous sinuses and the intracranial circulation as reviewed by Drs Ersner and Myers. Even though infection may be carried through other channels, one cannot disregard the fact that the internal jugular vein does carry the major portion of the venous blood from the cranium into the general circulation. After all other treatment has been carried out and there is evidence of continued sepsis and advancing infection, I feel that ligation of the vein may be a valuable adjunct in the treatment of this condition. The authors report some astounding statistics. Had they stated at what period of the disease ligation of the vein was performed, I feel that these statistics would be of greater value. They cite one author who reported seventy-four deaths after 132 ligations. If these were eleventh hour ligations and after general septicemia had occurred, it seems to me that these statistics have little significance in condemning ligation of the vein. I am not surprised that with a mortality of 56 per cent this author abandoned one phase of mastoid surgery. The authors quote another author who reported twenty-six cases out of thirty as showing a metastasis after ligation. I cannot but wonder whether these cases were not late ligations. These unexplained statistics impress me as more argumentative than convincing. I wish to commend the authors on their well prepared paper. I agree that it is only by exchange of ideas and comparison of methods employed that the treatment of this dangerous complication will some day be settled to the satisfaction of all.

DR MARVIN FISHER JONES, New York An old subject which has been settled satisfactorily to most competent surgeons has again been exhumed. This subject has been discussed recently, and the discussions have been supported by plausible argumentation. Notwithstanding this plausibility, it is known that they are wrong. There is no major surgical procedure used to cure serious illness which in experienced hands produces a higher percentage of favorable results. The only serious impediment results not from the established operation but from temporizing. Patients with septic sigmoid sinus thrombosis frequently died before the sinus and jugular operation was perfected. Now they rarely die. This statement is substantiated by the reports of any reputable institution. Transfusion is a valuable preoperative and postoperative method of treatment. In some cases a cure has resulted from transfusion. On the other hand, the dependence on transfusion has resulted in fatal procrastination. Two successive patients under my observation died probably as the result of nonligation. Within the past two years I have had one patient who was growing progressively worse following an operation without ligation and who recovered following a second operation to ligate the jugular. The second in this period in which the vein was not ligated had a greatly prolonged period of convalescence. A third received intravenous vaccine and bacteriophage, which so complicated the usual course of convalescence that I was at a loss to know what to do. A fourth went through a similar

agonizing fate. My day of altering a most satisfactory method of surgery in septic sinus thrombosis is past. Nonligation has a place in a few very carefully selected cases. The choice of such a procedure calls for fine discrimination resulting from critical experience. A properly performed operation which includes vein ligation should still be the rule, and nonligation a carefully weighed exception.

DR PHILIP E MELTZER, Boston Dr Ersner has for years included the ligation of the jugular vein as part of the surgical treatment of lateral sinus thrombosis. He has reconsidered the rationale of this procedure and questions the necessity of including ligation of this vein. He goes so far as to question the advisability of disturbing the thrombus in the lateral sinus. His present treatment is based on anatomic, physiologic and clinical facts. It is a frank declaration appealing for unbiased consideration of these facts. He asks that each case be considered as an entity and states that the treatment should be dependent on the symptoms and local conditions found at operation. His procedures are offered as the best means of assisting the patient to cope with the infection. When symptoms point to meningeal irritation due to an infected thrombus lying in contact with the medial wall, I prefer to remove the clot. When the symptoms are manifestly those of sepsis, I eradicate all bone over the sinus from beyond the knee, practically to the bulb. I also remove any suspicious outer wall of sinus and infected clot, if present. Should the clot continue to break down, I do not hesitate to go back in my daily treatment of the wound to remove it. I firmly believe in getting rid of all locally infected material. In those cases in which a clot is present and breaks down in the region of the bulb, or if free pus wells up from the bulb, and from the symptoms it appears that the infection is descending, I do not hesitate to open into the neck, ligate the jugular vein, and sever it. All tributaries above the tie are also ligated and severed. Somewhere between the extremes of ultraconservatism and radical therapy is the type of treatment which will be appropriate for the majority of cases. As I see it, the principles of treatment as stated by the authors is that happy medium. I should like to make a correction about the number of cases stated with metastasis. There were 151 cases of ligation of the jugular between the years of 1921 and 1932 at the Massachusetts Eye and Ear Infirmary. All were treated by ligation of the jugular vein and local treatment to the lateral sinus. Of that number there were two series. I divided them in six years each. In series 1 there were fourteen and in series 2 thirty in which metastasis developed. Metastasis developed in nine after ligation and in five before. In twenty-six in series 2 out of the thirty, metastasis developed after ligation. This doesn't mean anything more to me than the fact that ligation does not prevent metastasis. It still is one of the most dangerous complications of otitis media, and 2 and 3 per cent fatality as reported by a previous surgeon falls too far below other reports. His may be a personal series, but the average in a large hospital clinic is somewhere between 20 and 30 per cent.

DR ISIDORE FRIESNER, New York It is a well known fact that in cases of sepsis from sinus thrombosis a section of the jugular shows streptococci in the walls of the vein. The sepsis is not due to the thrombus, it is due to the phlebitis, the phlebitis that invades the intima. One may have a phlebitis up here, and another one away down in the jugular. It is believed by all that thrombus is nature's method of protecting the individual from this disease. This was told by Aschoff when he first described the physical mechanism of the formation of a thrombus. But has it been forgotten that 25 per cent of cerebellar abscesses are due to infected thrombi? This isn't a clot. It is a thrombus, and there is an essential difference between them. It isn't a question of tying or not tying without regard to the pathologic changes. It must be remembered that bacteremia is due to the phlebitis and not to the thrombus. The thrombus is a protective mechanism until it becomes infected. There may be a phlebitis, with bacteremia resulting without any gross changes, those that can be picked up and looked at and determined at operation. Finally it must not be forgotten that 25 per cent of cerebellar abscesses are due to infected thrombi, and it is not right to toss them off and say that one never touches the thrombus.

DR J I KEMLER, Baltimore My experience has been different from the sad picture portrayed by the authors. In twenty-five years of practice I have seen about fifty cases of lateral sinus thrombosis. My routine has been as follows: In patients, after mastoidectomy, who have a chill with a rise in temperature to 104 F or over, with an abrupt drop to normal and a repetition within twelve to twenty-four hours with no other cause to account for it, whether the blood culture is positive or negative, I immediately tie off the jugular vein and open up the lateral sinus widely until free bleeding is obtained from both ends. Results have been excellent and I cannot remember having lost more than three or four cases of the entire series, including chronic as well as acute mastoiditis. Dr Harry Friedenwald in 1910 reported two cases in which he found a fistula in the lateral sinus, showing the attempt of nature to bring about drainage from the infected sinus. I have found walled off abscesses in the lateral sinuses when operation has been delayed, and in one case it was found at autopsy. In the last year I have tried to be conservative. One case of lateral sinus thrombosis with positive blood cultures was treated conservatively with transfusions and other supporting measures. The patient lingered on with a temperature of 105 or 106 F for four or five days and showed no improvement until the jugular vein was ligated and the lateral sinus opened. The blood culture taken twenty-four hours after the operation proved to be negative and the patient made an uneventful recovery. My second case I saw recently. Sulfanilamide was used here in full doses together with other supporting measures. The temperature was normal after the first chill and fever of 105 F and then remained normal for five days. After that there was another chill and a rise in temperature to 105 F. Another course of sulfanilamide together with other supporting measures and blood transfusions was kept up constantly. Sulfanilamide was given until the patient became cyanosed, after which her temperature remained normal for one week. She then had two chills and fever in one day. I then ligated the internal jugular vein and opened the lateral sinus. After a stormy course the patient got perfectly well. These two cases show that the old orthodox method of treatment of lateral sinus thrombosis cannot be abandoned.

DR MATTHEW S ERSNER, Philadelphia I thank my colleagues for their discussion. Most cases of sinus thrombosis or phlebitis are not emergency operations. I have learned that one can temporize with little difficulty. In many stormy cases in which I thought that there would be a great deal of pathologic change, little was found. These patients recovered rapidly after obliteration of the lateral sinus because the production of a thrombus helped nature along. No matter how well one knows the macroscopic pathology of the lateral sinus, it is difficult to judge the contents of the vessel. Exploration is therefore necessary. We do not ligate the internal jugular vein as a primary step. We usually incise the lateral sinus and if there is free bleeding from both ends we obliterate the vessel. If an abscess is found, we evacuate it without disturbing the thrombus. When a thrombus is found, we incise and institute drainage but do not disturb the thrombus. It is a well known fact that one of the complications in obstetric practice is phlegmasia alba dolens. The obstetrician does not rush into performing a radical operation. The very same principle applies in our field. When meningeal symptoms are present we remove the thrombus and excise part of the anterior wall so that we may inspect the visceral portion of the vessel. We are not convinced that thrombectomy and internal jugular ligation is the therapeutic panacea. We have treated sixteen cases in the manner described. One case in this series began with a lobar pneumonia, and an otitis media, mastoiditis, septicaemia and thrombosis of the lateral sinus with an abscess developed. In this case, we emptied the lateral sinus and obliterated it, we also exteriorized the internal jugular vein and, despite modern surgical methods and therapeutics, the patient succumbed. We believe that the thrombus should not be disturbed and that drainage should be instituted when pus is present. Many complications, including embolic phenomena, are due to the disturbance of the thrombus. We believe that our method holds greater hopes in combating lateral sinus thrombosis and we therefore present it for consideration and trial.

RIGHT COLECTOMY FOR MALIGNANT DISEASE

A DISCUSSION OF THE MORTALITY ASSOCIATED WITH VARIOUS OPERATIVE PROCEDURES

ARTHUR W ALLEN, M.D.

BOSTON

Right colectomy is technically an easy procedure. After the practically bloodless lateral peritoneal attachment is freed, the bowel, with an almost transparent mesentery, delivers mesially in such a fashion as to make its removal a simple matter. The gland-bearing area can safely be included in the dissection, the terminal ileum and transverse colon being left adequately supplied with blood vessels at convenient levels for suitable anastomosis. The slow development of cancer in the right colon, with its tendency to remain localized, makes that location a particularly favorable site for cure.¹ In spite of these facts, statistics show that, in the Massachusetts General Hospital, at least, the operative mortality is slightly higher for right colectomy for cancer than for extirpation of similar lesions in the left bowel. It seems reasonable to feel that greater consideration should be given the right colon, where the disease is less frequent and in connection with which the experience of any one surgeon consequently develops more slowly. The patient less often has obstruction, and thus the necessity of preliminary drainage does not present itself so regularly. The simplicity of resection aids in the temptation to subject these patients to a radical one stage operation.

The purpose of this study is to discuss the various factors associated with operative procedures on the large bowel in an effort to offer, if possible, some suggestions that may help in reducing the mortality. One is at once confronted with many confusing and complicated matters bearing on the subject in general. Various opinions regarding the choice of operation have hitherto been held. One group of surgeons feel that a one stage procedure should be done in the majority of cases² and offer good arguments to support their views. Others feel that the Mikulicz type of resection is the safest method of bringing about a successful end result.³ Still another group feel that some form of two stage operation should always be used.⁴ Considerable reliance has been placed on various technical procedures, the entire success often having been credited to the proper preparation of the patient before operation, preliminary intraperitoneal vaccination, the anesthetic used or the type of anastomosis made. That there may be value in all these various points in the hands of one surgeon or another cannot be disputed. However, no one can set down a series of rules which every surgeon can follow to a successful outcome. Certainly, one surgeon may work out a system that in his hands produces better results than would follow the same procedures carried out by another surgeon. Thus, one must look at the question with an open mind, admit the failure of one's

From the Surgical Department of the Massachusetts General Hospital. Read before the Section on Surgery, General and Abdominal at the Eighty Eighth Annual Session of the American Medical Association, Atlantic City, N. J. June 11, 1937.

pet ideas, if such exist, and strive to fit into the plan of management all the known aids that have proved useful to others, provided there is any reason to feel that the mortality could be lowered. To clarify existing ideas concerning the treatment of cancer of the right bowel, it seems justifiable to consider the subject on a comparative basis with similar lesions in other sections of the colon, where the disease is more common but has a less favorable prognosis and is technically more difficult to treat.

Regardless of details, certain definite general principles dealing with cancer of the bowel are now generally accepted. These cannot be ignored, regardless of any less important adjuncts in which one may have faith. Although it is unlikely that any of these more important factors are wifully neglected, it can do no harm to set them down.

PREOPERATIVE PREPARATION

The patients come to the surgeon in all stages of health, from the phase of almost no interference to that of full blown general peritonitis from perforation. Obstruction, anemia and depletion are often present in varying degrees. Each patient must be considered on the basis of operability, whether this is dependent on the lesion itself, complications secondary to the primary growth, associated diseases or age. A considerable proportion arrive at the hospital in a hopeless state. In cases of perforation of the bowel either at the growth or proximal to it, even a palliative procedure can rarely be carried out successfully. Patients with acute obstruction should have an early preliminary drainage of the bowel, by cecostomy or colostomy for lesions distal to the hepatic flexure and by ileotransverse colostomy if the growth is in the cecum or the ascending colon. Ileostomy as a preliminary operation for drainage is not recommended, owing to the high incidence of peritonitis following its use and to the complications it brings about when one wants at a later date to get at the primary area to be resected.

Cecostomy usually suffices as a preliminary procedure in cases of acute obstruction by any lesion beyond the hepatic flexure and should not be delayed, since local necrosis due to distention of the cecum will bring about perforation in a comparatively short period.⁵ This operation is useful as a first stage to resection of the left bowel in the presence of partial obstruction or even if no obstruction exists. Although it does not eliminate the cramplike discomfort that accompanies the lesion of the left bowel, it does diminish it sufficiently in the majority of cases to allow the proper intake of food and fluids by mouth preliminary to resection of the primary growth. Also, it makes a valuable safety valve proximal to the suture line after the resection, thus eliminating the necessity of including this operative step at the time the growth is resected.⁶

Colostomy proximal to the obstruction in the left bowel is much desired by many surgeons. I grant that it relieves the obstruction more satisfactorily than cecostomy and makes the patient more comfortable at an earlier date. It does complicate future procedures, however, and I have rarely found it sufficiently superior to cecostomy as a preliminary to radical operation to warrant its use.

Depleted patients should be brought into a more normal state of physiologic balance prior to resection of the bowel. In addition to administering water, chlo-

rides, dextrose and blood, one must take advantage of more recent research along the line of deficiency diseases in general. Without doubt, the tendency for wounds to heal poorly and patients to withstand operation badly can be remedied to a large extent by the preliminary and coincident use of vitamins. Certainly, the striking improvement in some of these patients following the use of cevitic acid⁷ and the intramuscular injection of liver extract is worthy of consideration.

My experience with intraperitoneal vaccine has been too limited to warrant discussion. I have the very distinct feeling that part of the benefit derived from any two stage procedure on the large bowel may come through the added resistance that the peritoneal cavity attains after the less radical preliminary stage. This may not be true, since it has not been established at what time after exploration or inoculation the peritoneal cavity reaches its maximum immunity. The time varies in the estimation of different workers from twenty-four hours to six weeks. The smoothness of convalescence of the average patient who has had a preliminary drainage or short circuit from seven to fourteen days previous to resection of the large bowel, as compared to the often stormy postoperative course following the same operation done in one stage, has been observed by every surgeon who has had experience in this field.

Anesthesia continues to offer opportunity for argument whenever the subject is introduced. Every surgeon must select for himself the type of anesthesia he can best use under the circumstances in which he works. More important than the type of anesthesia is the person who administers it. A properly controlled patient, regardless of the agent used, is really the most important feature of anesthesia. A technic must be used that eliminates pain, cyanosis, marked changes in blood pressure and damage to parenchymatous organs and minimizes postoperative complications in the respiratory tract. I myself prefer a well given intratracheal gas-oxygen-ether mixture in a closed machine, although I have had many satisfactory spinal anesthetics administered.

ELIMINATION OF DISEASED AREA

If a lesion of the large bowel is operable, the disease is not necessarily still confined to the bowel itself. Although the percentage of cures is low when lymph nodes are involved in the process, enough patients do not have recurrence after radical operation under this circumstance to warrant including the mesentery in the resection. One cannot assume that, if the lymphatics in the immediate vicinity of the growth are involved only a local resection of the bowel itself or even a more palliative proximal colostomy or short circuit is all that is worth doing. One should remove all the obviously diseased material, provided such a procedure is compatible with an early good result. When the mesentery is not grossly invaded, it is even more important to remove it. Too many resections of the large bowel include no mesentery at all, and such resections unfortunately are apt to be done in cases in which a permanent cure might have been effected. I believe it is more important to remove as much mesentery as is consistent with the supply of blood to the remaining part of the colon than it is to have the specimen contain a long section of normal bowel on either side of the growth. Lymphatic involvement in the right colon is very apt to be limited to the easily spared right colic vessels.

⁷ Lanman, Thomas and Ingalls, Theodore H. Vitamin C Deficiency and Wound Healing: an Experimental and Clinical Study. *Ann Surg* 105: 616 (April) 1937.

The dissection should be carried well on to the transverse colon, as this structure is so well supplied with anastomotic blood vessels that malnutrition of the remaining bowel is unlikely. This is not true in certain areas of the sigmoid, and careful attention to an adequate blood supply must be given. Certain knowledge of the normal blood supply must be borne in mind, I feel, however, that it is more important to use one's power of observation in determining the viability of the intestine that is to undergo anastomosis. One can rarely fail to recognize cyanosis or lack of pulsating vessels if one looks for them.

One is often justified in removing the local growth and its immediate glandular involvement even in the presence of distant metastasis. The best operation for an obstructing lesion of the bowel is resection with anastomosis regardless of the extent of the disease. Patients with known metastasis have lived comfortably for a number of years after such a palliative resection. This attitude has a tendency to increase one's operative mortality, but the patients who survive will be much happier for the remaining months of their lives.

Gross contamination should be avoided during the operative procedure. The most frequent technical error in surgical procedures on the large bowel is gross soiling of the peritoneal cavity or the retroperitoneal tissues with contents of the bowel. Such soiling usually comes about by the slipping of a clamp or basting stitch and occurs most frequently when the operator is inexperienced or the patient is improperly prepared owing to incomplete cleansing of the bowel preoperatively or failure to institute preliminary proximal drainage. The peritoneal cavity will withstand a considerable amount of contamination but not often gross soiling with spilled fecal matter. This is particularly true if the content of the bowel is liquid, since in this case the tissues not covered by peritoneum, such as the cut mesentery, with its fatty padding, or the retroperitoneal spaces, may be contaminated. From this area, infection is prone to spread with appalling rapidity. Any type of operation or number of stages used is justifiable if this catastrophe can be avoided. Aside from so-called accidental contamination, there is frequently too little regard for the consequences of an open anastomosis in the large bowel. It is frequently stated that a well protected operative field will allow an open anastomosis to be done with safety. This argument is based on the fact that the peritoneum will take care of a certain amount of soiling. The champions of the open anastomosis defend it not only on this basis but on the claim that they can be more certain of the blood supply and the function with such an anastomosis than with any of the so-called aseptic methods of suture. Most of this argument is true, and certainly in the hands of some operators an open anastomosis can be successfully accomplished in a creditable percentage of cases. It is true also that the patients more often have stormy convalescence owing to residual abscesses, sepsis of the wound and intestinal obstruction than do those that are operated on with a more nearly aseptic technic. Also, in the hands of some surgeons there is a high percentage of fatal peritonitis. One may argue that this complication is not due to the soiling that takes place during the operation but to a leaking suture line. This is not always the case, as the suture line is often found intact at autopsy when general peritonitis has been the cause of death.

A leaking suture line will almost invariably result in fatal peritonitis unless the leak is of slow development

resulting in an abscess formation that, when drained, ends in a fecal fistula, under which circumstances recovery may take place. There are certain points regarding the suture on which all authorities agree, such as the necessity of adequate blood supply, the prevention of distention within the bowel proximal to the anastomosis, an accurate apposition of the serous coats without eversion of the mucosa, the absence of strain or tension on the line of sutures and the allowing of no foreign body, such as a drain, to rest near it. If these general principles are carried out the anastomosis will heal and will not leak. The type of suture material is unimportant, provided it is of a character to resist absorption for a few days and is not tied so tightly that the tissues will be rapidly cut through.

Denuded areas must be peritonealized. The careful elimination of raw surfaces following any abdominal operation brings about such gratifying results that one should exert every reasonable effort in this direction. In the radical extirpation of extensive malignant disease, this ideal refinement of technic cannot always be carried out, but usually it is possible to reduce the danger of postoperative obstruction to a marked degree. The cut edge of the fat-lined mesentery is a frequent site for the adherence of a loop of small intestine, and one can afford any amount of pains to avoid this complication. Traps must be carefully closed. I have seen several instances of failure in an otherwise well resected lesion due to inadequate closure of apertures through which a loop of small bowel may pass and produce obstruction. Such failure most often occurs in the V-shaped resection of the mesentery after the anastomosis is made or in the lateral gutter after an end colostomy. It is certainly worth while to close the space between an end colostomy and the parietal peritoneum, particularly if the bowel is brought out anteriorly. One may damage the supply of blood to the bowel if one accomplishes this carelessly or leaves a small trap, which is more dangerous than a large one, but these arguments do not offset the fact that a more ideal situation can be established if care is used. Too often, I have seen undue confidence placed in the use of omentum to cover unperitonealized defects. The value of this structure cannot be minimized, but if it is traumatized, like any other tissue containing fat, it may prove to be a boomerang, since nature will cast off un nourished cells and in the process of repair an abnormal point of attachment for a loop of the small bowel occurs.

POSTOPERATIVE CARE

Immediately after a resection of the colon, one should almost as a matter of routine give the patient a transfusion. This is important for other reasons than the loss of blood at operation or a fall in blood pressure. Blood may be looked on as the best intravenous food available, and the added resistance to postoperative complications afforded by this simple procedure cannot be overemphasized.

Special nursing for the first twenty-four hours, at least, after an operation of this magnitude will prove to be a good investment. Pulmonary complications can often be avoided by immediate and constant attention to details during this clinical period. The relative frequency of postoperative pneumonia in ward patients as compared to private patients in the Massachusetts General Hospital is very striking. Although other factors may be involved, I am certain that the nursing problem is a most important one.

Liberal use of morphine is desirable after any abdominal operation, particularly when known contamination, however slight, has taken place. Not only does it have the desired action of maintaining the tone of the bowel but it induces a state of sedation and euphoria, so that intravenous needles, the Levine tube and other discomforts are borne with greater ease. One's only guide as to the amount should be the rate of respiration. Morphine should be given regularly—"by the clock"—in doses commensurate with the size and condition of the patient. From one-eighth to one-fourth grain (0.008 to 0.016 Gm.) every three hours is

TABLE 1—Carcinoma of the Large Intestine, from 1925 to 1936

	One Stage Resection			Two Stage Resection		
	Cases	Deaths	Mortality	Cases	Deaths	Mortality
Right	73	15	20.5%	18	2	11%

Left	96	19	20%	73	10	13.7%
Rectum	212	40	18.8%	150	19	12.6%
Total	400	77	19.2%	253	33	13%

usually well tolerated for forty-eight hours without ill effects. It is well to keep within limits that do not depress the respirations below 16 a minute. This drug diminishes the amount of distention within the bowel and maintains a slow, regular peristalsis in a satisfactory fashion.⁸ I believe that morphine is superior to extracts of the pituitary gland on the basis of its soothing action and the less vigorous and more lasting effect on the tone of the bowel.

Fluids are best maintained by the intravenous administration of dextrose and salt solutions. An inlying Levine tube will eliminate nausea by keeping the stomach empty. It is important to keep the lower segment of the bowel clean, and this is best done by the administration of a few ounces of physiologic solution of sodium chloride by rectum every four hours. The patient absorbs this fluid until about the beginning of the third postoperative day, after which a certain portion of the liquid will be siphoned back with gas and particles of feces. After this stage is reached, nourishment may be given by mouth and the dose of morphine diminished. One should be careful never to introduce enough salt solution by rectum at one time to distend the lower segment, and the amount should not be sufficient to flow up the suture line. After a low resection of the sigmoid 4 ounces (120 cc.) is sufficient, if the anastomosis is high more may be given, but never enough to produce a peristaltic cramp.

The diet during the early postoperative course should consist of foods which are not gas producing,⁹ carbohydrates, fruit juices and milk should be withheld until there is free elimination of gas from the cecostomy or from the rectum. In the case of depleted patients, transfusions should be repeated and cevitic acid administered. Liver extract administered intramuscularly is advantageous for some of these patients, particularly if they have difficulty in regaining a safe stage of nutritional balance. One should not overlook the advantages of iron given by mouth in convalescence.

CHOICE OF PROCEDURE

Statistical data cannot always be accepted at their face value. This seems particularly true in the analysis of the case records of carcinoma of the colon treated

8 Orr, Thomas G. The Action of Morphine on the Small Intestine and Its Clinical Application in the Treatment of Peritonitis and Intestinal Obstruction. *Tr. Am. S. A.* 51: 319-323 (1933).

at the Massachusetts General Hospital from 1925 to 1936. During this period there was a definite tendency toward a one stage operation except in the presence of acute obstruction. Also, two stage procedures were often selected on the basis of the poor operative risk which had to be dealt with. The patients were operated on by a fairly large group of surgeons, each of whom based his operative procedure on a variety of individual impressions. New ideas were carried out for better or for worse. A tendency to subject a patient with extensive invasive disease, usually considered inoperable, to radical extirpation is evident. Training development of various principles and a hope to accomplish the impossible all had a rôle in the mortality. One cannot help being impressed by the marked influence that the teaching of D. F. Jones has had on surgery of the colon in this clinic. This is most strikingly illustrated in the observation of only one fatal leakage of the suture line from deficient blood supply.

It is impracticable to divide the cases into groups according to the individual surgeons involved, as the figures would then be reduced sufficiently to have no statistical value at all. It is fair to say that one stage procedures and open anastomoses gave better results in some hands than in others. The type of anastomosis done, whether end to end, end to side or lateral, apparently had little bearing on mortality, while the more or less aseptic methods as opposed to open anastomoses are strikingly superior. This is particularly true of the Parker-Kerr¹⁰ type of anastomosis, which was accompanied by far the lowest mortality in the entire series.

It is necessary to look at the figures for the entire group of resections of the large bowel to obtain any idea of the safety of a one stage as compared to a two stage procedure. In these data I have considered any preliminary operation that reduces the flow of intestinal contents through the involved segment, followed at a future time by resection of the lesion, as representing the first part of a two stage operation. Therefore preliminary short circuit, ileostomy, cecostomy, colostomy and first-stage dissections with colostomy have all been considered as first-stage procedures. The Mikulicz type of resection has been included in the one stage group unless it was preceded by cecostomy. Some

Rectum	31	43

patients with carcinoma of the rectum and rectosigmoid with obstruction had a preliminary cecostomy followed by a combined abdominoperineal operation at a future date—the second operation under these circumstances amounting to a one stage procedure. However, it seems fair to look on preliminary cecostomy in these cases as a first-stage operation, since otherwise the patient would have had to be previously relieved of his obstruction by some two stage plan. To be sure, about ten deaths followed a first-stage drainage operation when a two stage procedure had been hoped for. These

10 Parker, Edward N. and Kerr, Harry H. Intestinal Anastomosis Without Open Incision by Means of Basting Stitches. *Bull. Johns Hopkins Hosp.* 19: 132 (1908). Kerr, Harry H. The Development of Intestinal Surgery. *J. A. M. A.* 81: 641-647 (Aug. 25) 1923. Allen, Arthur W. An Aseptic Technique Applicable to Gastrojejunocolic Fistula Surgery. *J.* 338 (March) 1937.

cases are excluded from the series as are all cases of palliative drainage or short circuit operation. It seems unlikely that any of these patients would have survived a radical one stage operation. One wonders in how many cases of a successful two stage procedure a radical one stage operation could safely have been substituted certainly in some, but on the whole during this decade the two stage operations represented the most serious risks in the group. The choice of operation was often limited by the condition of the patient on admission. In spite of this, in this series of cases there was a definite increase in safety with the two stage procedure which seems to offset the many desirable features of a single radical operation (table 1).

The increased number of hospital days in the two stage group is less than had been supposed (table 2). One cannot but feel that the added two weeks or less is justifiable in view of the overwhelming increase in safety. These patients realize that they are faced with a serious disease. It is not difficult to persuade them that two procedures may be necessary, and if they understand this beforehand they rarely object to a second trip to the operating room. This is particularly true if the first stage diminishes their previous discomfort or in itself is not uncomfortable. Frequently, much less reaction follows the more serious and time-consuming resection than the preliminary anastomosis. This may be attributed to a variety of reasons, such as tolerance, improved condition or intraperitoneal immunity. In addition, there may well be other unexplained factors. The smoothness of the average convalescence from a two stage operation as compared to that in many cases of a finally successful one stage operation, however, is very striking.

CAUSE OF DEATH

Peritonitis accounted for 30 per cent of all the deaths following resection of the large bowel (table 3). These represented 6 per cent of the 400 one stage operations and 3.5 per cent of the 253 two stage procedures. The majority of the deaths occurred in cases in which an open anastomosis was used. I have a definite feeling that this complication can be materially reduced, and any system that will lower its incidence is worthy of adoption. One cannot depend on a single principle, such as intraperitoneal vaccination or a two stage procedure. One must take into consideration the chief factor, and that is gross soiling.

Pulmonary complications such as collapse and pneumonia rank next in importance. Twenty-eight of the 110 deaths were attributable to these causes. It is interesting to note that the ratio of fatalities in the one and the two stage groups is distinctly in favor of the two stage procedure. This is in spite of the so-called double opportunity, which is often cited as an objection to the two stage operation. I believe that better anesthesia and better nursing are the important factors here, but one cannot overlook the fact that the two stage patients are in better condition to withstand their more serious second stage.

Intestinal obstruction is the next important fatal complication. Here there is a less marked contrast between the one and the two stage groups. Although the number of two stage operations on the right colon is too small for comparison, I feel that one may be justified in drawing the conclusion that obstruction will have a role in the mortality as the series increases in number. This brings to attention the necessity of obliterating raw areas and eliminating traps whenever possible.

Infection, postoperative shock, heart disease and postoperative hemorrhage all take a definite toll. Some conditions can be foreseen and prevented, while others, like uremia, cerebral hemorrhage and embolism, will continue to give rise to the so-called irreducible minimum of deaths following surgical procedures of this magnitude.

SUMMARY AND CONCLUSIONS

Carcinoma of the right colon is a favorable lesion for cure. It is technically easily removed, still, the mortality is higher than for resections for cancer elsewhere in the large bowel.

The lack of obstruction in cases of cancer of the right bowel so often eliminates the necessity of preliminary drainage that one is tempted to subject the patient to a one stage operation. Thus, the mortality is comparable to that for one stage resections elsewhere in the colon.

TABLE 3—Carcinoma of the Large Intestine, from 1925 to 1936 Cause of Death

	One Stage Resection		Two Stage Resection	
	Cases	Segment	Cases	Segment

A preliminary ileotransverse colostomy through a left abdominal incision is recommended, either a lateral or an end to side anastomosis, followed in from ten to fourteen days by a resection of the excluded bowel through a right abdominal incision.

The aseptic anastomosis of the Parker-Kerr type gives a lower mortality for all intestinal suture in the Massachusetts General Hospital than any of the other methods used.

ABSTRACT OF DISCUSSION

DR. FRED W. RANKIN, Lexington, Ky. There are two general factors which influence not only mortality and morbidity but satisfactory end results: the ability of the patient to withstand a formidable operative procedure and technical considerations. Cancer of the right colon, as Dr. Allen pointed out, occurs in a favorable location, easily accessible, and, if the operating maneuver can be held to a reasonable mortality, gives a better end result than elsewhere in the gastro-intestinal tract, except in the low grade rectal cancer. One of the greatest advances in handling cancer in this location is the preliminary, preparatory period to which all these patients should be subjected. Obviously, surgical decompression is called for in cancer of the right colon with acute obstruction, and that decompression may be done either by ileostomy or by ileocolostomy as the first stage of the two stage maneuver.

Fortunately, obstruction is rarely a factor in cancer of the right colon, whereas in cancer on the left side it occurs in approximately three-fourths of the cases. After satisfactory decompression has been done in these cases, the routine operation should be what Dr Allen says, an ileocolostomy between the terminal ileum and the transverse colon as the preliminary stage, and subsequently a resection, but occasionally a one stage procedure is desirable. The operation should be done end to side. The importance of doing a graded operation in the right colon is necessary because of the pericolic infection and the frequently accompanying anemia, which is the result probably of some perverted function of the mucosa of the right colon but which leaves these people materially reduced surgical risks. If one does an end to side anastomosis, one removes all the fecal stream from passing over the carcinoma. The mortality in my groups has been approximately 10 per cent over a period of years. I cannot agree that all carcinoma of the right colon should be done in two stages. I do not think Dr Allen means to imply that. Occasionally one finds an early case, a good risk without anemia, without obstruction in which the operation can be carried out in one stage but I think that invariably, if a one stage resection is done a complementary ileostomy 20 or 25 cm proximal to the anastomosis line should be one step of the operation. The end results following resection of the right colon are eminently satisfactory. I find 56 per cent of the patients alive after five years 43 per cent are dead. It is inexplicable to me that cancer of the right colon should give a 10 per cent better ultimate prognosis than cancer of the left colon.

DR HARVEY B STONE, Baltimore. Dr Allen was good enough to ask me to discuss his paper in view of the statistics of my own experience with cancer of the right side of the colon, predicting that the facts would show a less favorable outcome of the one stage resections than my offhand impression would lead me to believe. Most of the attempts to study problems like the present one by mathematical means are open to the objection that there is the great difficulty in selecting properly comparable groups of cases. Another approach to the problem seems to me to be better. I would say that both the one stage and two stage methods have their place. No one but an enthusiast without balance would do a one stage immediate resection and anastomosis in a patient in wretched general condition, with anemia, dehydration and acute obstruction. On the other hand, many patients are in such good condition, both generally and as concerns the local lesion that to me it seems much safer to carry out a well conducted one stage operation than to subject the patient to the undoubted increased hazards of two anesthetics, two operations and two convalescent periods, to say nothing of the added expense, loss of time, pain, anxiety and apprehension. In short the procedure should be adapted to the individual case, and no rules automatically applied. Dr Allen has done a real service in emphasizing the limitations of the one stage principle and the utility of the two stage attack. I should like to supplement his position by expressing the view that the one stage procedure has marked advantages over the two stage, and that some countervailing condition in particular cases must exist to justify the rejection of these advantages. In the matter of the desirability of some form of so called aseptic anastomotic technic, I heartily agree with Dr Allen. While it is true that other principles are essential to success, I believe that the avoidance of an open exposure of the lumen of the intestine and the direct handling of the mucosa are of great importance in minimizing the chances of infection and add not only to the safety but to the neatness and finesse with which the technic may be carried out.

DR ARTHUR W ALLEN, Boston. All surgeons would prefer to do any large procedure in one stage if they could. I was a one stage enthusiast ten years ago. I must say that it has required a good many unsuccessful attempts at one stage operations on the large bowel to convert me to the two stage operation. I realize that statistics are of questionable value. On the other hand I think one must bear in mind that these statistics during this decade were obtained during a time when operators were one stage minded and most of the two stage operations in this group were done because the patient was

a poor risk or was obstructed or depleted, and still, in spite of these facts, by the two stage method a much better showing has been made. As far as the mental attitude of the patient is concerned regarding second or third stage operations, any man who talks to the patient for five minutes before any operation can make him feel perfectly happy about the multiple stages necessary to get him through to a successful end result. I am grateful to Drs Rankin and Stone for taking part in this discussion. I know that the question is debatable, but I still feel that perhaps operators have been too oblivious to the outcome of these patients, particularly with carcinomas of the right colon, and should more seriously consider them on a two stage basis.

HYPERTROPHY OF THE LIGAMENTA FLAVA AS A CAUSE OF LOW BACK PAIN

R GLEN SPURLING, MD

LOUISVILLE, KY

FRANK H MAYFIELD, MD

CINCINNATI

AND

JAMES B ROGERS, MD

LOUISVILLE, KY

Low back pain with or without radiation into one or both lower extremities has been studied with increasing interest in recent years. That many factors may be involved in the production of this group of symptoms is attested by a voluminous literature.¹ Many recent authors have considered ligamentous strain about the lumbosacral and sacro-iliac regions from faulty posture to be the chief etiologic factor.² Intra-spinal pathologic changes have, however, received scant attention.

When this syndrome occurs in conjunction with objective neurologic changes, such as sensory or motor loss about the buttock, sexual impotence and possibly sphincteric disturbances, the lesion must be intraspinal, for bony disease peripheral to the neural canal simply cannot produce such a neurologic pattern. Any low intraspinal lesion, herniation of a nucleus pulposus, neoplasm or inflammatory disease may, of course, produce this clinical picture. Our purpose in this report is to discuss an intraspinal lesion which has not received general recognition, i.e., hypertrophy of the ligamentum flavum.

The ligamenta flava are composed normally of yellow elastic tissue and connect the laminae of contiguous vertebrae (fig 1). They blend with the interspinous ligament and enter into the formation of the capsules of the joints between the articular facets, and their lateral edge forms the posterior margin of the intervertebral foramina. At times they may undergo hyperplastic change and become so increased in thickness that they encroach on the spinal canal, thereby compressing the spinal cord. This hyperplasia presumably is possible at any level, but our experience with the lesion is limited to the ligaments connecting the fourth and fifth lumbar vertebrae. Seven cases in which this lesion was the pathologic entity form the material for this report. In six of the seven cases the lamina of the fourth lumbar vertebra was, likewise, found to be greatly increased in thickness and appeared to be at least a part of the pathologic anatomy.

Hypertrophy of the ligamentum flavum with compression of the cauda equina was first described by Elsberg³ in 1913. He reported a single case in which the hypertrophy followed direct injury to the fourth

Pain low in the back was the predominant complaint. In each instance there was elicited a history of trauma, which the patient felt was the causative factor. The most common story was "While lifting a heavy object in a bended position I felt a sudden severe pain in the lower part of the back." Usually the acute attack of pain low in the back was followed by a period of relief after a few days or weeks only to recur insidiously until the patient was incapacitated by the pain. In two cases, however, the onset of symptoms was gradual without history of an acute sudden attack. In none of our patients has the pain in the back been relieved by the recumbent position, most of them were more comfortable while sitting or standing. Sudden changing of position usually exaggerated the discomfort. Coughing, sneezing or straining at stool frequently augmented the pain.

Radiating pain into one or both lower extremities was present in all seven cases. In six it was unilateral (left) and in one it was bilateral. The pain usually followed the sciatic distribution except in two instances in which it was referred to the hip and testicle.

Sexual impotence was complete in three patients. Two patients were not within the age group in which

and fifth lumbar vertebrae. Since Elsberg's original description of the lesion there have been but six cases recorded: Towne and Reichert,⁴ two cases, Pusepp,⁵ three cases and Abbott,⁶ one case.

SYMPTOMATOLOGY

The duration of symptoms in this group of patients varied from three months to two years (table 1). In six instances there had been one or more recessions of symptoms. Each patient had been completely incapacitated for at least three months prior to operation.

Sexual potency was a factor. The two remaining patients gave a negative history in this regard.

Subjective sensory loss in the lower lumbar and sacral segments was noted by five patients. This sensory change was described as "numbness" either in the legs or about the buttocks. Paresthesias were not described.

Urinary incontinence was present in but one patient of the group.

Subjective motor loss in the legs was described by four patients. In two instances the weakness was unilateral and in two it was bilateral.

Objectively, all patients had some degree of postural deformity. In the most extreme case the deformity was so great that an erect posture was impossible. In the others nothing more could be demonstrated than spinal rigidity with tilting of the pelvis. Tenderness to pressure over the spinous processes or the lower lumbar

region was a constant finding. Mild tenderness to pressure over the sciatic nerve at the hip or in the thigh was present in five cases. Diminution of pain and temperature sensibility over the sacral skin segments was demonstrated in all seven cases. In four instances there was objective motor loss, in two patients this motor loss was accompanied by muscular atrophy. One

Fig. 2 (case 3, table 1)—Serial films showing filling defect between the fourth and fifth lumbar vertebrae after injection of 2 cc of iodized poppy seed oil into the spinal subarachnoid space.

patient had a trophic ulcer on the heel. The achilles tendon reflex was abolished or diminished in six of the seven cases.

We were unable to demonstrate by clinical or roentgenologic examination any of the manifestations usually observed in sacro-iliac disease.

DIAGNOSIS

A carefully performed neurologic examination is of primary importance in differentiating the "low back pain syndrome" of extraspinal origin from one of intraspinal disease. A knowledge of the arrangement of the sensory dermatomes, the regional reflexes and the muscular innervation of the buttocks and lower extremities is obviously essential. Most important of all is for the examiner to remember that disorders of the cauda equina may produce subjective symptoms identical to those of peripheral nerve disease.

When the neurologic examination is even suggestive of an intraspinal lesion, lumbar puncture studies should be made. If the puncture site is at the third lumbar interspace it is to be expected that no change in the hydrodynamics would be observed. If, however, the needle is inserted at or below the fourth interspace, a partial or complete obstruction may be demonstrated. In any event, the protein content of the fluid will probably be elevated since an obstructive lesion is characteristically associated with an elevated total protein above and below the lesion. The remainder of the spinal fluid examination in our group yielded no useful information: the cell count was uniformly low, the gold curve and Wassermann reactions were negative (table 1).

Fluoroscopic examination of the spine after injection of 2 cc of iodized poppy seed oil was the test that gave final conclusive proof of the presence and location of

the lesion. Our first case was examined without iodized oil studies because the neurologic manifestations were so advanced that accurate localization was untimely. In all the others we used the opaque medium, and in each instance the characteristic filling defect was shown opposite the fourth lumbar interspace (figs. 2 and 3).

Our technic of investigation with iodized poppy seed oil consists of fluoroscopy of the patient in a prone position on a tilting table. By the use of an ingenious cassette holder and the quick switch described by Dr. J. C. Bell,⁷ we are able to make instantaneous serial radiographic records of any filling defect observed on the fluoroscopic screen.

Plain x-ray films of the lower part of the spinal column have been negative for obvious bone or joint disorders. However, in every case the normal lumbar curve has been absent, the main axis of the lumbar spine being essentially perpendicular. This straight immobile lumbar spine is probably seen in other lesions associated with pain low in the back but certainly in this group it was a constant finding. In no case have we demonstrated narrowing of the intervertebral disks or spondylosis. In view of the hypertrophy of the fourth lumbar lamina that we have seen at operation, it is surprising that we have been unable to show it radiographically.

TREATMENT

It must not be inferred that the following remarks on treatment are concerned in any way with the broad problems of low back pain; our discussion is directed only at the treatment of this particular lesion. We

Fig. 3 (case 2, table 1)—Serial films to show filling defect between the fourth and fifth lumbar vertebrae after injection of 2 cc of iodized poppy seed oil into the spinal subarachnoid space.

are heartily in accord with the efforts made by the orthopedists and internists at conservative treatment and believe that radical operative procedures should be reserved for those in whom simpler methods have failed.

The treatment of this lesion resolves itself into removal of the involved lamina and ligament. The

⁷ Bell, J. C. Apparatus for the Study of Opaque Media in the Spinal Canal. *Am. J. Roentgenol.* 37: 416-419 (March) 1937.

operation is performed under local infiltration with procaine hydrochloride. If the dura is opened for inspection of the cauda equina and anterior wall of the spinal canal a low spinal anesthesia is added by instilling about the nerve roots from 20 to 30 mg of procaine hydrochloride crystals for spinal anesthesia in Ringer's solution after blocking off the subarachnoid space at the upper level of the wound with a cotton pledget. We have regularly removed the lamina above and below the lesion for the purpose, chiefly, of adequate exposure. The lamina of the fourth lumbar vertebra has been completely sacrificed, including its superior articular facets. This wide exposure is necessary in order that the lateral portion of the thickened ligament may be removed. No attempt at spinal fusion has been made in any case. The patients are usually allowed out of bed on the twelfth day and are discharged from the hospital about the fifteenth day.

PROGNOSIS AND RESULTS

One fatality occurred in our series. Streptococcal meningitis secondary to wound infection was the cause of death. Barring the possibility of a rare catastrophe such as this, the operation should incur very little risk, since it is carried out under local anesthesia with a minimum amount of trauma and hemorrhage.

The other six patients have experienced prompt relief of symptoms. Pain, except that in or about the

Fig 4 (case 3 table 1)—Appearance of hypertrophied ligamentum flavum.

operative wound, has disappeared within twenty-four hours. The sensory loss was usually restored before the patient left the hospital. Those with loss of motor power showed normal muscular tone within a few weeks after operation. The three men who had complained of impotence stated voluntarily that they were again potent in from one to five days.

Patient 1, with incontinence of urine and a trophic ulcer on the heel, had regained sphincteric control by the twelfth day and the ulcer was rapidly diminishing in size. A follow-up letter four weeks after operation stated that the ulcer had healed completely.

Patient 3 still complained after eight weeks of weakness in the back and discomfort in the scrotum, but the sexual impotence was relieved and he had no pain in the back or legs. He was fitted with a brace for the lower part of the back and is now symptom free. Three patients returned to hard labor at the end of six weeks and have had no recurrence of symptoms after seven months, six months and five months respectively.

The earliest operation was done eight months ago and the last one three months ago, so the late results cannot be recorded.

PATHOLOGIC ANATOMY

The thickened lamina of the fourth lumbar vertebra was the first gross abnormality noted at operation. In comparison with the third and fifth laminae it was from

50 to 100 per cent thicker than normal. The bone was spongy except for a thin hard cortex. Immediately beneath the lamina was found a mass of dense fibrous material totally different from the usual soft pliable ligamentum flavum (fig 4). It usually covered the posterior aspect of the dura from side to side (figs 5 and 6). In these masses numerous calcareous deposits were found and in one case there was a solid

Fig 5—Drawing of a dissection showing ligamenta flava between the fourth and fifth lumbar vertebrae in place after laminae have been removed.

calcified plaque on the inner surface of the mass making a mold of the dura. It was impossible to secure accurate measurements of all the specimens, as some of them were removed piecemeal. Those which were excised intact measured from 10 mm to 16 mm in thickness. The thickened ligaments were always adherent to the dura and frequently when separation of them was attempted the dura was torn. In six of the seven cases the greatest hypertrophy was observed on the left side and corresponded to the leg in which the clinical symptoms predominated. The predural fat was always normal above and below the lesion and absent beneath it.

The articular facets were in each instance smooth and glistening and showed no gross evidence of abnormality.

Microscopic studies of the laminae gave a normal appearance. The ligaments showed interwoven bundles of white fibrous tissue and yellow elastic tissue, the former always predominating. There was no leukocytic infiltration, but the blood vessels in the surrounding tissue were thickened as from previous inflammation. In two of the specimens old blood pigment was found. All specimens showed many areas of calcification. The microscopic interpretation was difficult to make, since

Fig 6—A, cross section at level of the fourth lumbar vertebra showing the relationship of the lamina, ligamenta flava, cauda equina and vertebral body. B, diagram to illustrate compression of cauda equina by hypertrophied ligamenta flava.

it involved the explanation of scar tissue formation. As the usual signs of inflammation were not in evidence, it seemed most probable that trauma was the etiologic factor.

Since the hypertrophied bone did not show microscopic evidence of hyperplasia, the question arose as to whether the gross changes might not have been normal anatomic variations. Also it seemed desirable to know

the relative thickness of the ligamenta flava in the lumbar region. To answer these questions and to establish a satisfactory normal with which to compare the lesions, the following anatomic studies were made on cadaver specimens.

Measurements were taken through the lamina, half way between the articular process and the roof of the spinous process, of the third, fourth and fifth lumbar vertebrae (fig 7). The material studied consisted of ninety-three vertebral columns, fifty-three of them were cleaned and dried and forty were in cadavers. A summary of these measurements is shown in table 2. From these studies it may be concluded that the lamina of the fourth lumbar vertebra is not appreciably thicker than that of the third or fifth lumbar vertebra in any given specimen.

The ligamenta flava at the third, fourth and fifth lumbar interspaces were measured in forty cadavers after the vertebral column had been cut longitudinally with a hand saw along the plane indicated in figure 7. A summary of these measurements is shown in table 3. From these studies one may conclude that the ligamenta flava between the fourth and fifth lumbar interspace is not appreciably thicker than the other ligamenta flava of the lumbar region in any given specimen.

COMMENT

That the lesion which we have described has been responsible for the symptoms in this group of patients can best be attested to by the fact that they experienced prompt relief of symptoms. Furthermore the signs of disease of the cauda equina have promptly disappeared after operation, paralyzed muscles have regained their power, normal sensation about the buttock and back of the legs has returned, sexual potency has been restored, a trophic ulcer has healed completely and sphincteric control has been regained. These plus disappearance of the subjective complaints, are to us ample proof that the causative lesion has been removed yet we are unable to explain satisfactorily why it occurs. The history in most instances points to trauma, so does the microscopic pathologic study of the specimen. There have been no signs of infection grossly or

microscopically. Certainly neoplastic disease has been excluded. There has been no radiologic evidence of bony disease about the lumbosacral or sacro-iliac regions.

Direct trauma to the ligament and lamina, either acute or chronic, appears to us to be the most likely cause. This supposition is strengthened further by the fact that the lesion has always occurred at the lumbar spinal joint of greatest mobility. The ligamenta flava are

Fig. 7.—Diagram showing plane of measurements.

placed on increased tension with the body in flexion. Also any shift of the pelvis which decreases the lumbar lordosis puts an increased strain on the ligaments. This postural deformity, therefore would presumably cause continuous trauma to the ligamenta flava and lamina, and one would expect the greatest burden to fall on the joint of greatest mobility. The work of Schmorl⁸ and Williams⁹ indicates that torsion of the ligaments about the articular facets is responsible for the pain in cases of acute back strain. Since the

ligamenta flava enter into the formation of the capsules of joints between the articular facets, it appears likely that they too may be injured by faulty alignment. The clinical history of our patients would indicate that the pressure on the cauda equina developed many weeks or months after the onset of backache. This finding fits well with the micropathologic study of the specimen for all the ligaments have shown replacement of the

normal yellow elastic tissue with white fibrous tissue in which there were calcareous deposits. These observations suggest that the ligamenta flava were probably traumatized in the beginning and in the process of healing or as the result of continuous trauma, an excess of scar tissue was laid down. When this fibrous mass attained sufficient size to compress the nerve roots in the canal, the neurologic picture of intraspinal disease appeared. In other words, we believe that this lesion is of late occurrence and is probably the end result of inadequate treatment of the acute or subacute lesions, whatever they may be.

SUMMARY

Hypertrophy of the ligamentum flavum in the lower lumbar region is associated with a group of clinical symptoms and signs which are remarkably constant. The chief characteristics of this syndrome are pain low in the back with neurologic signs of compression of the cauda equina.

321 West Broadway

ABSTRACT OF DISCUSSION

DR. G. E. HAGGART, Boston. We have seen two patients at the Lahey Clinic who appear to fall in the group of cases described by Dr. Spurling and his co-authors. Both of these patients were operated on by Dr. Horrax and Dr. Poppen of the neurosurgical service. At the level of the third and fourth lumbar vertebrae they found thickened ligamenta flava without calcification. Exploration of the subdural space gave negative results. To determine the etiology of low back pain and sciatica is often difficult. The authors emphasized the point made by Towne and Reichert that the diagnosis of cauda equina compression can be made without difficulty after careful neurologic examination and lumbar puncture. Speaking from the orthopedic point of view I feel that all patients with sciatica should certainly have a lumbar puncture. The necessity for this particular examination in this group of patients was impressed on me by three patients who later proved to have large tumors of the cauda equina. In each instance the neurologic examination by a neurologist was negative. The recent work on herniated disks still further stresses the need for

⁸ Schmorl, Georg and Junghann, Herbert. Die gesunde und kranke Wirbelsäule im Röntgenbild. Leipzig, Georg Thieme, 1932.
⁹ Williams, P. C. Lesions of the Lumbosacral Spine. Part I. Acute Traumatic Disruption of the Lumbosacral Intervertebral Disk. J. Bone & Joint Surg. 19: 343 (April) 1937.

lumbar puncture when sciatica is a symptom. If the studies should indicate caudal compression, then and only then should iodized oil be injected into the subdural space, followed of course by careful fluoroscopic examination. After the block is accurately localized, the treatment is laminectomy for removal of the obstruction, whether it is a herniated disk tumor of the cauda equina, subarachnoid adhesions or, as in this group of cases hypertrophy of the ligamenta flava. With regard to the reported hypertrophy of the fourth lumbar lamina, I am rather skeptical of the existence of this condition, because from experience with fusion operations on the lumbar spine I am impressed by the relatively larger appearing lamina of the fourth lumbar vertebrae when compared with the posterior elements of the adjacent vertebrae. It seems to me that this apparent hypertrophy might be an illusion resulting from the depth of the fourth lumbar vertebra as compared to the adjacent third and fifth lumbar and first sacral. I am further inclined to this belief because as the authors state in the roentgenograms of their patients there was no evidence of hypertrophy of the lamina of the fourth lumbar vertebra while the microscopic studies of the laminae showed normal bone. In two instances microscopic examinations of the ligament revealed old blood. Might this not be due to previous lumbar puncture?

DR CHARLES MURRAY GRATZ, New York. A large residue of patients suffering from pain low in the back remain undiagnosed after osseous disease and other etiologic factors have been excluded. The lack of a true diagnosis of this group prevents rational treatment. Dr Spurling and his associates have added one more definite weapon which will further reduce the number of undiagnosed cases. They have supported their clinical observations by actual measurements of the tissues involved and have shown that changes in the soft tissues of the back interfere with nerve function. A study of the entire course of the nerves and particularly the tissues with which they come in contact in locomotion should shed even more light on this subject. Biomechanical studies have been published and are now being applied clinically with an encouraging reduction in the number of undiagnosed cases. The route of the nerves, blood vessels and lymphatics is through the fascial spaces. These spaces form true joints lined normally by a single layer of mesothelial cells corresponding to the synovial tissues found in the joints between bones. Fascial joints are supported by the fibers of the fasciae and correspond in function to the ligaments and tendons surrounding the joints between bones. The mesothelial covering of the fascial spaces facilitates movement of the nerves corresponding to the movements in the thoracic and peritoneal cavities. The normal functional mechanics of these tissues is disturbed by traumatic or inflammatory lesions. Anatomically these changes are shown by the presence of fascial adhesions. Clinically fascial adhesions are demonstrated by using air as a contrast medium and the irregular distribution of the air is shown radiographically by pneumofasciograms. Clinical histopathologic observations confirming these changes are now available and are being reported in collaboration with Dr L. H. Meeker. There is a hyperplasia of the mesothelial cells lining the fascial joints which may interfere with normal nerve function similarly to the hyperplasia of the ligamenta flava interfering with normal nerve function in the lower back. Rupture of the fibers of the fascia by disturbing the normal contour of the mesothelial cells is also a competent producing cause of disturbed nerve function. The time of repair in this group of cases would be delayed if the patient was suffering from a rheumatic condition. As a result of these observations we believe that fascial adhesions may be the true diagnosis of many cases which have been previously placed in the undiagnosed group. It is further believed that the temporary success of the irregular practitioner may be explained by breaking up these adhesions rather than by their claims of changing any of the anatomic positions of the osseous structures.

DR FRANK R. OBER, Boston. I have a case that might be added to these. An aviator went into a 1200 foot spiral fall and hurt his back. From that time on he had a chronic lame back with sciatica. The sciatica was down both legs. The roentgenograms showed definite disturbance of the lumbar spine with thinning of the disk between the third and fourth lumbar vertebrae. He had had many years of conservative treatment and

he finally decided to have his spine fused. While the bones were being exposed for the fusion operation it was noted that the laminae were much more irregular than was apparent in the roentgenogram. Being convinced then that there was something more to the history than a chronic lame back I determined on a laminectomy and directly under the fourth arch was a cord of tissue about one-fourth inch wide and one-eighth inch thick. This was pressing on the cauda equina. This bit of connective tissue was removed without injury to the dura. The man made a complete and uneventful recovery. He was relieved of his pain as soon as he came out of the anesthetic and has had no recurrence in four years.

DR R. GLEN SPURLING, Louisville, Ky. I should not want to leave the impression that this operation is a panacea for low back pain and sciatic neuritis. As a matter of fact we have studied a fairly large group of sufferers from chronic pain in the lower part of the back in order to find this many cases. I think probably it is a relatively uncommon lesion. With regard to Dr Haggart's question about the old blood pigment found in the specimen, I will say that it might have been due to previous lumbar puncture—certainly not to a lumbar puncture in our own hands because the needle was never inserted into an involved interspace. Furthermore the blood appeared to be from a very old hemorrhage and it was always associated with calcareous deposits in the ligament. I feel that iodized oil is a very valuable diagnostic adjunct and while not ideal it is the best available. I have used it in the spinal canal for ten years and I have seen no permanent untoward effects result from its use. However I have never used more than 2 cc and usually I employ 1 cc. Two cc seems to me to be adequate for demonstrating lesions in the lower canal. I did see one patient injected elsewhere with 7 or 8 cc who had such intractable pain that a chordotomy was necessary to relieve it.

CULTURE OF HUMAN MARROW

LENGTH OF LIFE OF THE NEUTROPHILS, EOSINOPHILS AND BASOPHILS OF NORMAL BLOOD AS DETERMINED BY COMPARATIVE CULTURES OF BLOOD AND STERNAL MARROW FROM HEALTHY PERSONS

EDWIN E. OSGOOD, M.D.

Assistant Professor of Medicine and Head of the Division of Experimental Medicine, University of Oregon Medical School
PORTLAND, ORE.

The development of a simple method of culture of human marrow,¹ by which actively motile mature neutrophils, eosinophils and basophils have been observed as late as fifty days after culture was started, suggested a new approach to the problem of the duration of life of the leukocytes of the blood.

That more data are needed on this question is indicated by the recent review of Garrey and Bryan, in which they stated: "The idea that leukocytes are very short lived and that their intravascular life is limited to hours or three or four days (Weiskotten 1930) is undergoing modification." They then cited the literature on the duration of life of leukocytes which, on analysis shows a complete lack of agreement, various authors finding durations of from four to twenty-eight days. Examination of this literature reveals that most of the conclusions were based either

on experiments on animals³ or on indirect evidence Margaret R Lewis⁴ cultured human blood on cover slips and reported that living human cells were seen as long as four weeks after culture was started but that these cells resembled clasmotocytes, epithelioid cells or giant cells, were phagocytic and appeared to develop from the monocytes, she said nothing about the duration of life of the mature neutrophils, eosinophils or basophils

METHOD

Details of the method of culture have been described.⁵ Briefly, the cultures are made in 30 cc vaccine vials in a medium consisting of about 35 per cent of human cord serum and 65 per cent of the balanced salt solution of the Geys.⁶ This medium was previously determined

medium so far investigated. It will be noted that the medium contains no substance not present in normal blood.

Cultures of bloods of twenty healthy medical students were made according to the technic for marrow, and cultures of the sternal marrow, taken from five to ten minutes after the blood, of ten of the same students were made. These cultures were adjusted to contain approximately the same number of total nucleated cells and were handled as nearly identically as possible. The average initial total number of white cells in the twenty blood cultures was 15 million, and the average initial total number of nucleated cells in the ten marrow cultures was 16.5 million. The initial count was computed from the average of two closely agreeing counts, made according to the author's technic for leukocyte counting,⁷ which gives the number of cells per cubic millimeter and, when this is multiplied by the volume of culture, which averaged 12 cc, or 12,000 cubic millimeters, gives the total number of nucleated cells in the cultures. From Wright's stained smears of these cultures, differential cell counts were made, 200 cells being counted in the blood smears and 500 cells in the

Nomenclature of Granulocyte (Myeloid) Series as Used in This Article*

Name Here Used	Names Which Have Been Applied to the Same Cell
Granuloblast	Myeloblast hemocyto blast lymphoblast lymphocyte stem cell
Progranulocyte S†	Promyelocyte I, myelocyte A myelocyte non filament class I
Progranulocyte A	Promyelocyte II leukoblast basophil myelocyte myeloblast promyelocyte
Granulocyte	Myelocyte myelocyte B nonfilament, class I
Metagranulocyte	Metamyelocyte juvenile myelocyte C nonfilament class I
Rhabdocyte	Staff cell stab cell band cell nonfilament class I rod nuclear polymorphonuclear
Lobocyte	Segmented neutrophil polymorphonuclear filament class II III IV or V

* Modified from table 2 in the Osgood and Ashworth Atlas of Hematology, reference 9.

† Any basophil from the progranulocyte to the lobocyte is sometimes called a mast cell.

Fig. 1.—Course of the total neutrophil lobocyte (polymorphonuclear) count in marrow and blood cultures. The ten numbered curves above the 100 per cent line represent the course of the total neutrophil lobocyte count expressed in percentage of the initial count in ten marrow cultures from healthy medical students. The heavy black line is the smoothed average of these curves. The twenty numbered curves below the 100 per cent line represent the curves of the neutrophil lobocyte count in twenty cultures of blood from healthy persons. The curves numbered from 1 to 10 are from the bloods of cultures made from five to ten minutes before the marrow cultures. The blood and the marrow culture from the same person have the same number. The broken lines are explained in the text and represent at the point that cuts the base line the probable time at which neutrophil lobocytes disappeared from the culture. The heavy black line is the smoothed average of the twenty blood cultures.

by the Geys to be satisfactory for the culture of human tumors, and we have found it to maintain cultures of human marrow in as nearly their natural state as any

marrow smears, and the cells were classified according to the nomenclature⁸ in the table and criteria described in detail elsewhere.⁹ Multiplying the percentage of neutrophil lobocytes (polymorphonuclears) by the total count gave the initial number of these cells present in each culture. The average number was 6.4 million in the blood cultures and 3.8 million in the marrow cultures. The smaller number in the marrow cultures was due to the normally lower percentage of neutrophil lobocytes in marrow. The initial count of neutrophil lobocytes was taken as 100 per cent for both the marrow and the blood cultures. These counts together with subsequent counts determined in a similar manner and calculated in terms of percentage of the initial count, are recorded in figure 1.

COMMENT

In figure 1 all the ten marrow cultures show an increase in neutrophil lobocytes (polymorphonuclears) at twenty-four hours to a level of from 120 to 300 per

cent of the initial count. The average increase indicated by the heavy black line is to 166 per cent. There is then a tendency for the counts to level off, as shown by the straight line of the smoothed average. Neutrophil lobocytes were present in the marrow cultures for as long as the cultures were kept, which, in some instances, was twenty-seven days. They were actively motile in supravital preparations and retained their ability to phagocytize bacteria either living or intro-

Fig 2—Neutrophil lobocyte ($\times 2100$) in Wright's stained smear made from a twenty day old marrow culture (from marrow 4) fifteen minutes after the addition of *staphylococcus vaccine*.

duced as vaccines (fig 2). It seems justifiable, therefore to conclude that the medium contained the ingredients essential for multiplication, growth, maturation and the preservation of normal morphology and functional activity of cells of the granulocyte series. It seems justifiable to conclude further that the technique of handling did not seriously damage the cells. The presence of many mitoses in the progranulocytes (promyelocytes) (figs 3 and 4) indicates that the probable reason for the continuous presence of mature cells is maturation from multiplying progranulocytes. The absence of any mitoses in the more mature cells of this series, not only in these marrow cultures but in hundreds of others, justifies the conclusion that probably neither mitotic nor amitotic division occurs in cells more mature than the progranulocyte.

Since normal blood contains only lobocytes (polymorphonuclears) and a very few rhabdocytes (staff cells) and these cells have never been observed to divide, it seems justifiable to conclude that multiplication of these cells does not occur in cultures of blood. Since maturation obviously occurred in the marrow cultures, it seems probable that further maturation and death of lobocytes will occur in blood cultures which are handled in the same way as the corresponding marrow culture. The results of the blood cultures are also summarized in figure 1. Note that all twenty showed a rapid drop in the number of neutrophil lobocytes and that this drop tends to fit an approximately straight line curve within the limits of error of the experimental method. The date when no appreciable numbers of neutrophil lobocytes were seen in the smears could not be used as the time of disappearance because, obviously, one did not know how many hours before the time of the count the cells had disappeared from the blood culture. Consequently, the most probable time of disappearance of neutrophil lobocytes was determined by projecting a line from the 100 per cent mark through the last count in which neutrophil lobocytes were present in significant numbers to the base line. It will be

noted that all these lines strike the base line at between twenty-five and eighty-nine hours and that all but three strike it at between forty-eight and eighty-nine hours. A smoothed curve plotted from the average of the twenty curves for the blood cultures forms a straight line and strikes the base line at sixty-one hours, which is also the average of the duration of life as computed from the point at which the projected lines strike the base line. The straight line curve is that expected if there were an equal number of cells of each age present at the time the blood was taken. It seems justifiable therefore to conclude that in such blood cultures neutrophil lobocytes live only from about forty-eight to eighty-nine hours (average sixty-one).

An occasional neutrophil lobocyte could be observed by prolonged search in these blood cultures at from four to seven days but in no cultures were there enough after three days to be included in the ordinary differential count of 200 cells. It seems probable that these neutrophil lobocytes represented the cells which were initially rhabdocytes. This suggests that the duration of life of the rhabdocyte from the time it gets into the blood until it becomes a lobocyte is about three or four days. More accurate calculations of the duration of life of the neutrophil rhabdocyte and other immature cells of the granulocyte series, based on the percentages in marrow cultures in a state of equilibrium, will be presented in another communication.

At the same time that the data were gathered on the duration of life of the neutrophil lobocytes, the duration of life of the eosinophils and basophils was studied. The data on these cells are not susceptible of graphic presentation because the normal percentages of the cells are too low for any feasible differential count to have great statistical significance. However, the slides were searched daily with an 8 mm objective, thousands of cells being looked over, and the last day on which any eosinophils or basophils were seen in the cultures was recorded. The results of these studies showed at once that eosinophils and basophils live

Fig 4—Progranulocyte in mitosis ($\times 2100$) from a twenty seven day old culture of marrow 1.

Fig 5—Lymphocytes ($\times 2100$) just completing amitotic division from culture of blood 19.

longer than neutrophils. In three of the blood cultures eosinophils were last found on the twelfth day, in seven, on the tenth day, and in seven, on the eighth or ninth day. It seems justifiable therefore to conclude that the duration of life of the eosinophils in cultures of normal blood, made according to this technique, is from about eight to twelve days.

The basophils survived even longer, well preserved basophils being found on the eighteenth day in one blood culture, on the fifteenth day in two and on the

twelfth day in four blood cultures. Considering the small numbers of basophils found in normal blood, it seems justifiable to conclude that the duration of life of these cells in such cultures is from about twelve to fifteen days.

It was shown by supravital preparations and by the addition of vaccines to cultures, smears being made from fifteen to twenty minutes later, that cells which retained good morphology in Wright's stained preparations were living cells and that dead cells disintegrated and disappeared within a few hours after they lost their motility and phagocytic ability.

A number of other observations were made on the blood cultures. The lymphocytes multiplied by amitotic division as long as the cultures were kept (fig 5). The occasional promonocytes present multiplied rapidly by mitotic division and increased greatly in size to resemble the tissue histiocytes, sometimes called clasmotocytes, thus confirming the observations of Lewis.⁴ Plasmablasts, proplasmacytes and plasmacytes were present in the blood initially and multiplied by both mitotic and amitotic division. No intermediate stages between any of these cells and cells of the granulocyte series were observed, nor any evidence that lymphocytes gave rise to any other cell except another lymphocyte. There was a tendency of the number of lobes in the lobocytes to increase, but some lobocytes with only two lobes were observed on the last days that any neutrophils could be seen.

A detailed presentation of these observations will appear in subsequent articles.

It is evident that conditions in such cultures are not identical with conditions in the blood stream, so that it is not justifiable to transfer the results directly. It may be objected that centrifugation may destroy cells that the medium used is not the patient's own serum and that the cells in the cultures are not exposed to phagocytosis by the cells of the reticulo-endothelial system or to opportunities of migration out of the vascular bed. This is all true, but it must be remembered that marrow cultures live longer in this medium than they do in serum from the subject from whom the marrow is taken, that the cells are not subjected to the trauma of circulation, which must be at least equal to that of the occasional centrifugation, and that they are exposed to phagocytosis by monocytes, promonocytes and macrophages developing from these cells, which are similar to, if not identical with, the phagocytic cells of the reticulo-endothelial system. Therefore while no claim is made that the figures recorded represent the actual duration of life of these cells in the blood, it does seem that the method offers the most direct approach to the problem so far available.

CONCLUSIONS

In cultures of human blood, by a technic which, with marrow, permits multiplication, maturation and functional activity of cells of the granulocyte series for at least six weeks the duration of life of the neutrophils averaged sixty-one hours and, in the majority of instances, was between forty-eight and ninety hours. It seems probable that these figures represent about the actual duration of life of these cells in the blood. The duration of the life of eosinophils, from eight to twelve days, and basophils, from twelve to fifteen days determined by this method is much longer than the duration of life of the neutrophils.

ABSTRACT OF DISCUSSION

DR ROY R. KRACKE, Emory University, Ga. Dr Osgood has provided a method whereby sterile blood can be introduced into a receptacle containing a medium that apparently is suitable for the growth of immature cells, since the medium contains practically the ingredients of blood plasma which has been fortified by the addition of cord blood. He also provides optimal temperature conditions and, what seems to me to be more important, the apparatus is so constructed that it provides optimal conditions of gas exchange, that is, there is a proper degree of oxygen tension in the culture medium. He has devised equipment that is capable of simulating conditions as they may exist in the bone marrow, including even the removal of waste products. An important consideration in a new method of this type is the establishment of normal values. Dr Osgood has been doing this for some time. Therefore his figures for the normal must be accepted when the applicability of this method for studies of the abnormal is being considered. Dr Osgood was kind enough to send me a culture of human marrow a few weeks ago which I have studied in considerable detail, after it had been transported from Oregon to Georgia over a period of four or five days. I found that the number of cells present as determined by ordinary counting methods was greater than when it left his laboratory. Mitotic figures were present in considerable numbers, the granulocytic cells were alive so far as could be determined, based on the criterion of motility and the capacity to take up vital stains. Apparently the criteria of cell growth and division are first, an increase in cell numbers in the cultures, and, second, the presence of increasing numbers of mitotic figures. I noticed many cells in amitotic division which condition has been said to be a sign of degeneration rather than active multiplication and reproduction. I have been concerned as to what may be done with such a method. In his exhibit Dr Osgood has outlined a large number of problems that may be studied by the use of this method. An important type of research would include the testing of various agents for the suppression or the acceleration of the maturation of the granulocytic cells. The question arises as to whether or not the results obtained can be applied to activity of the human marrow. This question of course, cannot be answered. I can subscribe to the view that this does represent probably one of the best methods for the determination of the length of life of these various cells. Weiskotten and his associates have done this before and found that the average length of life of the neutrophil was about four days as measured by the injection of benzene into rabbits. The method of Dr Osgood requires many years for development and many years for evaluation as to its actual value.

DR MAX B. LURIE, Philadelphia. I should like to ask Dr Osgood whether this method is suitable for the growth in tissue culture of other cells than those derived from the bone marrow. Carrel has shown in the bone marrow substances which he named trephones which have a particularly stimulating effect on the growth of cells. Is it possible that the reason leukocytes die is not that their life cycle is shorter or longer but that the blood is not a suitable medium for the multiplication of leukocytes whereas substances derived from the bone marrow support the multiplication of these cells?

DR W. E. GARREY, Nashville, Tenn. It is gratifying to find a direct approach to a problem such as that presented by Dr Osgood. One will appreciate the difficulties in evaluating the life span of the leukocyte if one has occasion as I have had recently to review the literature in this field. In a search to determine the causes of variations in leukocytes one finds repeated reference to the rapid death of leukocytes which are assumed to survive only for an hour or even for minutes in the blood, while other authors state that leukocytes neutrophils may live as much as two months. Dr Osgood's direct determination of the duration of life of a leukocyte is needed for it is an extremely important matter to make this decision if one is going to understand anything about the physiologic variations in the number of leukocytes under different conditions.

DR EDWIN E. OSGOOD, Portland, Ore. In reply to the question of Dr Lurie regarding the presence of trephones in the marrow in our cultures the cells are washed free from all

material from the marrow before introducing them into the medium. We also wash the blood cells free from their own serum and introduce them into medium of the same composition as that used for the marrow cells. Therefore if any trephones are carried in from the marrow, they must be intracellular rather than extracellular.

Clinical Notes, Suggestions and New Instruments

BACILLUS PROTEUS PYELONEPHRITIS WITH THROMBOPHLEBITIS OF THE INTRINSIC RENAL VEINS AND SEPTICEMIA

EDWIN F. HIRSCH, M.D. AND DOROTHY A. SHAPIRO, B.S. CHICAGO

Comprehensive summaries of focal and systemic diseases in man caused by proteus organisms have been published by Meyerhof¹ and Bengtson.² Since then other reports of specific tissue infections by proteus organisms occasionally with septicemia, have appeared.³ According to these sources of information bacteria of the proteus group have recognized importance in infections of the urinary tract, the acute enteritides of children and adults, meat poisoning, Weil's disease, other icteric diseases, chronic otitis media, peridental abscess, meningitis, empyema of the chest, periurethral infection, and perinephric and peritonsillar abscesses. Septicemia secondary to infections of the kidney usually is caused by colon organisms, less frequently by streptococci or staphylococci. Although infections of the urinary tract are due to bacteria of the proteus group, a proteus septicemia secondary to pyelonephritis in fact from any primary focus, is unusual. Lenhartz⁴ emphasized this in his report of proteus pyonephritis, accompanied by clinical symptoms of sepsis. Excision of the markedly diseased left kidney relieved the systemic manifestations of this patient. Proteus pyelitis is serious, according to Lenhartz, because the ammoniacal substances produced by the decomposition of the urine severely injure the renal parenchyma, especially with retention. The prognosis with proteus infections of the urinary tract, therefore, is much less favorable than with other bacterial invaders. Kretschmer and Mason⁵ also commented on the few published reports of proteus septicemia. They observed two patients with proteus septicemia secondary to renal infections. Both had renal concretions; one had renal tuberculosis and each recovered following surgical treatment. Among the 305 infections of the urinary tract mentioned in this report, a single organism was recovered in 224; eight of these were proteus. The other eighty-one infections were mixed; proteus organisms were present in twelve.

The pathways of invasion in an ascending infection of the kidney have been reviewed and discussed by Helmholz.⁶ He observed in animal experiments that ascending infections of the kidney were associated frequently with mural thrombosis of the renal veins and emphasized vascular and perivascular spread of the infection rather than ascent of the tubules. An illustration of venous thrombosis in acute pyelitis of infancy correlated his animal experiments with human infections. Although the pathologic processes in the spread of pyonephritis into a septicemic disease are not discussed in textbooks on urology or in individual reports, the basic principles are doubt-

less those of other septic disorders, namely, bacterial phlebitis or thrombophlebitis of blood or lymph channels. Bacterial phlebitis or thrombophlebitis of the intrinsic branches of the renal veins as noted by Helmholz provides the pathologic issue medium whereby septicemia develops from ascending pyonephritis.

REPORT OF CASE

A white man aged 45, in whom septicemia secondary to thrombophlebitis of the intrinsic renal veins caused by a proteus organism had developed, was admitted to St. Luke's Hospital, Nov. 12, 1936, in the care of Dr. K. H. Tannenbaum. He had been ill with fever and chills for one week. The patient had a constant pain in the region of the left kidney and hematuria on the first day of illness. Urgency, frequency and dysuria were marked. Three days before admission he had passed a urinary concretion. Dr. Tannenbaum had treated his patient for chronic prostatitis, seminal vesiculitis and urethral polyps. When admitted to the hospital he had a high fever, rapid pulse and symptoms of sepsis. The alkaline urine contained erythro-

Section of a mural thrombus in one of the large intrinsic branches of the renal vein. Reduced from a photomicrograph with a magnification of 198 diameters.

cytes, leukocytes, bacteria and a large amount of albumin. The leukocytes of the blood were 26,350 per cubic millimeter. An intravenous pyelogram disclosed large kidneys without concretion deformities or perinephric abscess. Dr. L. E. Schmidt in consultation made a diagnosis of left pyelonephritis and advised nephrectomy or drainage. The patient died November 16, a few hours after the nephrectomy, four days after admission to the hospital and eleven days after the acute onset of his illness. Cultures of the urine had yielded a heavy growth of proteus organisms and those of the blood on November 13 and November 15 contained more of these bacteria.

The excised left kidney weighed 280 Gm. and was 14 cm. long, 7 cm. wide and 5.5 cm. thick. Petechial and larger hemorrhages mottled the gray, smooth subcapsular surface. There were no obvious focal abscesses. On the surfaces made by hemisection of the kidney frontally, the edematous tan gray cortex was 7 mm. wide and the pyramidal tissue 15 mm. The cortical markings were distinct; there were no abscesses. The dark red pyramidal tissues with their radial markings contrasted sharply with the gray cortex. Several small granular calcium carbonate and calcium and magnesium phosphate concretions

were in one of the lower calices. The amputation of the blood vessels and ureter was at the level of the renal pelvis.

Histologic examinations demonstrated marked acute parenchymatous changes of the tubular epithelium and dense leukocytic exudates in the lumens of some tubules. There were multiple small abscesses in the subpelvic tissues. Branches of the renal vein in the kidney tissues had mural thrombi composed of dense masses of erythrocytes, polymorphonuclear leukocytes, monocytes and fibrin. The structure of one of these is shown in the accompanying illustration. Clumps of bacilli were found among the exudate cells in sections stained with methylene blue. The anatomic diagnosis was acute ascending pyelonephritis and thrombophlebitis of the intrarenal veins.

The postmortem examination of the trunk and lower portion of the neck demonstrated changes of the viscera that occur with septicemia. The body weighed 91 Kg. The tissues traumatized during the recent surgical nephrectomy were hemorrhagic. A concretion 6 mm in diameter obstructed the left ureter at the urinary bladder. The lumen above was dilated to a circumference of 2 cm. The lining was gray and hyperemic. The right kidney, weighing 250 Gm., showed acute parenchymatous changes. Several granular concretions from 1 to 5 mm in diameter were in the lower calices. The spleen weighed 510 Gm., the pulp tissues were soft, friable and hyperemic. The liver weighed 2,475 Gm. and the tissues had a marked cloudy swelling. Colonies of proteus organisms were isolated in pure culture from fluids in the left ureter from the liver and from the spleen.

The routine histologic examinations of the viscera of the patient obtained post mortem demonstrated in the right kidney marked parenchymatous changes, a few small foci of chronic inflammation but no acute inflammatory exudates of an infection. The liver showed focal fatty changes and small infiltrations of polymorphonuclear leukocytes of the periportal tissues. There were no abscesses. The pulp tissues of the spleen were hyperemic. They contained multiple hemorrhages, focal infiltrations of polymorphonuclear leukocytes and a hyperplasia of the reticulo-endothelial cells. Many acini of the prostate contained dense collections of polymorphonuclear leukocytes. The papillary tissues of the neck of the urinary bladder had blunt vascular fibrous stalks covered by thin layers of stratified squamous epithelium.

The strains of slender motile gram-negative bacilli isolated from the spleen, liver and left ureter after death and from the blood and urine during life formed spreading flat gray, non-hemolytic colonies on blood agar. They grew abundantly without producing pigment on plain agar and Endo's mediums. Serum of the patient obtained during the postmortem examination agglutinated organisms from all sources in dilutions as high as 1:2,400 and those from the blood cultures and spleen in dilutions of 1:4,800 and 1:7,200 respectively. The patient's serum was tested for agglutinins with three proteus strains obtained through Dr. G. M. Dack from the department of bacteriology of the University of Chicago and designated P₁, P₁₀ and X₁₀. Another stock culture was designated 14V. The organisms of P₁ were not agglutinated by the patient's serum; those of X₁₀ were agglutinated in dilutions of 1:160 and those of P₁ and 14V in dilutions of 1:320. The patient's serum had no effect on a strain of *Bacillus coli* and human serum from other sources did not agglutinate the proteus strains recovered from the patient. The cultural reactions of the organisms from various sources of the patient were alike. The Voges-Proskauer reaction was positive and nitrates were reduced to nitrites. Acid and gas were produced in dextrose mediums; acid in sucrose, levulose and galactose. Lactose, salicin, mannite, maltose and dextrin were not fermented. Indole was produced. Lead acetate was blackened; milk was peptonized and gelatin was liquefied. Broth cultures inoculated intraperitoneally did not kill white rats. Similar cultures inoculated intracutaneously and subcutaneously in rabbits produced indolent abscesses. Intravenous injections of broth cultures did not kill rabbits. A rabbit so injected became markedly emaciated and when killed after two weeks its liver, spleen, kidneys, lungs and heart's blood were sterile.

COMMENT

The fatal proteus septicemia of this patient has been traced to a thrombophlebitis of the intrinsic divisions of the renal vein, a complication of an ascending pyelonephritis. The

ureteral concretion impacted at the orifice into the urinary bladder doubtless contributed to the ascending spread of the infection from the bladder. Thrombophlebitis of the intrinsic branches of the renal veins is important not alone in the spread of an infection into the kidney with ascending infections as Helmholtz has suggested but also for the hematogenous spread of bacteria into a septicemic disease. The isolation of bacteria with the specific cultural characteristics of proteus organisms from the blood and urine of this patient before death and from the spleen, liver and left ureter after death is substantial evidence favoring the causal relationship of the bacteria to the disease. The high agglutinin titer of the patient's serum obtained post mortem for these strains (from 1:2,400 to 1:7,200) and for several stock strains of proteus organisms (from 1:160 to 1:320) is convincing support for this relation. According to van der Hoeden⁷ the presence of agglutinins in the serum of patients with proteus infections favors the view that the bacteria are pathogenic. Garry⁸ stated that the agglutination of proteus organisms by high dilutions of the patient's serum is specific but in low dilutions has only relative value.

BLEEDING PEPTIC ULCER IN MECKEL'S DIVERTICULUM

JAMES E. THOMPSON, MD, NEW YORK

History.—A girl, aged 8 years, was brought to the Roosevelt Hospital Jan. 14, 1936, with the history that she had been passing blood by the rectum for twenty-four hours.

Three years before she had passed a copious amount of blood in a bowel movement and was taken immediately to a Brooklyn hospital where she was kept under observation for five weeks. The mother was told at the time that the child was an easy

bleeder. Since this one episode the child had been completely free from symptoms until the onset of her present illness.

She had never bruised easily, nor had she ever shown petechiae or purpuric spots. There was no history of nausea, vomiting or abdominal cramps.

Twenty-four hours before admission and

Fig. 1.—The diverticulum as seen at operation.

without any warning signs she passed several large dark clots of blood and much black watery material in a bowel movement. The mother recognized it as a recurrence of bleeding but waited until morning to see what would happen.

Results of Examinations of the Blood

Blood 1/13/36	RBC 3,640,000	Hgb 60%	WBC 4,640
	Polymorphonuclears 64% Lymphocytes 30%		
	mononuclears 6%		
	Bleeding time 2 minutes		
	Clotting time 20 minutes		
	RBC, WBC and platelets seem normal		
1/16/36	RBC 2,830,000	Hgb 58%	
1/17/36	RBC 3,570,000	Hgb 61%	clotting time 10 minutes
1/18/36	RBC 3,010,000	Hgb 58%	
1/23/36	RBC 3,700,000	Hgb 66%	bleeding time 4 1/2 minutes
	clotting time 6 minutes		
2/13/36	RBC 4,430,000	Hgb 78%	
2/21/36	RBC 4,210,000	Hgb 84%	

The child was allowed to attend school the next morning and returned at noon and passed a few more clots. She went back to school in the afternoon but that evening she passed such a

7 van der Hoeden, J. Abstr. Centralbl. f. Bakt. 111:404, 1933.
8 Garry, Gerschon. Med. Klin. 28:1205 (Aug. 26) 1932.

great quantity of clotted blood and black fluid stool that an ambulance was called. The child became faint and complained of not being able to see clearly.

Shortly after admission to the hospital she was given a bed pan and passed clotted blood which assumed an appearance identical to that of a freshly passed placenta with its central dark mass and liquid bright red blood about the periphery.

Fig 2—Ulcer in gastric type of mucosa ($\times 15$). Marked zone shows field of figure 3.

The father and mother aged 32 and 27 and three siblings were living and well. The mother had had two abortions. There was no familial history of bleeders.

Examination—Physical examination was in general negative except for the condition chiefly concerned. The tourniquet test was positive after five minutes. The temperature was normal, the pulse 108 and the respiration rate 20.

Fig 3—Ulcer with hyaline fibrous base and eroded artery in which organization is well advanced ($\times 60$).

Results of examinations of the blood are given in the accompanying table.

The stools were grossly bloody for two days. The urine was normal throughout except for an occasional faint trace of albumin.

The diagnosis of a bleeding peptic ulcer in Meckel's diverticulum was made the day following admission. It was decided to defer operation, however, until her general condition improved unless there continued to be gross evidence of active bleeding.

The guaiac test for blood was intermittently positive for two weeks, after which time it was consistently negative. A transfusion was given at the end of the first week and her general condition steadily improved.

Operation and Result—On the thirty-fifth day after admission and when the hemoglobin was 78 per cent and the red blood cell count was 4,390,000, operation was performed.

Under general anesthesia through a lower right rectus incision a Meckel's diverticulum was found 22 inches from the ileocecal valve attached at a point along its circumference anteriorly and immediately adjoining the mesentery. It measured 2 cm in length and had a base 1 cm in diameter; its tip was so flat that it presented the appearance of a tiny stove pipe hat.

It was removed by simple excision and care was taken not to leave any of the diverticular wall. The edges of adjoining ileum were inverted and closed by means of a purse-string suture of linen reinforced by two rows of tanned catgut. The appendix was then removed in the usual manner and the abdomen closed.

Grossly the body of the diverticulum showed numerous prominent rugae on its mucosal surface which diminished in size as the neck was approached. Many pinpoint hemorrhagic areas could be detected in the mucosa.

Fig 4—Tubular glands showing chief and parietal cells ($\times 200$).

Microscopically the section showed a transition from intestinal mucosa to that of stomach mucosa as it passed from the neck into the body of the diverticulum. The gastric mucosa showed the typical glandular formation with the tubules lined by chief and parietal cells. The glands were numerous and the acid cells stood out prominently. No pancreatic tissue could be found.

A definite peptic ulcer was found which was in a healing phase. Beneath the ulcer base a large artery could be seen with fibroblastic invasion filling two thirds of its lumen. It was logically assumed that this represented the amount of healing and obliteration of the artery that had taken place since the child last gave evidence of hemorrhage.

The child made an uneventful convalescence and has been symptom free ever since.

COMMENT

This case illustrates the one variety of Meckel's diverticulum in which a preoperative diagnosis can be made. In doing so emphasis is to be made on the history, the character of bleeding by rectum and the essential lack of physical changes.

This case adds another one to the mounting list of Meckel's diverticula already reported in which aberrant mucosa lining the diverticulum has been almost universally present.

Special Clinical Article**AUTOMOBILE INJURIES**

CLINICAL LECTURE AT ATLANTIC CITY SESSION

CLAIRE L. STRAITH, M.D.

DETROIT

Were it not for the possibility that a gloomy forecast on the future of medicine might be expected, I would have entitled this paper "Surgery at the Crossroads." This title, properly interpreted, presents graphically what I consider one of the most pertinent problems of present day medicine—the proper care and management of the ever growing numbers of victims of motor car accidents. This surgical problem has its origin on the highways, commonly at the crossroads. It is there also that the victims receive preliminary treatment, and it is from there that they carry away too often it seems to me, preventable and deplorable aftermaths. That is my interpretation of "Surgery at the Crossroads." I know of no other aspect of modern surgical practice which requires greater emphasis and merits greater effort toward enlightenment of the general public as well as of the members of the medical profession. Other surgical problems commonly discussed (appendicitis for example), numerically at least, fade into insignificance when compared with the rising toll of automobile injuries and their devastating physical and psychologic sequelae.

To emphasize the need of studying this modern surgical problem, I shall cite a few figures. During the past year, 38,500 deaths resulted from automobile accidents alone. The total number of nonfatal accidents was 1,340,000, of which 110,000 resulted in permanent disability. Present figures indicate a 28 per cent increase in deaths for the present year. If these figures are compared with those showing the progressive decline, year by year in mortality and morbidity from diseases and other hazards, the contrast is startling. What a hue and cry would be raised if typhoid fever or smallpox were to bring a similar epidemic of death or disability, or even a much lesser one! In its most destructive years, the "white plague" was hardly more devastating.

For this gloomy picture in an era of supposed enlightenment and progress, many obvious causes can be listed. One of the chief is progress itself. The ability of the engineer to design and of the industrialist to make easily available, speedier and ever speedier motor vehicles far surpasses the intellectual ability of the average man to utilize them safely. Man's ingenuity has enabled him to perfect a Frankenstein's monster which now turns about to destroy. Mechanical progress has become a double edged sword. Added to the mechanical perfections which permit greater speed are the splendid new highways which encourage it. Safety features incorporated in motor cars of modern design, however fool proof in the hands of the sane and sober driver are of little use in the hands of the moron. The shortcomings of laws and law-enforcing agencies are, of course, apparent. Laziness in granting driving permits to the physically and mentally handicapped, failure to punish adequately the traffic offenders and granting of permits to chronic violators—all these and many other factors serve to handicap the splendid

efforts of safety engineers and traffic experts, who are confronted by the impossible task of making a powerful machine fool proof for fools. The factor of intellectual irresponsibility is however, no greater than that of moral irresponsibility. The role of alcohol in the present rise of automobile accidents is illustrative of the latter. The drinking driver is an important factor in automobile mishaps. Studies show clearly a decided increase in the number of accidents during the "cocktail hour," in the late afternoon, and late at night, 'after the brawl is over,' so to speak. The holiday mood of the week-end with its carefree jollity and attendant inebriety provides somber headlines for "blue Monday's" newspapers. The situation is not merely a national one. Similar accounts are emanating from England and the continent. Whether legislation or engineering can do more seems doubtful. A moral renaissance of the general public is the one thing needful.

Such then is the situation which prompts me to discuss the surgical problems developing in ever increasing numbers on the highways and at the crossroads. The problems which concern the physician especially are those dealing with the surgical care of the injured. This phase is as much in need of more intelligent

Fig. 1—Delicate handling of wounds is of extreme importance. On this gelatin model note the use of small horsehair mattress stitches to prevent inversion of the wound edge. Double twisted but single tied horsehair stitches for accurate wound approximation. The use of fine books avoid skin trauma. A double subcuticular stitch is used to produce a fine line scar with practically no stitch marks.

thought as are the phases concerned with regulation of traffic licensing of drivers and punishing of offenders. It is a more hopeful one, because its message is directed toward a profession whose group conscience and intelligence are amenable to suggestions and prompted by a desire for betterment.

The large variety of injuries which may be encountered as a result of traffic accidents defies any attempt to discuss the subject comprehensively. I shall therefore give particular attention to a consideration of facial injuries, leaving the discussion of important traumatic lesions involving other portions of the body to more competent hands. My discussion of even such a limited subject as injuries to the face must be cursory. I shall confine myself largely to a consideration of the basic principles of treatment.

Facial injuries sustained in motor car accidents may be divided roughly into two main groups: those sustained by pedestrians and those sustained by occupants

of automobiles. The first group is not clearly defined, owing to the great variety of objects which may inflict the injury (bumpers, radiator grills, door handles) as well as to the trauma which results when the body of the victim is dragged along the ground or pavement (brush marks, cinder marks). The second group (i. e., injuries to occupants of cars) is more distinct, and the injuries are of two general types: (1) those sustained by other occupants of the motor vehicle ("guest-passenger injuries") and (2) those sustained by the driver ("steering post injuries"). The lesions sustained by the driver and the guest passengers are different both as to cause and as to the type of involvement. I shall discuss these injuries presently, after considering first certain basic principles of first aid treatment.

Fig. 2 (patient E. P.)—Note the wire at attachments on the head cast to which traction wires were attached pulling the mandible up and the mandible forward.

The first principle of treatment at the time of the accident involves a knowledge of what must be treated and what in the interest of the patient's safety should be left alone. *Primum non nocere*—first of all do no harm—is an ancient medical adage which is especially applicable here. In the excitement of the occasion well intentioned persons (lay and professional alike) often jeopardize by hasty action the patient's chances of recovery. I need scarcely point out the dangers of energetic manipulation and hasty transportation in the presence of shock or serious head injury. Such warnings have been made repeatedly. Except in the exigency of a severe, life-threatening hemorrhage, the patient in shock had better be kept quiet and warm at the roadside or in a nearby dwelling rather than be bundled post-haste to a distant hospital, even by ambulance. Mock's slogan, "A live skull fracture in a farmhouse is better than a dead one in a hospital," applies to head injuries accompanied by shock. Mock's warning about the danger of immediate operation in the case of skull fracture is also applicable to facial injuries. "Haste lays waste" (if I may be permitted to paraphrase an old proverb). It is safer to wait for a good opportunity to do good work than to perform a hasty so-called emergency operation on a patient in poor condition under adverse circumstances. Serious hemorrhage is practically the sole emergency which requires immediate treatment of a heroic nature. Every facial injury accompanied by loss of consciousness should be considered a potential skull fracture and treated as such until proved otherwise.

The second principle in the first aid treatment of facial injuries is cleanliness. The simple expedient of applying a sterile or clean compress over a lacerated area will accomplish two things: 1. It will usually control superficial bleeding. 2. It will guard against further contamination of the wound. This suggests the desirability of every car carrying a simple first aid packet with at least a clean dressing and bandage in it. Immediate closure of the laceration should not be

attempted. Before any effort is made to suture the wound it must be thoroughly cleansed. This applies also to the surrounding skin. Foreign bodies (dirt, glass, splinters, cinders) must be carefully removed. Primary healing is impossible without these precautions, which can be observed only in a properly lighted and well equipped operating room of a hospital or surgical office.

The third principle in the treatment of facial wounds is concerned with end results. Every effort should be made to minimize scar formation. To accomplish this aim, closure of the wound should be attempted only under conditions which permit thorough cleansing of the laceration. But this is by no means all. The surgical technic employed is of the utmost importance. The use of skin clips, large needles, coarse suture materials (silk, catgut, silkworm gut) and crude instruments which intensify trauma of the tissue must be condemned. Delicate instruments, fine needles and suture materials and a proper regard for tissues are necessary. Scrupulous attention to details is essential. No precaution is trivial. The neglect of cinder and brush marks, for example, leaves telltale bluish or black streaks in the surrounding scar and skin which call attention to an otherwise inconspicuous defect. The simple expedient of scrubbing away these marks with a stiff brush soaked in soap and water while the patient is under local anesthesia will remove what would otherwise remain as a permanent discoloration, a permanent reminder of neglect. The attainment of minimal scars necessitates an infinite capacity for taking pains. The use of local anesthesia incidentally, is a distinct aid in insuring good results: first because it enables the surgeon to cleanse the wound thoroughly and painlessly, second, because it enables him to take time. Before closure is begun the edges of the skin should be trimmed so that when they are approximated the wound is straight rather than jagged. Fine hooks or delicate tissue forceps should be used to avoid traumatizing the border of the skin. Exact approximation of the wound is best accomplished, I believe, by means of a double subcuticular suture—the deeper one of a heavy material

Fig. 3—From the bicuspid region on the arch bar a traction wire is passed through each cheek by means of a surgical needle.

such as dermal and the superficial one (just beneath the surface of the skin) of thin horsehair threaded on a semicurved needle with a small eye (fig. 1).

Heavy dressings are always possible sources of infection, especially in wounds near the mouth where they can readily become contaminated. Lighter dressings are therefore more desirable. A single thickness of gauze held in place by collodion gives suitable protection. The patient is instructed to apply an ice bag over the wound for at least twenty-four hours after closure.

to minimize the resulting edema. So much for minor injuries and first principles.

The severe crushing facial injuries present major surgical problems with wide ramifications. Associated skull fractures are of course frequently present and must be suspected, as I have said, whenever loss of consciousness is present, or when bleeding (from nose,

Fig. 4—Fixation is made possible by embedding coat hanger wire with suitable projections into the plaster cast.

mouth or ear) and respiratory difficulties are encountered. Hasty transportation and brusque, ill-timed examinations may endanger life. Extreme caution in this regard cannot be too strongly emphasized. Special examinations and x-ray studies should be delayed until the primary shock has passed. When this stage has

Fig. 5—Author's method. Special head band is embedded in the plaster cast. The traction wires are fixed to wires on the head band. The exact amount of traction to bring the teeth in proper occlusion is determined before attaching wires to head band.

been reached, and only then, is detailed examination permissible. Examination must be thorough, inspection, palpation, x-ray visualization and neurologic survey are all important and fundamental to the last step, which is treatment. The type of treatment to be instituted depends on the nature of the injuries or groups of injuries encountered.

Of the severe crushing types of facial injuries sustained in motor car accidents, the steering post injuries, involving the driver, and the guest-passenger injuries, affecting particularly the person riding beside the driver, are the most commonly observed varieties. The latter type is more frequent and generally more severe. The reasons for this difference are obvious, since the driver is afforded at least relative protection by the steering wheel to which he may cling for support during the impact. Indeed he may, as not infrequently happens, escape injury altogether. In cases, however, in which the driver has relaxed his grip on the wheel or falls asleep or in which the collision is unusually severe, the typical steering post group of injuries may result. The mechanism for their production is clear. When the impact occurs the head and the upper part of the trunk are propelled forward violently, so that the head strikes on the wheel. This results in injuries involving chiefly the lower third of the face, lacerations of the chin and fractures of the mandible and necks of the condyles. When the entire face strikes the wheel, more extensive injuries naturally follow—fractures of the nose, maxilla

Fig. 6—Crushed nasal bones are elevated and supported laterally by the author's nasal fracture appliance.

and maxillae. Associated fractures of the ribs, sternum, knees and ankles are not uncommon.

Let me cite a typical example of the steering post type of injury. The treatment which was instituted in this case will serve to illustrate many points of practical importance in the management of similar cases.

Patient E. P. fell asleep while driving. His car hit a steel post with such force that his face was crushed by striking on the steering wheel. In this case the injuries were more severe than usual because the patient, being asleep, could not brace himself against the force of the impact. The chin, nose, cheeks and upper jaw received the brunt of the injury.

He was first seen a few hours after the accident, fully conscious and not in shock but with his face swelling rapidly to a point beyond recognition. He was examined immediately. The facial bones were first carefully palpated. This is important since x-ray examinations often give negative or inconclusive evidence as to the existence of fractures of these bones. Using the two index fingers simultaneously, the operator carefully felt the orbital rims. Next, the malar attachments were examined. A depression of the left malar eminence was noted. This was accompanied by the usual anesthesia of the lateral aspect of the nose and upper lip that is associated with fractures extending through the infra-orbital foramina. The zygoma was next examined and showed tenderness over the region of the left malar articulation. Palpation of the nasal bones revealed multiple fractures with deviation of the nose toward the right side.

The oral cavity was next examined. Extreme mobility of the maxilla occasioned by both a transverse and a midline fracture, was disclosed. The left maxillary bone was crushed, as was evidenced by sharp fragments of bones the edges of which could be palpated beneath the mucosa overlying the fractured left malar. A laceration of the chin (typical of steering post injuries) was present. This overlay a fracture of the mandible extending through the symphysis and resulting in posterior

which served to bring the fragments into proper alignment. The respiratory difficulty caused by the fractured condyles necessitated holding the jaw forward. This was accomplished by attaching a wire to the cuspid region on each side and passing the wires through the lower lips. Forward traction on these wires held the jaw forward. The fractured nasal bones were aligned by manipulation.

To maintain the normal position of the maxillae and the mandible through continuous pull on the wires the application of which I have described, some form of fixation is necessary. A plaster head cap is the most satisfactory method of providing fixation points. Properly applied the cap fits closely on the head and extends if possible below the occiput and behind the mastoid processes. It must be padded lightly and have no projecting objects on its inner surface.

The plaster cap is made by covering the head first with stockinet and next by a few turns of cotton wadding. This is covered with 4 inch (10 cm) plaster bandage. Attachments for the traction wires pulling the maxillae upward and the mandible forward are embedded in the plaster while it is still relatively soft. Coat hanger wire, which is generally readily available, may be used to provide fixation points. A much better method is the use of a radio binding post mounted on a metal band which is embedded in the plaster. Better

Fig 7—Full thickness defects of the ala and other structures are best treated by sewing mucous membrane to the skin edge around the defect and relying on a subsequent plastic repair. A plastic rule. Never distort tissue to close a defect applies here. The immediate closure of this defect would badly distort the nasal tip.

displacement of the entire jaw and tongue, giving rise to difficult respiration. Palpation over both temporomandibular joints elicited bilateral tenderness and crepitus, denoting fractures through the necks of both condyles. X ray examinations verified these observations. Later in the day, serious respiratory difficulty brought about by the posterior displacement of the mandible necessitated immediate intervention.

The following treatment was carried out:

With the patient under local anesthesia the left malar bone was elevated into normal position by passing a strong curved instrument (trocar) through the mucosa inside the cheek behind the last upper molar. Upward pressure on the lower surface of the depressed malar bone corrected the deformity. This relatively simple maneuver usually suffices to produce complete correction and prevents what would otherwise result in an unsightly flat cheek. It should be carried out as early as possible after the injury since it becomes technically more difficult, if not impossible, after long delay.

The fractured left maxilla was next brought forward and held in position by wiring the teeth to a steel arch bar. From this bar a double fracture wire was then passed upward through the cheek on a long needle. Upward traction on the wire corrected the maxillary depression. Upward traction was maintained by fixing the wire to a plaster cap which I shall describe presently. Meanwhile the fractured mandible was treated in a similar manner by wiring the teeth to an arch bar

Fig 8—Subsequently, lining flaps were inverted and a full thickness graft from behind the ear was used to cover the defect. The graft matches well and no distortion is produced.

still according to my experience is the special head band which I have devised which permits a number of attachments. After these attachments have been fixed in the plaster the cap is completed by turning the edges of the stockinet up and catching the edge beneath the final turns of plaster bandage (figs 4 and 5).

When the cap has dried thoroughly, the traction wires on the maxillae are fixed to the attachments on the head cast. Traction on the upper jaw can readily be

increased or diminished by adjusting the pull of these wires. Backward displacement of the jaw (which caused respiratory distress) was prevented from recurring by making an anterior arch of coat hanger wire to which the traction wires (fixed to the cuspid teeth and passed through the lower lip) were attached by elastic traction. This contrivance held the jaw forward

Fig 9—Note tooth marks on the instrument panel. This injury resulted in the loss of all the front teeth, fracture of the maxillae malar and nasal bones and laceration of the chin. The rigid instrument panel is a great source of injury to guest passengers in the front seat. Inset shows patient treated with maxillary traction wires and author's nasal appliance.

and permitted the patient to lie in bed comfortably without experiencing the choking sensation occasioned by the posterior displacement of the mandible. Elastic traction between the upper and the lower arch bar later regulated the dental occlusion so that all the patient's teeth could be saved and a normal "bite" maintained. The depressed fracture of the malar bone was also completely corrected, so that no residual deformity remained as a result of a large series of fractures of facial bones. So much for the management of steering post injuries in particular.

Guest-passenger injuries are unfortunately even more frequent and more severe. Fully 75 per cent of the persons with the more serious crushing facial injuries under my care are young women, guest passengers who occupy the front seat beside the driver. The injuries which they receive are so typical that they have come to be recognized as a distinct type. This is because they are caused by other factors than those which bring about steering post injuries. When the impact occurs, the guest passenger (who has nothing comparable to a steering wheel to which to cling for support) is thrown violently forward against the windshield or instrument panel, with resulting injury to the middle third of the face. Crushing of the nose, cheek bones and maxillae,

facial lacerations and rupture of the eyeballs result. The seriousness of many of these injuries could be greatly minimized if projecting handles, knobs, cranks and other fixtures on the instrument panel and doors could be eliminated entirely or altered in construction. It seems possible that many if not most of these projecting fixtures could be recessed or made flush with the body of the car. Heavy metal robe rails have caused serious facial injuries to occupants of the rear seat. Removal of these rails entirely or substitution of soft materials (e. g. leather straps or cords) would easily prevent such injuries.

For several years I have had crash padding installed in my own cars to cover prominent portions of the instrument panels for the protection of children and other guest passengers. Designers of automobiles should I believe make further efforts to eliminate these hazards by some such means (fig 10).

The treatment of guest-passenger injuries does not differ, in principle at least, from that which I have recommended for injuries of the steering post variety. The same careful examination is essential to determine the individual treatment required.

Depressed malar bone fractures are treated in the manner I have described. Maxillary fractures may be corrected by traction wires passed through the cheeks and attached to an arch bar.¹ This arch bar can easily be applied by twisting a 20 gage silver or ordinary wire around the last molar tooth on each side. The four wires are then united in the midline by being twisted together in front of the teeth. Each tooth is then wired firmly to the arch wire.² The traction wires attached to the arch bar and passed through the cheeks are later fixed to the plaster head cast as I have suggested.

Maxillary impaction, causing upward and backward displacement of the jaw (so that the anterior teeth are separated and the molars approximated), is not an uncommon complication. The impaction should be

Fig 10—For years the author has had his car equipped with a velure covered sponge rubber pad to cover the upper portion of the instrument panel. Certainly this should at least minimize a guest passenger's injuries.

freed by manual manipulation. Elastic bands are then applied between upper and lower arch bars to draw the upper arch down and forward. If this correction is carried out early, the maxillae may be restored in from twenty-four to forty-eight hours to normal position. If the condition is left untreated however, a most troublesome malocclusion will result.

¹ Feiderspiel method.

² Risdon's arch bar method.

Fractures of nasal bones should be reduced with the patient under local anesthesia with procaine hydrochloride. The nasal framework is first elevated and reshaped as well as possible. Elevation of the fragments must then be maintained. This may be accomplished by intranasal packing, which, however, has the obvious disadvantage of obstructing drainage. To obviate this disadvantage I have devised a nasal splint assembly which permits ample drainage and, at the same time, elevates the nasal bridge and provides lateral pressure to reshape the nose. This splint assembly is employed after the application of a plaster head cast. It is usually left in place for approximately three weeks. Hemorrhage within the antrum, a common complication of injuries of this type, may necessitate puncture of the antrum to provide drainage. Congestion and tenderness of the nasal mucous membrane will require the administration of astringent nasal drops.

Lacerations of the skin should be sutured as I have previously recommended. Severed pieces of skin or partially detached fragments should have careful attention. Flaps with apparently adequate circulation should of course be preserved. Detached or apparently non-vital flaps can be used as Wolfe grafts, all fat tissue is first removed, and the skin is carefully sutured into the defect. A pressure dressing is then applied.

Actual losses of skin should be restored at once if possible. Small losses of facial skin can be restored by grafts taken from the upper lid or from the skin behind the ear. These grafts are carefully sutured in place and covered by a pressure dressing. Tying the sutures over a small gauze pad in a good method of insuring adequate pressure. Such dressings should be left in place at least one week (figs 7 and 8).

SEQUELAE

Despite the physician's best efforts, it must be admitted, unsightly scars will occasionally develop. These should later be carefully excised. The time for secondary plastic procedures is at least two months after healing has taken place. Here also, the subcuticular stitch is recommended for closure to obtain minimal scar formation.

Crushed noses and depressed cheek and frontal bones also require attention. Transplants of rib cartilage may be used to fill in these defects. The transplant of cartilage may be taken from the patient, or from another person provided the Wassermann reaction of his blood is negative. Following Pierce's example in using preserved human cartilage, I have been using cartilage that has been preserved and refrigerated for several months. Although this is meeting with apparent success, I still regard it as somewhat experimental.

Severed noses, especially in males, are distressing deformities. Attempts should be made to reconstruct missing portions. I shall not try to discuss the details of this plastic procedure. Complete nasal losses provide even more urgent indications for restoration. If a good lining is present or easily provided, Wolfe grafts may be used to good advantage if the loss is not too extensive. Larger losses can be replaced only by pedicle grafts. The forehead flap method is best suited to women because it provides hairless, well matched skin. The resulting scar on the forehead is readily concealed by the hair-dress. In men however, the scar on the forehead is almost as obnoxious as the nasal disfigurement itself. Hence I prefer to use a flap formed from the skin just below the ear and overlying the sternocleidomastoid muscle. This is generally quite free from hair and closely matches the facial integument. The

graft is brought to the face via a tube pedicle attached primarily to the region of the sternal notch. From this point it is secondarily attached to the nose. It is easily molded and gives admirable results, as I have been able to demonstrate in several instances. The resulting scar on the neck is inconspicuous.

I wish to emphasize the fact that many other medical aspects of the problem of motor car accidents need earnest consideration. One of the most pertinent of these concerns the mental and emotional health of the many victims. Above and beyond the physical suffering which they must endure as a result of horrible injuries such as I have described is the mental agony which lasts throughout life in the presence of facial disfigurements, however slight. Complexes and near psychoses brought about by brooding over facial disfigurements have removed many of these unfortunates from active social and business activities. That their worries are not unfounded on the whole, is borne out by the fact that employers place a high premium on good appearance in selecting employees who must meet the public. How large a part these injuries have in contributing to the ranks of the unemployed and unemployable can only be conjectured. It is undoubtedly a large one. For this as well as the many other reasons I have attempted to convey, I submit that "Surgery at the Crossroads" is an important aspect of modern life which merits earnest consideration.

WINTER AIR CONDITIONING

Comfort as Affected by Method of Heating—The object of air conditioning for human comfort is not to heat or cool the body but to control its rate of heat loss within certain limits by methods that are most conducive to comfort and health. Temperature and humidity are means to an end. Their values depend on the system used, the main objective being the comfort and health of the individual.

Heating systems are usually designed on a basis of warmth rather than of comfort, although the two terms are often used synonymously. The basic assumption is that the degree of warmth or comfort experienced depends solely, or largely, on the rate of heat loss by radiation and convection combined, irrespective of their relative proportions. This is not necessarily true. A room with walls and ceiling uniformly at 80 F and air at 60 F is as warm as one with all surfaces at about 62 F and air at 80 F, but the comfort experienced under the two conditions differs appreciably, the first room is fresh and pleasant, while the second one is stuffy and depressing. Heat loss by radiation and convection combined is approximately the same in the two rooms, but in the first the loss is by convection alone.

This is the second report of the committee established by the American Medical Association to study air conditioning. The first report appeared in THE JOURNAL May 15 1937 pp 1708-1713. The committee includes Carey P. McCord, Detroit, chairman; Emory R. Hayhurst, Columbus, Ohio; William F. Petersen, Chicago; Horatio B. Williams, New York; and Constantin P. Yaglou, Boston.

and in the second by radiation alone. Heat loss by evaporation is assumed to remain constant in both instances.

Although a combination of warm walls and cool air is unquestionably more comfortable and pleasant than one of cold walls and warm air, the former is difficult to maintain in many buildings, as there is no way to prevent the heated walls from raising the temperature of air without wasting energy. A remote approach to the former method, known as radiant heating, is employed to some extent in England by attaching low temperature heating panels to the ceiling and sometimes to the walls whereby the mean temperature of the room surface is kept just a few degrees above the air temperature by means of radiant heating alone. Much of the freshness claimed for these systems is thus lost in the practical application of the principle. In a physiologic study of radiant heating in various buildings, the Vernons¹ found little confirmation of any inherent qualities claimed to be conducive to comfort and to insure comfortable conditions at temperatures much below the customary degree.

Developments in the United States have proceeded mainly along the lines of convection heating (warm air, hot water or steam radiators), in which the temperature of the air is usually a few degrees higher than the temperature of the walls, although in buildings of poor construction the difference may be as high as 15 degrees F or more, approaching the undesirable extreme just described. With the exception of southern parts of the United States and sections along the Pacific Coast, it is doubtful whether radiant heating as used in England can be satisfactorily adapted to the colder sections in this country without being supplemented by ordinary radiators under windows for counteracting the down-draft of cold air leaking through window and door cracks. Another objection is the difficulty of producing a uniform radiation effect on all occupants of a room and over the body surface of each occupant by radiant heat alone. As an auxiliary source of heat, however, portable electric heaters of the radiant type are most useful in furnishing extra heat in nurseries and in rooms of the aged or ill.

No general agreement exists as to which of the three convection heating systems is the best from the standpoint of comfort and health, although the direct hot water system has many good features to recommend it. It provides a small amount of radiant heat which permits a reduction of from 1 to 2 degrees F in the temperature required for comfort by comparison with warm air systems, without, at the same time, overheating the air passing over the radiators to the point of scorching dust and soot. When the temperature of the radiator surface exceeds 150 to 175 F, ammonia and various hydrocarbons are volatilized from atmospheric dust and soot, and the products irritate the mucous membranes of the nose and throat, resulting in complaints of excessive dryness.² If radiant heating is desired, greater possibilities would seem to lie in supplementing low temperature convectional systems with a truly radiant source in the form of ceiling lamps which in addition to infra-red would supply visible and ultra-violet radiations in suitable proportion.

Comfort as Affected by Building Construction and Insulation—The kind and quality of building materials used for walls, ceiling and floor have an important

bearing on the comfort and heating economy of a building and probably on its healthfulness also. The main reason why some rooms must be kept between 75 and 80 F to make them comfortable in cold weather is to compensate not for the low humidity, as is often contended, but for the cold walls and glass in buildings of poor construction.

According to Kratz's³ experiments, when the outside temperature is 0 F and the inside 72 F, the inside surface temperature of a typical exposed frame wall is 60 F with no wind and 55 F with a wind velocity of 10 miles an hour. A room with three such exposed walls is uncomfortably cold at 72 F, and to make it comfortable at all the temperature must be increased to between 77 and 80 F.

If, however, this typical frame wall is insulated by filling the studding spaces with insulation, the temperature of the inside surface of the exposed walls would be about 68 instead of 55 and the room would be comfortable with air at from 72 to 73 instead of from 77 to 80 F.

Ordinary single-pane windows are often more troublesome than cold walls in rooms having a number of windows. With an outdoor temperature of 0 F, Kratz³ observed a temperature of 18 F on the inside surface of the glass. By installing tight-fitting storm sashes, the temperature on the inside pane surface increased to 44 and the infiltration of cold air was practically eliminated.

An illusive feature in the heating of rooms with cold walls and glass is that the ordinary thermometer is not affected as much as the human body by these cold surfaces. Special instruments⁴ are necessary for indicating the influence of such cold surfaces on warmth and comfort.

Aside from the direct effects of negative radiations, uninsulated cold walls and windows chill the air in contact with them and allow considerable leakage of outside air. Thus cold air in falling to the floor produces uncomfortable drafts and a steep temperature gradient from floor to the breathing zone, which often results in stuffiness and congestion in the nose.

Adequate building insulation not only materially improves the comfort of rooms but also effects a substantial saving in fuel consumption by reducing structural heat loss and by permitting a lower room temperature. The size of the heating plant, including boiler, radiators and pipes, is considerably reduced and the total savings will pay for the cost of insulation in a few years. In warm summer weather the insulation will keep the house cool. While the monetary savings are generally recognized by the engineers, the benefits to comfort and health have not been fully appreciated in the past, particularly by the layman.

Humidification—Artificial humidification, about which so much is heard in connection with winter air conditioning was shown in the first part of this paper to be relatively unimportant from the standpoint of comfort and so far as is known, not essential from the standpoint of health.

While a relative humidity of between 40 and 60 per cent would probably be more normal and perhaps more healthful than one between 20 and 30 per cent, it is practically impossible to maintain this high range in

cold weather on account of excessive condensation and freezing on the windows and sometimes inside the exposed walls

Kratz³ has shown that with an outside temperature of 0 F the indoor relative humidity at which frost or condensation will appear on window panes is about 15 per cent with single glazed windows and 40 per cent with a tightly fitting storm sash. With an outside temperature of 20 F the corresponding limits are 25 per cent and 50 per cent respectively.

More serious is possible damage to exposed walls and roof by absorption and penetration of moisture. Fungous growth or chemical disintegration may result from accumulation of condensed water in certain building materials composing the outside walls. The wallpaper may loosen. Moreover, if the water should soak through to the outside sheathing, frost may cause serious damage.

Artificial humidification, therefore, is not recommended in buildings of usual construction, as the natural humidity prevailing there is as high as can be carried safely. If humidification is desirable, the building must be specially designed and built, with suitable insulation and moisture proofing of all exposed surfaces. The attic space must be well ventilated or else no humid air must be allowed to escape there. Even with these precautions, relative humidities in excess of 40 per cent are not to be recommended in cold weather.

Theoretically, humidification makes the air feel comfortable at a somewhat lower temperature, but under practical conditions the effect on comfort is quite small, almost imperceptible by the average person. An increase of 20 per cent in the relative humidity (from 20 per cent to 40 per cent), the maximum increase allowable in cold weather, permits a temperature reduction of but 2 degrees F from about 72 to 70 F.

No fuel economy results from this reduction in temperature, as it takes more fuel to raise the humidity 20 per cent than to keep the building at a temperature 2 degrees F higher. While on first thought one would expect a material reduction in heat loss from the structure, when the temperature is lowered 2 degrees there is a simultaneous increase in the heat conductivity of building material with humidity,⁶ the importance of which is not appreciated at present.

Ventilation—Artificial ventilation and air filtration are necessary in theaters and auditoriums where large volumes of air must be regularly supplied, but in homes and uncrowded offices such provisions are of doubtful value, except under unusual circumstances.

The average house has too much air leakage to require artificial ventilation during the cool season of the year. The leakage usually amounts to between one and two air changes per hour. By the use of weatherstripping or storm sash and storm doors, it may be reduced to half an air change per hour and still be sufficient for all practical purposes. Exceptions may arise in the kitchen and bathroom, which in any case must be separately ventilated by means of open windows or a small exhaust fan built into the outside wall or in the upper half of the window.

After a long period of speculation concerning ventilation requirements, in public buildings (schools, theaters and offices) the prevailing concept is that in most instances body odors constitute a limiting factor, fixing the minimum amount of fresh air necessary. This is because it is possible to heat, cool, humidify or

dehumidify the air of a room without necessarily introducing outside air, but the most effective and practical method for removing odoriferous matter at present is by dilution with clean outdoor air. Washing the air with a clean water spray is also effective in removing some of the odor, thus reducing the outdoor air requirement.

Until recently an outside air supply of 30 cubic feet per minute for each person was thought necessary for good ventilation on purely chemical and physical grounds. Recent experimental evidence⁷ showed this quantity to be excessive in many instances from the standpoint of every practical need. It also showed that it is impossible to fix any single value that would apply to all cases.

Accepting the present concept of body odor as a limiting factor in the ventilation of public buildings, the amount of outside air required to remove objectionable odors was found to vary mainly according to the type of building and air conditioning apparatus, the air space in a room per occupant, the room temperature, and last, but not least, the socio-economic status of the occupants, especially the bathing habits and cleanliness of clothing. The variation is from a minimum of about 5 cubic feet

Rate of disappearance of body odor and odor of cigarette smoke in a closed room. Different points represent experiments at different seasons of the year.

per minute for each person in spacious living rooms and offices to a maximum of 40 cubic feet per minute for each occupant in crowded schoolrooms attended by children of the poorer class. In the latter case the problem is one of personal sanitation rather than of ventilation.

The influence of per capita air space on fresh air requirements arises from the fact that body odors are not stable but tend to disappear rapidly of their own accord⁸ as shown in the accompanying chart. Large rooms have an advantage over small ones as they act as reservoirs, allowing body odors to disappear with a minimum outdoor air supply. On the other hand smoking rooms should be made as small as possible and ventilated fast. This is not only because the odor of tobacco smoke remains longer in the air but because its intensity increases during the first three hours following the smoking period, an observation which agrees with the common experience that the odor of stale tobacco smoke is more offensive than that of fresh smoke.

The usual ventilation requirements in public buildings where people do not smoke are between 10 and

20 cubic feet per minute for each occupant with normal habits of personal sanitation. This quantity is usually sufficient to satisfy the thermal requirements except in warm weather when the air is not cooled artificially. A substantial percentage of this amount may be recirculated when the air is washed in a spray humidifier or dehumidifier. When the air is not cooled in warm weather, a sufficient amount of outside air must be introduced to prevent the temperature and humidity from rising too high. A somewhat higher air supply is needed in smoking rooms, but exact figures are not available at present. The foregoing values are tentative and may be scaled downward in the future with developments in deodorizing apparatus which would allow for greater recirculation of air in the interest of economy.

In industrial rooms where the primary consideration may be the control of dusts, fumes or gases in the general atmosphere, the amount of outside air to be introduced is that necessary to dilute the polluting elements below the physiologic threshold concentration.

Limitations of Winter Air Conditioning—There are many fields in which winter air conditioning⁹ is of real value in overcoming adverse conditions, but in the average home or office it is doubtful whether it will serve a useful purpose. After all, winter air conditioning for comfort is largely a matter of rational heating supplemented with adequate building insulation. Modern automatic heating systems can fulfil the requirements very well. Mechanical ventilation, humidification and air cleaning require complicated and expensive apparatus, as well as considerable attention and trouble on the part of the owner.

The claims of public utility companies that winter air conditioning improves the health and efficiency of office employees is difficult to explain and could not be substantiated by the experience of the Metropolitan Life Insurance Company.¹⁰ Absenteeism due to illness among 12,000 employees, half working in a conditioned building and the other half in a building not conditioned but otherwise properly heated, failed to show any measurable difference between the two groups.

The advantage of air conditioning is that the system lends itself easily to summer cooling and dehumidification by the addition of suitable apparatus, or by circulation of cool night air through the building. By the use of proper filters much of the pollen can be filtered out of the air during the pollen season. Street noise may be partially shut off, as the windows can be kept closed.

Residential winter air conditioning systems installed at a price to compete with modern heating systems are inferior to the latter and seldom give satisfaction. Unless a good system is installed, there is nothing to gain and much to lose.

SUMMER AIR CONDITIONING

The Problem of Summer Cooling—If we try to reproduce the comfortable winter air conditions on a warm summer day, we should find them uncomfortably cold. This is because we become adapted to higher temperatures and at the same time we wear fewer and lighter clothes. As a result of these physical and physiologic changes, the comfortable temperature in warm weather may be from 10 to 20 degrees F higher than in cold weather.

Cooling for comfort in warm weather is an intricate physiologic problem, much more involved than heating

in winter. The difficulty is due in part to complex variations in the rate of metabolism and sweating according to a number of variables, and the liability of chilling warm and perspiring body surfaces. An ordinary air condition that is comfortable to persons with dry skin and clothing may prove too cold for those perspiring, as is the case, for instance, with employees and transient patrons in a cooled store or theater on a warm day. Idiosyncrasies vary, some persons like heat, others dislike it very much. The differences appear to be metabolic and circulatory and cannot very well be taken care of by changes in clothing.

In cold winter weather, when the body surfaces are dry sudden temperature changes of the order of 70 F or more have little or no effect on healthy persons suitably clothed. Gradually during the autumn and early winter the organism has had an opportunity to become adapted to increasing temperature contrast and is therefore capable of prompt response to chilling emergencies by compensatory changes in metabolism and blood circulation. Clothing further mitigates the effects of exposure.

Adaptation to summer heat, on the other hand, renders the organism sensitive to much smaller temperature changes especially when the body surfaces are covered with perspiration. Not only may the physical loss of heat by evaporation be very great, but a person may not be successful in quickly increasing heat production in response to sudden chilling, owing to a depressive action of external heat on the heat-producing organs of the body.

The experimental animals of Ogle and Mills,¹¹ after having been adapted for a few weeks to summer heat, were able to endure safely degrees of excessive heat that in a few hours prostrated and killed those adapted to cooler conditions. But when subjected to sudden chilling, they could not quickly increase their heat production and so suffered a fall in body temperature and were prostrated. Their resistance to infection was considerably affected. On the other hand, animals shifted daily from heat to cold were remarkably resistant to sudden chills but they could not stand rises in temperature beyond that to which they were adapted.

Data on human subjects are scarce, but relevant work by Stuart Mudd and Grant, Winslow and Greenburg, and Gafafer, and some unfinished data shown further on in this present report are particularly suggestive.

Mudd and his co-workers¹² studied the vasomotor reactions of human subjects to chilling and drafts. Their experiments were carried out in midsummer and some ten cases of cold and sore throat developed among the six men serving as subjects. In a number of instances the clinical symptoms were accompanied by interesting bacterial changes. One of the affected subjects was chilled again the following winter with no after-effects.

In similar experiments carried out by Winslow and Greenburg¹³ during the cold season of the year, only one of seven subjects developed a cold during the course of the experiments despite the rigorous chilling.

Gafafer's¹⁴ extensive study of weather changes in relation to upper respiratory diseases likewise strongly suggests that changes in weather during the warm

seasons are more associated with the incidence of the common cold than changes in weather during a cold season

The highest respiratory incidence and mortality is seen in hot trades, steel mills, deep mines and the like,¹⁵ and the hazard is not due to heat per se but largely to the imprudent habit of the workers in passing suddenly from an overheated atmosphere to cold air

An Conditions in Cooled Buildings—There is much to be learned about cooling systems for comfort and about optimal air conditions in cooled buildings. The conditions to be maintained depend to a large extent on the climate, the prevailing outdoor temperature and the length of time the occupants remain in the cooled space. Temperature contrasts must not be great. Health, sex, clothing and idiosyncrasies are also important factors to be taken into consideration

As a rule, little difficulty is experienced in cooled homes and offices when the occupants remain indoors most of the day and so escape, to a large extent, sudden temperature contrasts. Moreover, the amount of cooling can be controlled according to the needs of the occupants, as there are usually few persons in a room

Laboratory experiments¹⁶ with conventional cooling apparatus place the summer comfort zone at temperatures between 72 and 82 F with relative humidities between 45 and 60 per cent for exposures of two hours or more

Studies in cooled homes and offices, including the Metropolitan Life Building in New York, indicate desirable temperatures between 75 and 80 F with a relative humidity of from 40 to 55 per cent. The criterion in all these studies was the comfort of the majority, so that the air conditions, although satisfactory from the standpoint of comfort, may not necessarily be the best

In theaters and restaurants, where the occupants remain an hour or two before going out to warm air again, current practice follows a sliding temperature scale from 2 to 15 degrees F below the prevailing outdoor temperature. When the mean outdoor temperature is 70 F over a period of hours, the indoor temperature is adjusted to 72 and the humidity approximately at 60 per cent, with a prevailing outdoor temperature of 95 F, the temperature indoors is kept at 80 and the humidity at about 45 per cent

Unsatisfactory experience with this schedule has resulted in much discussion and criticism, but so far no substitute has been found acceptable to the industry. On entering a building cooled to 80 F in 95 degree weather, one generally experiences a feeling of chilliness. After an hour or two in such an environment the majority would be comfortable, a few would still shiver, and a few may feel a little too warm. On coming out to the warm outside atmosphere, the majority experience no serious discomfort, a few may momentarily feel dizzy and depressed, and others may be glad to get out

Complaints are often greatly aggravated by overcooling which results from faulty control equipment or operation, sometimes being done deliberately by overzealous operators for advertising their system. For instance, it is reported with pride by the management of a recently conditioned department store that the temperature in their fur department was lowered to 60 F last summer, although employees shivered, sales soared to the great satisfaction of the owners

It is perfectly natural for inhabitants of a stimulating climate, like ours, to run to excesses of this kind. All through winter, spring and autumn we have been accustomed to frequent climatic stimulation leading to a vigorous and restless life. A few warm days in the summer depress us severely and we long for the opposite extreme, eager to grasp the opportunity whenever we can

Disturbances of Heat Loss on Exposure to Great Temperature Contrasts—The unsatisfactory experience in cooled theaters, stores and railway cars in warm weather would seem to be largely due to the unusually rapid development of the art along purely engineering lines without a requisite preinvestigation of the physiologic requirements of the human body in warm weather

In a preliminary series of experiments, two young men were selected who seldom complained of cold and two women who always complained when the temperature was lowered below 85 F in warm weather. After initial exposures of one hour or more to a conditioned room kept at 95 F and 40 per cent relative humidity,

TABLE 1—Disturbances of Heat Loss on Exposure to Great Temperature Contrasts

‡ Determined by oxygen consumption

the subjects passed to a cooler room kept at 80 and 45 per cent relative humidity and remained there two hours for observation. At the end of this period the subjects went back to the hot room again for about an hour. The foregoing sets of air conditions are those frequently used in the design of cooling systems for theaters, restaurants and railway cars

In the hot room the skin was flushed and the major part of the heat loss was by evaporation of perspiration, as shown in table 1, column 1. When the cold room was entered, the heat loss by radiation and convection suddenly increased owing to the lower temperature, while the heat loss by evaporation continued for a few minutes at least at the previous rate in the hot room because of the perspiration in the skin and clothes. The total heat loss was thus suddenly increased to a high rate (column 2) with no immediate compensatory change in the metabolic rate during the first few minutes. This seems to be the explanation for the transitory sensation of chilliness, popularly referred to as "cold shock"

After an hour or so the two men subjects succeeded in adapting themselves to the relatively cold atmosphere, one with a decrease in the metabolic rate (initial rate 98 calories per hour) and the other with a slight increase (initial rate 81 calories per hour). The women were not as successful and remained cold throughout the two hour period. Their initial metabolic rate was low (56

¹⁵ Yaglou C P. Abnormal Air Conditions in Industry. Their Effects on Workers and Methods of Control. J Indust Hyg & Toxicol 19 12 (Jan) 1937
¹⁶ Yaglou C P and Drinker Philip. The Summer Comfort Zone. Climate and Clothing. J Indust Hyg 10 350 (Dec) 1928

and 63 calories per hour) and apparently did not increase enough to keep them warm.

When the subjects returned to the hot room there was again a disturbance of heat loss, the reverse of that seen on entering the cold room from the hot one (table 1, column 4). Heat loss by radiation and convection immediately decreased, but the loss by evaporation continued for some minutes at the previous low rate in the cold room, until sweating broke out. The result was a transitory depression of heat loss with no compensatory depression of heat production, which explains the oppressive feeling of warmth. The women felt quite comfortable on returning to the hot room, presumably because they were cold before the change.

It is not possible to say at this time just what would be the effect of such sudden changes in temperature on the health of persons if made frequently when the body is warm and perspiring. So far as the two women subjects are concerned, the effect is certainly not beneficial.

The disturbances of heat loss can be moderated to a large extent by providing air conditions that are more

consistent with the manner in which the body loses heat in warm weather. In table 2 are shown reactions of the same subjects to a temperature of 88 F with 27 per cent¹⁷ relative humidity as contrasted with a temperature of 80 with 45 per cent relative humidity in table 1. Not only were the contrasts moderated when the subjects entered and left the dry and warm room, but all four subjects were capable of adjusting themselves satisfactorily to this air condition without experiencing untoward symptoms in the transitional period of readjustment.

No sweeping conclusions can be drawn from these limited physiologic data, but the observations must be amplified and repeated on a large group of persons to determine what is the best compromise under all summer weather conditions. Although a number of persons were found who prefer somewhat lower temperatures for comfort than the majority, the problem in public buildings is to work out a compromise that will satisfy both the 'heat intolerant' and the 'cold susceptible' throughout their stay in the conditioned space.

Dehumidification of air with but little cooling is especially indicated in tropical climates, as was first suggested by Tyler¹⁸ thirty-five years ago. It may also

prove the best method in banks and stores where the customers come and go, spending but a few minutes in the cooled space. The method avoids the extremes of overcooling and yet seems to conform to that important biologic principle of preserving balance between contrasting requirements of individual groups, especially between employees in a store and transient patrons.

In the past few years, dehumidification systems have appeared on the market but have not proved at all popular for summer air conditioning. The concept of cooling by dehumidification of air encountered considerable resistance in the industry, owing largely to the changes from convectional refrigeration apparatus that it implied. Research now in progress may settle the disputed points.

Possibilities and Limitations of Summer Air Conditioning—Cooling in hot weather unquestionably contributes much to the comfort and efficiency of man and under certain circumstances is an important factor in the course and prognosis of some diseases. The open questions are: What are the best methods of cooling our living and working quarters? Can we afford this luxury at present? and When is the cost justified by the results obtained?

The first question can be answered only by research, but this is not a sufficient reason to condemn present methods of cooling altogether. In many public buildings and railway cars, cooling in warm weather is as important as heating in winter. Its commercial value is great. Cooling is more important in the South than in the North, and more important to some persons than to others.

Experience in a number of large office buildings, including the spacious offices of the Metropolitan Life Insurance Company, has been entirely satisfactory from the standpoint of comfort.¹⁹ The employees were able to pursue their daily duties without the depression and discomfort experienced prior to the installation of the system.

Cooling may be a potential necessity for the average home, but for the time being it is still a luxury, owing to high costs. The field is at present limited to expensive residences where cost and service are matters of secondary consideration.

In many parts of the country where the temperature usually drops at night, natural and preventive measures are usually sufficient in affording relief during the heat of the day. This holds particularly in the average home, the uncrowded office or the shop. Adequate insulation, including the use of awnings on the sunny side of the building and the circulation of cool air by means of an exhaust fan in the attic space, will keep the building reasonably comfortable during the daytime. When no such provisions exist, the use of an ordinary desk fan will alleviate discomfort.

When cooling is desired in an ordinary home, it may be sufficient in the interest of economy to cool one or two rooms in the day time by the use of a unit room cooler. The bedrooms can be cooled at night by the circulation of cool night air. Where ice can be had conveniently at a low price it is more economical to use than mechanical refrigeration, as the period of cooling in the North is only twenty to thirty days every year.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION
OF THE FOLLOWING REPORTS HOWARD A. CARTER Secretary

BARR SW-15 SHORT WAVE RADIO- THERMY AND ELECTRO SUR- GICAL UNIT ACCEPTABLE

Manufacturer Barr Laboratories, Inc., New York City

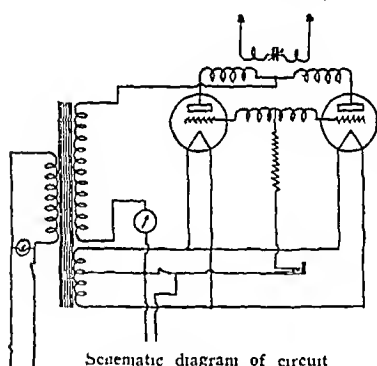

The Barr SW-15 Short Wave Radiothermy unit is recommended for medical and surgical uses. This machine is an oscillating short wave generator employing two tubes. The wavelength is approximately 15 meters. It has a single knob control for both therapeutic and electrosurgical currents with only one set of outlets in the patient circuit. The electrosurgical current for tissue cutting, coagulating and desiccating are monopolar.

The input wattage on this machine is approximately 875 watts on 105-125 volts, 60 cycle, alternating current line. The power output of the SW-15 was measured as 395 watts. The means employed for obtaining this value was to couple a 500 watt incandescent bulb to a standard set of large applicators. The luminosity of the bulb was then checked by a calibrating photo electric cell. As a conservative statement only 375 watts is claimed by the firm. It is pointed out, however, that no acceptable method of determining the output of a short wave diathermy unit has been developed.

Standard equipment of this unit consists of one pair of rubber molded applicators 5 by 7 inches, one pair 3½ by 4½ inches,

Barr SW 15 Short
Wave Radiothermy
and Electro Surgical
Unit

Schematic diagram of circuit

one foot switch, one chuck handle and three tips for cutting coagulating and desiccating. Cuff electrodes are included as part of the regular equipment. Its shipping weight is 125 pounds.

As is customary, the firm submitted evidence to substantiate the claims of the temperature elevating influence of the SW-15 machine on the living human thigh. A reliable investigator was appointed by the firm to perform these tests. He carried out eight tests, using the cuff technique. Four normal male subjects were used with an average thigh circumference of 49 cm. Cuffs measuring 48 by 36 cm were wrapped about the thigh 20 cm apart from edge to edge, over two thicknesses of toweling.

Average of Eight Observations, Cuff Electrodes

Deep Muscle		Subcutaneous		Rectal		Skin	
Initial	Final	Initial	Final	Initial	Final	Initial	Final
97.7	103.5	92.2	102.2	98.6	98.9	87.4	92.5

The temperature measurements were taken by thermocouples before and after twenty minute treatments. The thermocouples were inserted into the subcutaneous and intramuscular tissue in the usual manner. Skin temperatures were also taken by thermocouple readings. Rectal temperatures were observed. The room temperature varied from 68 to 70 F. The humidity ranged from 40 to 50 per cent. Eight observations were made, two on each subject, first on the left and then on the right thigh. Each reading in the table is an average of eight observations.

The transformer temperature rise taken over a two hour period with the machine running at full load was found to be

within the limits of safety prescribed by the Council. Burns may be produced but can be avoided by taking ordinary precautions.

This unit was investigated with the cuff technique, in a clinic acceptable to the Council, and found to be satisfactory.

In view of the foregoing report from the Council's investigator, using cuff technique, the Council voted to include the Barr SW-15 Short Wave Radiothermy unit in its list of accepted devices.

HEALTH RAY TWIN CARBON ARC SUN LAMP NOT ACCEPTABLE

Manufacturer Health Ray Manufacturing Company, Inc., New York

From time to time the Council is called on for information on ultraviolet generators for example carbon arc and mercury arc lamps, sold to the public for irradiating the body without the supervision of a physician.

Aside from differences in total ultraviolet output, the chief distinction between therapeutic ultraviolet generators for use by physicians and so-called sun lamps for unsupervised home use is that, in order to be acceptable to the Council, the latter shall not emit an appreciable amount of ultraviolet radiation of wavelengths shorter than 2800 angstroms.

In a previous communication¹ the single arc, carbon electrode Health Ray Sun Lamp was found unacceptable by the Council because it is not provided with a Corex-D glass window to exclude the ultraviolet of wavelengths shorter than 2,800 angstroms. But, even if it were provided with such a window, it could not be accepted because the intensity is below the minimum requirements of the Council.

The Health Ray, Twin Arc, Sun Lamp (Model 35) consists of two arcs, between two pairs of carbon electrodes, confined in a metal housing 12 by 7 by 5½ inches in outside dimensions, with openings in the sides and top for ventilation.

The front side of the housing has an opening 6 inches in diameter, covered with a small mesh wire screen, through which the arc radiation emanates. This opening could be covered, easily and cheaply, with a Corex-D window, to conform with the Council's requirements limiting the spectrum at 2,800 angstroms.

The rear side of the box consists of a hinged door, on the inside of which is mounted a porcelain insulating base that supports the two pairs of carbon electrodes, and the ballast resistance.

The arc is formed by rotating a knob on the outside of the door and, once formed, it continues to burn for about four minutes. If the arc is not adjusted, the exposure is limited to about four minutes, which is commendable in a home model lamp.

Radiometric Tests—Following the recommended procedure, by means of a differential thermopile and filter radiometer, measurements of the ultraviolet radiant flux, of wavelengths shorter than and including 3132 angstroms, were made in a laboratory acceptable to the Council.

As received from the manufacturer, the lamp is provided with 'supertan' (sun tan) carbon electrodes, 8 mm in diameter, and when operated as directed, the current used was about 9 amperes (110 volts, alternating current) at the start, decreasing to about 65 amperes when the arc burned out. The arc burned quietest on 80 to 85 amperes, requiring a total power input of from 800 to 850 watts.

At a distance of 24 inches from the front face of the lamp housing the ultraviolet radiant flux (intensity) of wavelengths shorter than and including 3132 angstroms with only the wire mesh in front of the arc ranged from 99 to 114 microwatts per square centimeter ($\mu\text{W}/\text{cm}^2$), or an average of about 110 $\mu\text{W}/\text{cm}^2$ during a run of four minutes. This intensity is about twice the minimum value (55 $\mu\text{W}/\text{cm}^2$) required by the Council for acceptance as a therapeutic lamp using polymetal (Therapeutic C) electrodes and hence is acceptable to the Council for use as a therapeutic lamp.

In a biologic (erythematogenic) test a series of exposures of the untanned inside upper arm was made at a distance of

¹ Health Ray Sun Lamp Not Acceptable J A M A 107:498 (Aug 15) 1936

20 inches from the front of the housing of the arc. A minimum perceptible erythema (one that disappears within twenty-four hours) was produced in about five minutes. The action of the lamp is therefore too rapid in inexperienced hands.

Radiometric measurements were made also on this Twin Arc Lamp (using "supertan" electrodes) when covered with a window of Corex-D glass, which excluded radiation of wavelengths shorter than 2,800 angstroms. The total ultraviolet output, of wavelengths shorter than and including 3,132 angstroms, ranged from 20 to 22 $\mu\text{W}/\text{cm}^2$, or from 24 to 27 $\mu\text{W}/\text{cm}^2$ if the wire screen had been removed. This is about twice the minimum value required by the Council for acceptance of such a lamp for home use.

Since the type of housing has little or no effect on the ultraviolet output, which is controlled principally by the kind and size of the electrode and the electric current through the arc, the foregoing measurements should apply to the various twin arc lamps, using "supertan" electrodes 8 mm in diameter, taking from 8 to 9 amperes, now appearing on the market under various trade names.

If manufacturers of twin carbon arc sun lamps for home use would provide the housings of such lamps with windows of Corex-D glass to intercept radiation of wavelengths shorter than 2,800 angstroms, the Council could include them in its list of accepted devices.

The Council voted not to include the Health Ray Twin Carbon Arc as a sunlamp for home use in its list of accepted devices, because (1) when the lamp is used without the Corex D window the ultraviolet of the wavelengths shorter than 2,800 angstroms is greatly in excess of the value acceptable to the Council for sunlamps for home use and (2) because the lamp is recommended for use without the supervision of a physician.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
PAUL NICHOLAS LEECH Secretary

THIAMIN CHLORIDE

The pure form of vitamin B₁ has recently become commercially available in the form of a crystalline hydrochloride. As the product has been submitted to the Council this necessitated the coming of an acceptable nonproprietary name. Dr. Jansen of Amsterdam coined the name Aneurin. The Council recognizes the right of the discoverers to coin names for their products, but it cannot accept those names if they are therapeutically suggestive. Dr. Jansen has been very cooperative in discussing the matter or nomenclature for vitamin B₁ and suggested certain other names. Dr. Jansen suggested that Dr. R. R. Williams, who recently accomplished the synthesis of vitamin B₁ crystals, propose a name based on the chemical structure. Dr. Williams informally proposed the term Thiamin Chloride.

A communication was sent to Dr. Jansen by the Council office (March 30) as follows:

"Out of these discussions came the possibility that the name Thiamin Chloride would be an acceptable type. The Council discussed formally the proposed name, Thiamin Chloride, at its meeting of March 12 and 13, and it formally approved of this name, tentatively awaiting, of course, final approval by you. In the meantime, the name will also be proposed at the meeting of the American Society of Biochemists.

"Upon investigation in this country, we find that the name Thiamin Chloride is not trademarked. It is indicative of the chemical composition, and easily pronounced.

"This office shall be indeed grateful for your consideration of this name, and your frank comment. The Council wishes to cooperate with you to the fullest extent on this matter, and will take no final action until it has had an opportunity to consider your reply."

To this Dr. Jansen replied (in part) May 1:

"Many thanks for your letter of March 30, 1937. As I told you in my first letter, I do not insist on the name 'aneurin,' and

so I have no objection against the name Thiamin Chloride, on the sole condition that it is adopted internationally. Otherwise I fear it will augment the confusion. Now in Europe the name aneurin finds more and more acceptance, so e.g. it is now adopted in the 'Abderhalden's Handbuch der biologischen Arbeitsmethoden'."

In the meantime, the American Society of Biological Chemists, the American Institute of Nutrition and the Committee on Nomenclature of the American Chemical Society have all tentatively approved the term Thiamin Chloride suggested by Dr. Williams. Dr. Jansen also suggested that the matter be referred to the International Committee on Nomenclature. The Council feels however that the delay which would be involved amounting to many months, makes this provision difficult to accept in toto. Since manufacturers have already asked for the acceptance of the product under a nonproprietary name, a delay would seriously endanger the project of introducing an acceptable nonproprietary name into the literature. The Council desires to express to Dr. Jansen its deep gratitude for his cooperation in this matter and wishes to comply as far as possible with the spirit of Dr. Jansen's suggestions for consideration by an International Committee on Nomenclature. The Council therefore decided to adopt the name Thiamin Chloride as a common name for Vitamin B₁ Hydrochloride with the proviso that if the International Committee in 1938 should adopt some other suitable name the Council will feel free to concur in the use of the international name, with Thiamin Chloride as a synonym. It is understood that if other salts are found suitable they should be named accordingly 'Thiamin Sulfate,' 'Thiamin Bromide,' and so on.

AVERTIN WITH AMYLENE HYDRATE II

Avertin, the trade name of the Winthrop Chemical Company for tribrom ethyl alcohol (designated in the foreign literature also as "ethobrom," "rectanol," "renarcol," "narcotyl," "E 107," "Byck 250") and its dosage form, avertin fluid (now "avertin with amylene hydrate"), were the subjects of a preliminary report by the Council¹ in 1930. The Council decided not to admit avertin and its dosage form to New and Nonofficial Remedies.

"(1) until satisfactory studies of its properties its advantages and its disadvantages have been made (2) until the contraindications have been satisfactorily established, (3) until a generally accepted technique whereby it can be used as satisfactorily as ether has been established (4) until the action of the amylene hydrate in avertin liquid—whether by addition or by potentiation—has been determined and the amount declared and (5) until the advertising has been revised to omit misleading statements contained in the present advertising and especially to recommend the product only for initiation of narcosis (basis narcosis) and not for complete narcosis.

Among the disadvantages of avertin with amylene hydrate pointed out in the aforementioned report were:

'1 Higher death rate than after ether 2 Depression of respiratory center 3 Depression of circulation 4 Acidosis as actively as after chloroform 5 Insufficient muscular relaxation in laparotomy (?) 6 Falling back of tongue making constant observation necessary until the patient is fully conscious 7 Lack of control from moment to moment (almost unanimous) 8 Want of exact dosage 9 Narrow zone between anesthetic and fatal dose 10 Disadvantages inherent in mixed narcosis 11 Lack of adequate pharmacologic study of avertin and its synergistic action with morphine ether and other substances 12 A lack of agreement concerning the indications and contraindications.

In 1932 the Council again considered avertin fluid and again decided not to accept the product, largely because of comments of members of the Council who considered that in the dosages commonly employed avertin with amylene hydrate was not safe. Doubt was expressed as to possible deleterious effects of the amylene hydrate component in the amounts usually administered.

Four years later the Council once more considered the available evidence as to the therapeutic usefulness of avertin with amylene hydrate and concurred in the opinion of the referee that there can be no question that experience with this mixture has established the range of its usefulness and that its indications and limitations are now well known. Up to the middle of 1936, approximately 700 papers had been published on avertin or avertin with amylene hydrate since the introduction of

¹ Avertin. Preliminary Report of the Council on Pharmacy and Chemistry. J. A. M. A. 95: 1427 (Nov. 8) 1930.

tribromethanol, of these nearly 400 were reviewed by Anschütz, Specht and Tiemann² in a 200 page monograph published in 1930. The present referee collected about 300 references published subsequently. The number of cases in which avertin with amylene hydrate has been used undoubtedly amounts to many hundred thousands (early in 1935 Desmarest claimed this to be 600,000). Only a portion of these cases has been reported in the literature but this fraction alone appears to be more than adequate for an estimate of the usefulness of this preparation, thus, in fifty papers chosen at random from among those published between 1932 and 1935, approximately 20,000 cases were reported. The overwhelming majority of the reports are favorable.

It is obviously not feasible to review in detail all the available literature, this would require a monograph even more extensive than that of Anschütz and his collaborators. Therefore in this report only a brief summary of the more pertinent data in available literature will be presented. References will be given only in a few instances, compilation of a complete bibliography as part of this report is obviously not practicable.

Avertin with amylene hydrate is now the only form of tribromethanol marketed. It is a 100 per cent weight/volume solution of tribromethanol (tribromethyl alcohol) in amylene hydrate (tertiary amyl alcohol), each cubic centimeter contains 1 Gm of tribromethanol and 0.5 Gm of amylene hydrate.

Tribromethanol is relatively unstable, it decomposes slowly on standing and rapidly on heating above 40°C with the liberation of the irritant hydrobromic acid and dibromacetaldehyde. The firm supplies a vial of congo red indicator with each bottle of avertin with amylene hydrate to detect acidity in each dose of the drug as it is prepared by dilution in warm water. However, congo red has a range of pH 3 to 5 and thus, as pointed out by several authors, it is useless in detecting any but a high acidity. Ashworth³ has therefore suggested the employment of a more suitable indicator, capable of detecting early deterioration of avertin. He proposes a mixture of methyl orange, methyl red, naphtholphthalein and phenolphthalein ("universal indicator" of Martindale's "Extra Pharmacopoeia") having a range of pH 4 to 11. In order to meet this objection the firm has revised its directions for use of the congo red indicator requiring that the color of the avertin solution to which the indicator has been added should match that of distilled water plus indicator. This enables the detection of smaller quantities of acid. The A. M. A. Chemical Laboratory is studying this question further.

Serious toxic effects noted in the early clinical use of avertin are now recognized as having been due chiefly to the administration of large doses (150, 175 and even 200 mg of avertin per kilogram of body weight, either as avertin itself or as avertin with amylene hydrate) and to a poor knowledge of the contraindications. It is now recognized that 100 mg per kilogram as avertin with amylene hydrate is ordinarily a maximum dose and with this dose untoward effects appear to be uncommon. However, even the 100 mg dose occasionally produces complete and not basal anesthesia and accompanying circulatory and respiratory depression. A number of anesthetists have obtained excellent results with smaller doses, namely from 60 to 80 mg of avertin per kilogram (30 to 40 mg of amylene hydrate per kilogram) with a consequent further reduction of deleterious effects. The Council believes that a dose of 80 mg per kilogram should be established as the ordinary maximum in perhaps the majority of cases less will be sufficient. With this maximum dosage and with proper attention to the contraindications, avertin with amylene hydrate appears to be quite safe for basal anesthesia. In young vigorous subjects however, from 90 to 100 mg per kilogram may in some cases be employed with safety. The total amount of avertin with amylene hydrate should not exceed from 6 to 8 cc for women or from 9 to 10 cc for men, regardless of weight.

The contraindications (relative or absolute depending on the condition of the patient) include liver or kidney dysfunction, severe cardiac disease, old age, shock or dehydration, sepsis, toxemia, severe pulmonary tuberculosis, emphysema, marked

hypothyroidism, obesity, asthenia, cachexia, ileus, tumors of the colon, enteritis and acidosis.

Sir Francis Shipway,⁴ in presenting his experience with 1,600 administrations of avertin with amylene hydrate, discusses contraindications as follows:

Provided the dose be suitably adjusted the contraindications are exceedingly few. This statement however needs qualification. It should apply only to the anesthetist who has had not only considerable experience in anaesthesia but in avertin anaesthesia. *The practitioner who is called upon to administer anaesthetics on few and irregular occasions or is but a beginner in this arduous and hazardous specialty, will be well advised to leave avertin severely alone [emphasis the referee's].* The chief danger lies in depression of the respiratory centre, the blood pressure is also lowered. It is better therefore if there is any doubt in the mind of the anesthetist to withhold it in the case of advanced pulmonary tuberculosis where the respiratory exchange is poor in acute emphysema or states of drowsiness whether caused by drug or toxæmia. Extreme thyroid deficiency or a condition of very low blood pressure due to shock, haemorrhage, sepsis or cachexia would also speaking generally render the patient unsuitable for avertin in inexperienced hands. Colitis and intestinal obstruction should also be looked upon as contraindications. Cyanosis due to congenital heart disease or chronic valvular disease does not forbid its employment although it does of course prescribe a smaller dose than the average. Deepening of cyanosis after absorption has occurred should be countered by a plentiful supply of oxygen and the maintenance of a free airway. It is true that coramine, ephedrine and carbon dioxide are efficient antidotes to excessive dosage of avertin if given in time and with judgment. Washing out of the rectum on the first sign of overdose such as slow shallow respiration and slow feeble pulse is also a measure not to be despised. I have noticed that on those occasions on which the solution has been returned even as late as half an hour after injection or on which it has been deliberately syphoned off—for example before the performance of a plastic operation on the perineum—there has been a definite diminution in the depth of the narcosis. In one case of extreme overdose (10 times) reported to me, washing out the rectum was effective and the operation was completed without mishap or complication.

Studies on absorption and elimination have been concerned chiefly with the avertin component of avertin with amylene hydrate. When administered in a 3 per cent solution, 50 per cent of the avertin is said to be absorbed from the colon in ten minutes, 75 per cent in twenty minutes, 85 per cent in twenty-five minutes and from 90 to 95 per cent in two hours. Narcosis is said to occur with a concentration of avertin in the blood of from 6 to 10 mg per hundred cubic centimeters and awakening to occur when it falls to 2 or 3 mg per hundred cubic centimeters. Tribromethanol is detoxified by conjugation with glycuronic acid (largely and perhaps entirely in the liver) and the glycuronate is excreted by the kidneys, from 70 to 80 per cent in forty-eight hours, from 90 to 95 per cent in seven days. Amylene hydrate is in part excreted (unchanged?) by the kidneys, in part eliminated in the expired air.

Objection has been made to the use of avertin fluid because of possible danger of the amylene hydrate component in the dosage used. While some authors have claimed that this substance does not partake in the narcotic effect, this is manifestly absurd. It has been claimed that the amylene hydrate tends to slow absorption through its solution affinity for tribromethanol, but the observations on which this claim is based were made with the 100 per cent solution administered to rats. While this delay might occur from the 100 per cent solution, it is quite unlikely to occur from the 2.5 or 3 per cent dilution used clinically. In fact, with this dilution no such delay has been observed in patients. It appears, nevertheless, that the danger of the amylene hydrate component has been much exaggerated. The maximal single hypnotic dose for man is ordinarily stated to be 4 Gm. For a 70 Kg man, a dose of 100 mg of avertin per kilogram (as avertin with amylene hydrate) would represent 70×50 mg of amylene hydrate, or 3.5 Gm. With the smaller doses recommended as the ordinary maximum in this report (80 mg per kilogram) a maximum dose of 2.8 Gm of amylene hydrate would be administered to a 70 Kg man. This may seem excessive when added to a narcotic dose of avertin. However, investigation of the literature reveals relatively few cases of intoxication from amylene hydrate. Kochmann⁵ states (translated) "noteworthy is the small number of fatal poisonings." He cites only one fatality, this followed a dose of from 28 to 29 Gm by rectum. Two other cases are cited repeatedly in the literature, apparently they have become classic. One patient, a 73 year old man, received

² Anschütz W, Specht K and Tiemann F. Die Avertinnarkose in der Chirurgie. Ergebn. Chir. u. Orthopädi. 23: 406-605, 1930. Also published as a monograph by Julius Springer, Berlin.
³ Ashworth H K. Sensitive Test for Purity of Avertin Solution. Brit. M. J. 2: 489 (Sept. 9) 1933.

⁴ Shipway Sir Francis. Avertin. An Analysis of 1,600 Administrations. Brit. J. Anaesth. 12: 150 (July) 1935.
⁵ Kochmann M. Schlafmittel. Gruppe des Amylenhydrats, Urethan und Paralydehyd. Handb. exper. Pharmacol. 1: 426-1923.

18 Gm of amylene hydrate and recovered after a thirty hour period of unconsciousness. The other patient received 27 Gm but recovered after several days. The minimal fatal dose for man is impossible to estimate from data available in the literature, but it must be several times the maximum hypnotic dose. Kochmann gives the minimum lethal dose for rabbit or dog as 15 Gm per kilogram and for the cat as 1 Gm per kilogram. Harnack and Meyer⁶ state the minimum lethal dose to be 2 Gm per kilogram for the dog and from 1 to 15 Gm per kilogram for the rabbit or cat.

Amylene hydrate in doses of from 3 to 5 Gm in man is said to produce little change in the circulation and to cause acceleration and increased depth of respiration. With larger doses, depression of both occurs. Tolerance to amylene hydrate is readily acquired, this may also occur with repeated administrations of avertin with amylene hydrate (Maddox, cited by Shipway).

It appears that amylene hydrate contributes a more prolonged action to the avertin mixture than that possessed by the somewhat more evanescent avertin alone. Amylene hydrate also adds to the side effects, these include a fall in temperature, often of several degrees, and proper care is required to combat it clinically.

With proper dosage of avertin with amylene hydrate and care of the patient, significant depression of circulation and respiration are said not commonly to occur. With larger doses, and occasionally with smaller doses, marked respiratory and/or circulatory depression does take place. Carbon dioxide, ephedrine, caffeine with sodium benzoate, among other drugs, are said to be effective antidotes. Thyroxine, if administered sufficiently in advance to increase the metabolic rate, is claimed to hasten the elimination of avertin but, except with respect to the use of avertin with amylene hydrate in cases of hyperthyroidism, in which large doses appear to be well tolerated, this observation probably has little practical significance.

While large doses of avertin with amylene hydrate administered repeatedly to animals cause moderate but reversible liver damage, in the clinical use of the preparation no functional hepatic deficiency appears to occur, as determined by the brom-sulfalein test.

Acute renal insufficiency appears to be an absolute contraindication to the use of avertin with amylene hydrate, although it has been used with claimed safety in chronic low grade renal insufficiency.

Arnheim and Tuchman⁷ have reported a detailed study on fifteen patients, these included ten males and five females who were admitted to surgery for comparatively minor operations (chiefly inguinal herniorrhaphies) but were otherwise in good health. These patients received 100 mg of avertin per kilogram (as avertin with amylene hydrate), studies were made immediately before administration and one and four hours after administration of the drug. Pulse rate, arterial and venous blood pressure, respiratory rate and amplitude, temperature, basal metabolic rate, blood chemistry, blood histology, blood clotting time and urinary examinations were recorded. Operations were not performed until the studies were completed, little additional anesthesia was found necessary (this is further evidence that the 100 mg dose is excessive, as a relatively strong effect persisted for more than four hours). Following is a summary of the observations: Average increase in pulse rate of 16 per minute and of respiratory rate of 6 per minute, amplitude of respiration was decreased. Average decrease in systolic blood pressure of 24 mm of mercury, average decrease in rectal temperature of 1.3 degrees F (0.7 degree C), average decrease in basal metabolic rate of 22 per cent, average decrease in blood clotting time of three minutes. There were slight early rise in blood sugar, slight fall in blood carbon dioxide, slight rise in blood plasma volume, negligible or no change in venous pressure, blood cholesterol and esters, blood calcium, chlorides and formed blood elements. There were slight oliguria and increase in specific gravity of the urine. Conjunctival and tendon reflexes were lost, but cutaneous and pharyngeal reflexes were retained. Slight cyanosis occurred

in two cases, increase in secretion of mucus was noted in five and slight vomiting in three cases. No residual untoward effects were detected.

The foregoing study agrees in general with more extensive experimental and clinical reports in the literature, notably by Bourne and his associates, Sebening, Desmarest, Anschutz, Lendel, Barlow, Goldschmidt, Field and Pilcher and many others.

Bourne has observed a moderate acidosis after avertin with amylene hydrate associated with an increased excretion of phosphates. He therefore administers an alkaline phosphate mixture by rectum as a routine following each operation in which this drug is used.

Avertin with amylene hydrate has been found by a number of authors (Berman, Boyce and McFetridge, Cole, Fawcett, Harrison and Higgins, Mitchell, Simons and others) to be of value as an adjunct to the use of tetanus antitoxin in the treatment of tetanus, repeated doses are administered, sufficient to interrupt the convulsive seizure and to keep the patient quiet over a period of several days if necessary.

The necessity for special nursing care of patients who receive avertin with amylene hydrate has been mentioned in many reports. This is emphasized by a number of authors and has been well stated by Field and Pilcher.⁸

The longer duration of unconsciousness and irregular as well as increased restlessness after avertin meant that it was necessary to give avertin patients special postoperative care for a much longer period than with other anesthetics. The patient was undoubtedly much more comfortable—especially since the events of the first few hours after operation were usually entirely forgotten—but the nursing problem of the hospital was greatly increased. The patients appeared just as irresponsible during the prolonged drowsy, restless period of awakening from avertin as during the shorter excitement stage following ether. Several patients who had had avertin anesthesia complained a few hours after operation of a severe headache lasting twenty-four to seventy-two hours. This headache in many instances seemed much more distressing and persistent than the usual type of postoperative headaches.

Field and Pilcher report one case of bromide rash following the administration of avertin with amylene hydrate.

While avertin with amylene hydrate appears to be useful in practically all fields of surgery (provided dosage limitations and contraindications are rigidly observed) there is considerable disagreement as to its value in obstetrics, in which it is used for analgesia in dosage below that usually necessary for basal anesthesia. It is said by some to delay labor, to make the patient unmanageable and often to depress the fetus. Others who have developed a special technique for its use claim good results. Dodek⁹ found that in the dosage commonly employed in obstetrics (60 mg per kilogram) avertin with amylene hydrate prolongs intervals between contractions, that analgesia does not last long enough to warrant the special care these patients require, and that many patients become unmanageable when the effect begins to wear off.

The question of the number of fatalities from avertin with amylene hydrate is a difficult one to estimate with any degree of accuracy because, as has been pointed out repeatedly, the majority of fatalities are not reported and in those that are the role played by the avertin preparation in the ensuing death is often impossible to determine. Recent reports of several series of cases ranging in size from about 400 to more than 3,000 each indicate that the estimate of one death in 10,000 cited by the Council's referee from the German literature in 1932 is probably accurate. This, however, like all such figures, is impossible either to confirm or to refute for the reasons stated.

The deaths due to avertin or to avertin with amylene hydrate that have been reported belong almost without exception in one or more of the following categories: (1) patients in whom crystalline avertin alone or avertin with amylene hydrate was used in excessive doses, (2) patients who would now be recognized as having definite contraindications to avertin with amylene hydrate, (3) patients who received previous medication with morphine (with or without atropine or scopolamine) followed by a large dose of avertin with amylene hydrate, (4)

patients who failed to receive adequate postoperative nursing care (maintenance of open airway, and so on)

Shipway⁴ warns that the preliminary use of morphine or other drugs which depress the respiratory center may carry a considerable hazard

'morphine although exceedingly useful in the right place should not be given without the most careful consideration of all the circumstances of the case

Shipway used morphine in about one third of his 1600 cases (in which there was no death due to avertin with amylene hydrate). Others use it more frequently. Mueller,¹⁰ in reporting a series of 3,338 cases (without a death which the author considers may be attributed to avertin with amylene hydrate) states

Usually a hypodermic of morphine gr one sixth or one fourth with atropine or scopolamine is given forty five minutes before operation

It is significant that this author reports, "The chief complication which we have had to combat was respiratory depression." She believes that in most cases this was due to failure to maintain an open airway rather than to depression of the respiratory center, but it is obvious from the subsequent discussion that stimulants were required in many cases

Bovd¹¹ reported 700 cases in which avertin with amylene hydrate was used as a complete anesthetic in children in doses of 175 and even 200 mg per kilogram (children are known to tolerate relatively high doses of this mixture). He administered preliminary morphine from $\frac{1}{40}$ to $\frac{1}{20}$ grain and atropine from $\frac{1}{80}$ to $\frac{1}{150}$ grain, depending on age. Eighteen of these patients required coramine to combat respiratory or circulatory depression. Only two deaths from any cause occurred in this series of 700, one from brain abscess, the other from intestinal obstruction due to tumor. Despite the fact that this author had no fatal accidents directly caused by the anesthetic, apparently because of careful vigilance of the anesthetist and the nursing staff, the Council believes that avertin with amylene hydrate should not be used as a complete anesthetic even in children, owing to the hazards involved in the use of a nonhalothal anesthetic in this way

Bourne and O'Shaughnessy,¹² in reporting 1,000 "avertin anesthetics" (without a death attributed to avertin with amylene hydrate), do not even mention the use of morphine, whether because they do not use it or because they take its use for granted is not clear

The Winthrop Chemical Company has agreed to market avertin with amylene hydrate for *basal anesthesia only* in accordance with the conditions of the foregoing report. The Council has, therefore, accepted avertin with amylene hydrate for inclusion in New and Nonofficial Remedies. The description appears in the New and Nonofficial Remedy column of this issue

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLE HAS BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION

PAUL NICHOLAS LEECH, Secretary

AVERTIN WITH AMYLENE HYDRATE—Tribromethanol in amylene hydrate—A solution of tribromethanol (tribrom ethyl-alcohol, $\text{CBr}_3\text{CH}_2\text{OH}$) in tertiary amyl alcohol $[(\text{CH}_3)_2\text{C}(\text{OH})\text{C}_2\text{H}_5]$. Tribromethanol contains 84.78 per cent bromine. Each cubic centimeter of avertin with amylene hydrate contains 1 Gm tribromethanol and 0.5 Gm amylene hydrate

Actions and Uses—Avertin with amylene hydrate is used for basal anesthesia by rectal administration. It should not be employed in dosage sufficient to cause complete anesthesia. When employed for basal narcosis the amount of inhalation anesthetic necessary to establish and maintain complete anesthesia is diminished. A prolonged period of sleep usually follows termination of inhalation anesthesia, during this after-

period careful nursing care and continuous vigilance are necessary to maintain an open airway and to prevent the cyanosis and respiratory failure which sometimes follow. Ephedrine, carbon dioxide and caffeine with sodium benzoate are said to be effective antidotes against respiratory and circulatory depression occurring from avertin with amylene hydrate

Contraindications to the use of avertin with amylene hydrate (relative or absolute depending on the condition of the patient) include liver or kidney dysfunction, severe cardiac disease, old age, shock or dehydration, sepsis, toxemia, severe pulmonary tuberculosis, empyema, marked hypothyroidism, obesity, asthenia, cachexia, ileus, tumors of the colon, enteritis and acidosis

Avertin with amylene hydrate is said to be useful in the control of certain convulsive conditions such as tetanus. In the latter condition it is used in repeated doses in conjunction with administration of tetanus antitoxin to control the seizures over a period of several days if necessary

Cautions—Avertin with amylene hydrate should never be employed by those inexperienced in its use except under expert supervision

Dosage—Avertin with amylene hydrate is administered rectally in 2.5 per cent solution in warm distilled water at a temperature not exceeding 40°C. A small quantity of the solution should be tested with the congo red indicator supplied with the preparation just before administration, the color of the solution should match that of an equal amount of distilled water containing an equal quantity of the congo red indicator. If the colors do not match, this indicates the presence of irritant hydrobromic acid and di-bromacetaldehyde, and the solution should be discarded

The ordinary maximum dose for basal anesthesia is 80 mg of avertin (40 mg of amylene hydrate) per kilogram of body weight. Often less will be sufficient. In young, vigorous persons the dose may sometimes be increased to 90 or 100 mg of avertin (from 45 to 50 mg of amylene hydrate). The dose is usually stated in milligrams of the avertin component only. As the amylene hydrate adds materially to the narcotic effect it should be kept in mind that, with each dose of avertin, half this dose by weight of amylene hydrate is administered

The total amount administered should not exceed from 6 to 8 cc of avertin with amylene hydrate for women, or from 9 to 10 cc for men, regardless of weight. Dosage tables are supplied by the firm

Manufactured by Winthrop Chemical Company, Inc., New York. U. S. patents 1,572,742 (Feb. 9, 1926, expires 1943), 1,725,034 (Aug. 20, 1929, expires 1946), 1,882,984 (Oct. 18, 1932, expires 1949). U. S. trademark (Avertin) 233,204

Tribromethanol is a white crystalline powder with a slight aromatic odor and taste, unstable in the air, sparingly soluble in water, about 1 in 35, readily soluble in purified petroleum benzine. Its aqueous solution is neutral to litmus. The solution is unstable. Tribromethanol melts at from 79 to 82°C.

Dissolve about 0.2 Gm of tribromethanol in 10 cc of water, add 1 cc of sodium hydroxide solution, warm slightly, add 2 cc of nitric acid and 1 cc of silver nitrate solution; a yellow precipitate results, soluble in an excess of stronger ammonia water

Dissolve about 0.1 Gm of tribromethanol in 5 cc of water at from 35 to 40°C, cool, add 1 cc of a 10 per cent phenylhydrazine acetate solution; no precipitate should form even after thirty minutes (di-bromacetaldehyde)

Dissolve about 0.1 Gm of tribromethanol in 1 cc of sulfuric acid; the solution is colorless (readily carbonizable substances). Dissolve about 0.5 Gm of avertin in 50 cc of water; separate portions of 10 cc each of the filtrate yield no opalescence with 1 cc of diluted nitric acid and 1 cc of silver nitrate solution (uncombined halides); no turbidity with 1 cc of diluted nitric acid and 1 cc of barium nitrate solution (sulfates); no coloration or precipitation on saturation with hydrogen sulfide (salts of heavy metals)

Incinerate about 0.5 Gm of tribromethanol accurately weighed; the residue does not exceed 0.05 per cent. Dry about 1 Gm of tribromethanol accurately weighed to constant weight over sulfuric acid; the loss in weight should not exceed 1 per cent. Transfer about 0.15 Gm of tribromethanol to a bomb tube, determine the bromine content according to the Carius method; collect the precipitate of silver bromide in a Gooch crucible; the amount of bromine found should not be less than 84 per cent nor more than 85.5 per cent

AMYLENE HYDRATE—Dimethylethylcarbinol— $(\text{CH}_3)_2\text{C}_2\text{H}_5\text{C}_2\text{H}_4\text{OH}$ —Occurs as a clear, colorless, volatile liquid possessing a penetrating odor resembling a mixture of camphor and peppermint and having a pungent taste. It is soluble in alcohol, chloroform, ether, glycerin and water (about 1 in 8). The specific gravity of amylene hydrate at 25°C is from 0.803 to 0.807; it boils at from 97 to 103°C.

Amylene hydrate forms acicular hygroscopic crystals on cooling to low temperature. It is oxidized into acetic acid and acetone with chromic acid

Dissolve 1 cc of amylene hydrate in 20 cc of water and divide into two portions of 10 cc each; to one portion add 1 cc of an ammoniacal solution of silver nitrate and heat on a water bath; no reduction takes place in ten minutes (absence of aldehyde); to the other portion add 0.1 cc of tenth normal potassium permanganate solution; no complete decolorization within ten minutes (limit of amyl alcohol). Shake 8 cc of amylene hydrate with 0.6 Gm of anhydrous copper sulfate; the latter does not become blue (absence of water)

Evaporate 20 cc of amylene hydrate in a platinum dish on a water bath to about 2 cc and allow to evaporate spontaneously to dryness; the residue if any is colorless. Now dry at 100°C and weigh the weight of the residue does not exceed 0.05 Gm

THE TOXICOLOGY OF NEW INDUSTRIAL COMPOUNDS

The introduction into industry of many new synthetic chemical compounds has created innumerable diagnostic and other clinical problems for the medical profession. McConnell¹ has indicated the nature of this development. The House of Delegates at the Atlantic City session, this year, authorized the establishment of a Council on Industrial Hygiene. Laboratories for the investigation of the toxicologic and pharmacologic properties of such compounds are now being developed in many industries.

In spite of this increasing recognition, medicine is frequently put in the position of attempting to lock the door after the horse has been stolen. Many industrial compounds have received wide use and caused considerable damage before their destructive properties have received sufficient investigation. An example is manifest from the study made by Lehman and Newman² of the Stanford University School of Medicine on propylene glycol, which has had wide use as a solvent for technical purposes. They determined the toxicity, hemolytic action, fate of the compound in the blood and in urine, absorption, content in the blood, excretion and diuretic effect. They found that propylene glycol, which incidentally may be considered as a prototype of many of the glycols now commercially available, has an acute toxicity less than half that of ethyl alcohol, that hemoglobinuria does not occur after ingestion of large doses, that the compound is rapidly absorbed from the gastro-intestinal tract, that rapid distribution after absorption occurs throughout the tissue, that combustion in the body proceeds at a constant rate, irrespective of dosage, and that the narcotic action is about one-third that of ethyl alcohol.

While this study is useful because of the applicability of its specific results, it serves also as an example of the type of study that should be followed prior to

¹ McConnell W J. Volatile Solvents as a Problem in Industrial Medicine. *J A M A* 109:762 (Sept 4) 1937.

² Lehman A J and Newman H W. Propylene Glycol. Rate of Metabolism Absorption and Excretion with a Method for Estimation in Body Fluids. *J Pharmacol & Exper Therap* 60:312 (July) 1937.

the introduction into industry, and particularly into medicine, of new synthetic chemicals. It is an established procedure of industrial chemical laboratories to determine the chemical and physical and technical properties of new products over a wide range. Should determination of the effects on the human organism be regarded as of less importance? What is needed is that technical chemistry shall be supplemented by pharmacology in its broadest sense in the introduction of these compounds. These studies should be carried out as part of a systematic investigation rather than left to chance.

Both McConnell's discussion and the investigations of Lehman and Newman indicate the importance of a definite policy with regard to new industrial synthetics. Indeed, much can be said for the view that such studies should be made mandatory before the introduction into industry of new chemicals.

THE CITADEL

Dr A J Cronin, author of a new medical novel, "The Citadel," after graduating in medicine practiced in South Wales in a coal mining area. He contributed several items to medical research, including one article entitled "Dust Inhalation by Hematite Miners" and another on "First Aid in Coal Mines." The list of British doctors who write for a living is long, and many of them, such as Francis Brett Young, Somerset Maugham, R Austin Freeman, L A G Strong and others of lesser rank, are quite successful. In the United States we have had a few successful physician-fictionists. The great medical novels have not been written by doctors but by those outside the profession. True, Oliver Wendell Holmes, S Weir Mitchell and many others reflected the work of the doctor in their writings, but not one of their medical novels attained a stature comparable to their work in other fields. Perhaps the doctor is too close to his own work to do a really first-class novel about it. Among American contributions "Arrowsmith," by Sinclair Lewis and Paul DeKruif, reflected some of the difficulties that concern the worker in the field of medical research. Yet that novel was largely a reflection of the personal disturbances in the life of DeKruif and hence can hardly be considered representative.

"The Citadel,"¹ published several months ago in Great Britain and just now released in the United States, purports to reflect the life of a young physician named Andrew Manson, whose life seems to follow rather closely that of A J Cronin. Out of college without a penny, he accepts a job in contract practice. Disappointed with what he can do there he next becomes associated with a surgeon in a nearby town, where he finds that he has to pay a percentage of his salary regularly to his chief. Next he is involved in research in London, where bureaucratic stupidity keeps

¹ Cronin A J. The Citadel. Boston: Little Brown & Co., 1937.

him from the advancement that he seeks. He then purchases a dying practice and gets into Harley Street, where he finds that fee splitting prevails and commercialism seems to be the rule. The story and the formulas are, of course, familiar to American physicians. They have heard these abuses condemned so often by the profession itself that it is no new thing to see them condemned in fiction or in essay. In the United States, as in Great Britain, these abuses constitute but a small part of the medical scene. The Literary Supplement of the London *Times* succinctly evaluated the case in its review:

As a novel Dr Cronin's book may be reckoned his best piece of work. As propaganda it is lopsided. Any one familiar with the medical profession or with social work has met Dr Cronin's characters here and there. True he has given us the picture of honest doctors in great and humble positions but not enough of them. All over the country today are county and municipal officers who care less for fees than for healing in general practice are insignificant men and women living devoted, anxious lives with only fourteen days a year away from the clamorous telephone by day and night. In Harley Street are men who might stand beside Lister without shame. Above all, in the research departments of many a hospital are heroes and martyrs. These should have been made an offset to Dr Cronin's selected types.

In England the publishers tried to boost the sales of the Cronin book not on its qualities as a novel but by calling attention to its controversial aspects. It was hoped to start an investigation in parliament. Endeavors were made to incite the British Medical Association to resolutions and perhaps a boycott. Doctors bought the book because doctors like to read about themselves, as do other people.

Taking an idea from the plan of the British publishers, the American publishers are attempting a similar procedure to help them with the sales of the Cronin book in this country. They are circulating a photostatic copy of a letter written to them by Hugh Cabot on the stationery of the Mayo Clinic. Dr Cabot concludes his letter with the following paragraph:

I shrewdly suspect that this difficulty is considerably more serious in this country than in England. It is certainly one of the problems which is rapidly forcing us to face the question of whether or not medicine can continue to be practiced under this system. He makes allusions to the practice of fee-splitting, which I confidently believe is very much less common in England than it is here. The various types of contract and semi contract practice which he experienced are to be had here and are relatively similar.

"The Citadel" makes interesting reading, but it is not a fair picture of medicine in either Great Britain or the United States. Medicine has its scoundrels, its commercially minded practitioners, its inefficient and incompetent members. Is there any phase of human activity that does not have them? But medicine is proud of the fact that it cleans its own house and that it does its utmost to control these abuses without pressure from the outside. Its idealists are particularly proud of the fact that, unlike the cuckoo, they do not soil their own nests. What have the Cronins and the Cabots to gain by overemphasizing the small percentage of evil that every one knows about? Both Cronin and

Cabot know better than to believe much of what they say. As a social document in Great Britain, "The Citadel" seems to have failed of its purpose. Quite certainly it will make even less of an impression in this country. To the American doctors who read it, "The Citadel" will reveal the evils of panel practice and the obvious failure of the British system of medical service to give the British worker anything approximating the quality of medical care available to American workers.

PANIC, PUBLICITY AND POLIO

In the Middle Ages, when plague swept across any community, the inhabitants fled to the neighboring hills in panic. They did not know the cause of the disease and they had no specific method of prevention. They did know that, when plague came, people died. In a book by Frederick Prokosch entitled "The Seven Who Fled" there is an accurate picture of a Chinese city confronted with cholera. Among the Chinese an attitude of apathy apparently develops associated with the certainty that some people must inevitably die when the devastating epidemic strikes. In civilized communities, people should no longer be stricken with panic in the presence of disease. Much has been learned concerning the causes, methods of prevention, diagnosis and treatment of many of the infectious diseases. Patients are isolated. Modern methods of prevention are used to immunize those who are exposed. Known contacts are kept under control and in most instances after a reasonable time the disease disappears from the community or returns to what is called its normal incidence.

Toward poliomyelitis in the United States a somewhat abnormal point of view seems to have developed. The total incidence of that disease in any one year in the entire country is certainly less than 10 per cent of the number of cases of any one of the other common infectious diseases. Yet because poliomyelitis is a visibly crippling disease, panic appears in the minds of the public, which is frequently reflected in the statements and actions of public officials. Yet if ever rationality was needed it is demanded in the approach to this problem. One wonders, for example, whether the number of disabled as far as their hearts, kidneys and ears are concerned is any less from scarlet fever than the number of cripples of the arms and legs affected by poliomyelitis. Yet people everywhere are far more afraid of poliomyelitis—not knowing that the permanent "heart cripple" constitutes a much more serious problem. It is possible to splint, to reeducate and to rehabilitate a paralyzed limb. We have not yet found any method of splinting or reeducating a damaged heart, and the rehabilitation of the "heart cripple" is indeed difficult.

Men fear most what they do not understand. Let physicians and health officers alike admit that there is much that is not known concerning poliomyelitis.

We have not yet determined the exact cause of this disease. We know something concerning possible methods of transmission but we do not know with certainty exactly how it is transmitted to most human beings. We seem to know that considerable numbers of people have a natural resistance to the disease so that they would probably not become infected even if exposed.

Before the people of the country at this time, preventive medicine presents a lamentable aspect. Many health officers, following the lead of Chicago, are delaying the opening of schools. It is not clear whether this creates or allays panic. Some health officers are publishing day by day lists of cases actually diagnosed—with large lists of those suspected of having poliomyelitis. This enhances the panic. In other communities health officers have announced that they will not delay opening the schools or close the schools, since this seems to be contrary to fairly well established public health practice. In 1932 the health officers of Boston, San Francisco, Philadelphia, Los Angeles, Cincinnati and Chicago declared themselves opposed to delaying the opening of schools and to closing of schools to prevent epidemics of infantile paralysis. Similar views were expressed by Sir George Newman, Minister of Health in Great Britain, and by the Medical Director in the Department of Social Affairs of Oslo, Norway. Certainly there has been no new information or evidence since 1932 to warrant a change of opinion. There has only been new emphasis on poliomyelitis and perhaps too much publicity. Without the overemphasis in the press the vast majority of people would not have been concerned by the few hundreds of cases among many millions of people. The time would seem to be ripe for some organization in the public health field, either the Conference of State and Provincial Health Officers or the American Public Health Association, to endeavor to draw up some sort of regulations in relationship to this disease. Otherwise the ignorance of health officials and physicians will be made the excuse for erratic performances resulting from panic.

Current Comment

THE ZINC SULFATE SPRAY FOR THE PREVENTION OF POLIOMYELITIS

The successful use of a zinc sulfate spray in the prevention of experimental poliomyelitis in monkeys by Armstrong, Sabin, Schultz and their co-workers has stimulated much interest in its effectiveness as a preventive of the disease in human beings. Schultz demonstrated at Stanford University that in the experimental infection a solution containing 1 per cent of zinc sulfate, 1 per cent of pontocaine and 0.5 per cent of sodium chloride in distilled water is most effective in the monkey. The use of this technic in the human being has been too variable and uncontrolled to permit even an approximate estimate of its value. Dr J. C. Geiger, the director of public health of San Francisco, and his distinguished committee have recommended

that the use of this spray must be strictly limited until the proper technic has been worked out. There are possible side actions of the local anesthetic. Any physician applying the spray should be cognizant of possible symptoms of poisoning. The hazard of using a long tipped atomizer in the vicinity of the cribriform plate is also important. Attempts at home medication are absolutely valueless. The San Francisco report also states that no change in the constituents of the solution should be made without an investigation of the experimental result on monkeys. Treatments at present should be conducted in adequately supervised centers. Of special importance is the keeping of records of all treatments and the follow up of patients receiving the treatment. Only thus may adequate information on the preventive action be determined. In view, moreover, of the tendency of infantile paralysis to become rapidly less prevalent about the end of September and early October, the futility of starting such procedures at this time is readily apparent. If the evidence obtained this year is in any way encouraging, plans for determining the effectiveness of the attempted preventive might be worked out so that something resembling a serious scientific experiment may be tried next June, July and August.

MOTION PICTURE EDUCATION

Already many reservations¹ have been made for the motion picture film on syphilis, prepared jointly by the American Medical Association and the United States Public Health Service. It has become necessary to deny some requests although now several extra copies of the film are available. County medical societies, hospital conferences, medical schools and other assemblages of physicians have begun to take advantage of modern methods of visual education. The talking motion picture on syphilis was planned primarily for this purpose. Attention should be called also to the talking motion pictures, silent motion pictures and slide lectures now being offered by various medical industries. These are lent to medical societies without charge. At the Atlantic City session of the American Medical Association a talking picture film, developed by the American Committee on Maternal Welfare, was shown to the Section on Obstetrics, Gynecology and Abdom-

¹ Organizations desiring to avail themselves of this film either by purchase or by loan may communicate with Dr. Thomas G. Hull, director of the Bureau of Exhibits of the American Medical Association, 535 North Dearborn Street, Chicago.

The following reservations for the motion picture film on syphilis have been made:

September 9—The Hidalgo County Medical Society, County City Hospital, Edinburg, Texas.
September 21—Clinical Congress of the Connecticut State Medical Society, Dr. Maurice J. Strauss, 41 Trumbull Street, New Haven, Conn.
September 29—Staff Meeting, Veterans Administration, Hines, Ill. Dr. W. E. Kendall, chief medical officer.
October 6—Eighty-seventh annual session of Medical Society of the State of Pennsylvania, Philadelphia. Dr. Walter F. Donaldson, secretary, 8104 Jenkins Arcade, Pittsburgh.
October 8—Meeting of the Fifth District, Cleveland. Dr. C. L. Cummer, 1010 Hanna Building.
October 14—Medico-Military Inactive Duty Training Unit, Mayo Clinic, Rochester, Minn. Dr. F. L. Smith.
October 14—Annual meeting of Vermont State Medical Society, Dr. A. B. Soule, Jr., secretary, Mary Fletcher Hospital, Burlington, Vt.
October 16, 23 and 30—Dr. E. T. Sellers, chairman, Committee on General Disease Control, Jacksonville, Fla. If duplicate is available.
November 4—Evanston Branch meeting of the Chicago Medical Society, Dr. Harold C. Lueth, 636 Church Street, Evanston.
November 5—For monthly meeting of the local medical society, Dr. R. D. Millard, 378 Young Hotel Building, Honolulu, Hawaii.
December 29—Saranac Lake Medical Society, Dr. Edwin M. James, president, 6 Church Street, Saranac Lake, N. Y.
January 20—Dr. S. S. DeVaux, United Pa.

mal Surgery This film was made with the aid of Mead Johnson & Company and is planned to educate the public in the importance of antepartum care and in the importance of suitable feeding of the child. The film presents scientific material and is not in any sense of the word an advertisement. In its development Dr. Fred L. Adair, professor of obstetrics and gynecology at the University of Chicago, Dr. James R. McCord, professor of obstetrics and gynecology at Emory University, Dr. Everett D. Plass, professor of obstetrics and gynecology at the University of Iowa, Dr. Arthur J. Skeel, specialist in obstetrics and gynecology of Cleveland, and Dr. Philip F. Williams, professor of obstetrics and gynecology at the University of Pennsylvania, participated. It has been suggested that the film be shown not only to the expectant mother but also, in fact, to boys and girls of high school and college age. Certainly it will be well for physicians to view this film so as to be in a position to advise their patients concerning it. The development of the motion picture and of the talking motion picture for the advancement of medical education has been a gradual process in which many individual physicians have done pioneer work. Apparently their efforts are now bearing fruit. The time may well come when county medical society meetings will regularly include postgraduate instruction by leaders in the profession from all over the world whose knowledge, practice and experience are now made everywhere available directly in this form.

PUBLIC HEALTH FEATURES OF RHEUMATIC HEART DISEASE

Rheumatic heart disease, according to Hedley,¹ should not be considered a complication of rheumatic fever but its chief manifestation. Although this disease is not included in the synopsis on the control of communicable diseases prepared by a committee of the American Public Health Association, it offers several features which justify its examination in the same light as diseases which are included in that synopsis. In following the method adopted by the American Public Health Association, Hedley discusses the definition of rheumatic fever, its recognition, the probable source of infection, the probable mode of transmission, and susceptibility and immunity. The greatest frequency of rheumatic fever occurs from 7 to 10 years of age, with the peak incidence of initial cases occurring at about 7 years. Furthermore, an attack of rheumatic fever results in increased susceptibility to further attacks. The disease is found only in human beings and has not been experimentally transmitted. It is most frequent in cooler regions of the temperate zone. It is slightly more common in females and in white persons than in Negroes. The disease is found more in urban than in rural populations and more frequently among the poor than among the well to do. Malnutrition and poor living conditions seem to predispose to rheumatic infections. Rheumatic heart disease accounts for from 15 to 40 per cent of clinical heart disease in the United States. The exact proportion depends on the locality. In spite of the fact that the prevention of a disease is

usually dependent on adequate knowledge concerning its etiologic agent, mode of transmission and a reliable objective clinical serologic or roentgenologic basis for diagnosis, some preliminary tentative methods of control may be considered. Early recognition of the disease is of primary importance. Isolation of individuals in active stages is desirable. Because of the chronicity of the disease strict concurrent disinfection is almost impossible, but reasonable care should be exercised. No satisfactory methods of terminal disinfection, quarantine or immunization are at present available. The most important general public health measure in combating the disease urged by Hedley is the more thorough examination of school children for evidences of rheumatic heart disease. He emphasizes particularly that all pupils should be stripped to the waist for school physical examinations. This unusual method of approach to the rheumatic heart disease problem demonstrates that wide gaps in knowledge still exist. The mode of approach to the problem, however, should serve to help fill the gaps and to apply more effectively, from a public health point of view, the knowledge that does exist.

PNEUMOTHORAX FROM EXPERIMENTAL OVERINFLATION OF LUNG

Macklin² introduced a catheter in the right lower lobe of a cat's lung and insufflated osmic acid vapor in air for the purpose of fixing living lung substance. The insufflated air was supplied from the compressed air mains of the building. The animal died during the experiment as the result of a double pneumothorax with massive collapse of the lung, and the necropsy suggested the presence of air paths through the pulmonic interstitial tissue. The experiment was repeated a number of times. It was learned that the pneumothorax was related to overinflation of a limited part of the lung and that the osmic acid had nothing to do with it. Microscopic examination of the lung showed the presence of a fibrinous exudate, sometimes containing blood cells, which gathered in the alveoli, also a thickening of the finer perivascular sheaths, which became infiltrated with fluid, probably from the capillaries. The effect of the experiment on the animal depended on the air pressure used and the duration of the insufflation. When the air pressure was high, a swelling of the abdomen and chest quickly appeared and the respiratory movements ceased. When the insufflation was kept up vigorously enough the root of the neck swelled and later the valla, as the air extended through the connective tissue out of the superior mediastinum along the course of the great blood vessels. It seems likely, Macklin says, that finely subdivided air breaks through from the alveoli that abut on the perivascular tissue, which has become weakened through the imbibition of fluid. The bases of these alveoli collectively form a tunnel in which the blood vessels lie, and when that portion of the lung is hyperinflated this tunnel enlarges or expands like the inner circle of an expanding doughnut-shaped rubber balloon, that is, the hole becomes larger when the doughnut is blown up to a larger size. In this case

¹ Hedley, O. F. Silent Public Health Features of Rheumatic Heart Disease. *Pub. Health Rep.* 52: 164 (Feb. 5) 1937.

² Macklin, C. C. Pneumothorax with Massive Collapse from Experimental Local Overinflation of the Lung Substance. *Canad. M. A. J.* 36: 414 (April) 1937.

the rubber of the inner boundary is actually being stretched, likewise the membrane of the alveolar bases that bound the perivascular spaces during hyperinflation. Under normal conditions there is insufficient air pressure to produce these results. It is assumed, though not entirely proved, that the insufflated air breaks through at points in the periphery of the perivascular sheath system of the inflated part of the lung. The minute globules of air coalesce into larger ones, which move toward the hilus along lines of least resistance. The stream of air dissects its way to the root of the lung, where it occupies the sheaths of the great pulmonary vessels and then invades the mediastinum, which it distends and may even rupture, discharging the air into the pleural cavity to produce pneumothorax and massive collapse of the lung. The possibility was carefully considered that air might be leaking directly out of the inflated lobe through the pleura and thus cause a pneumothorax, in several typical cases, however, there was no evidence that the air was going directly through the pleura. The clinical application of these interesting experiments is not as yet clear. It is sufficient now to ask whether massive collapse with spontaneous pneumothorax may not arise in a human lung in which a main bronchus has been plugged with mucus and in which air may still enter during inspiration but in which the plug prevents its return during expiration. Pressure thus would arise in the blocked portion of the lung, owing to the accumulation of air. The alveolar bases abutting on the blood vessels might then become pervious to air and allow it to escape into the perivascular sheaths, from which it would go on into the mediastinum and possibly rupture into the pleural cavity. Such a mechanism would not involve a cough. LeWald² believes that in such cases there is a third type of massive collapse, which is due neither to atelectasis nor to rupture of the pleura.

THE DANGER OF EATING RHUBARB LEAVES

Because rhubarb sauce and rhubarb pie are frequent articles in the American diet, the use of the leaf blades for greens has frequently been suggested. J. H. Beattie¹ states that numerous cases of more or less serious illness and some fatalities have been reported in Europe and North America from the use of rhubarb leaves. The rhubarb leaf blades were eaten boiled in the belief that they were substitutes for the common greens. A fatal case of poisoning following the ingestion of rhubarb leaves was reported in *THE JOURNAL*, Aug. 23, 1919, page 627, while additional correspondence appeared in the issues of Sept. 20 and Oct. 11, 1919. Beattie states that "owing to the high content of oxalic acid and its soluble salts found in rhubarb leaves it is recommended that they be left entirely alone and not used under any circumstances as food. In the stalks, however, the oxalic acid is present in smaller amount and largely in insoluble form, and for this reason is harmless."

² LeWald, L. T. in discussion of Potter, R. P. Conditions Which Result in Collapse of the Lung. *Radiology*, 17: 271 (Aug.) 1931.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION AND PUBLIC HEALTH.)

ALABAMA

New Division of Industrial Hygiene—The Alabama State Department of Health has created a division of industrial hygiene with headquarters in Montgomery, and with Dr. William F. Queen, a graduate of Harvard University Medical School, in charge.

ARIZONA

Tuberculosis Mortality in 1936—A total of 1,101 deaths from tuberculosis in Arizona in 1936 gave a mortality rate of 264.9 per hundred thousand of population, the highest registered rate in the state in the past three years, according to *Public Health News*. The greatest number of deaths from this cause in the last decade occurred in 1929 when there were 1,471 deaths, giving a rate, based on estimated population at that time, of 345.8 per hundred thousand of population. At present tuberculosis is the leading cause of death in the state, comprising 17 per cent of the total mortality. Of the 1,101 deaths in 1936 there were 778 men and 323 women, an excess of 455. The disease accounted for the deaths of 678 white persons, 209 Mexicans, 163 Indians and fifty-one of other races. The largest number of deaths occurred in the age group 35-44. According to geographic distribution of these deaths it is startling to note that 39 per cent of those persons dying from tuberculosis actually contracted the disease in Arizona, the report states. Of the remaining 61 per cent, 17 per cent contracted the disease in places unknown or unstated on the death certificate. The length of residence in the state for persons who died of tuberculosis in 1936 is as follows:

Length of Residence	Number	Per Cent
One month	35	3
1-3 months	87	8
4-6 months	60	5
7-12 months	98	9
1-4 years	194	18
5-9 years	122	11
10 years and over	447	41
Unknown	58	5

ARKANSAS

Changes in Health Departments—Dr. Floyd S. Dozier, Clarendon, has been appointed health officer of the newly organized health unit in Polk County, with headquarters in Mena. He was succeeded by Dr. Albert S. J. Clarke, Little Rock, in a district unit composed of Arkansas, Prairie and Monroe counties, with headquarters in Clarendon. Dr. Winston C. Riggins, Little Rock, was named to the district composed of Ashley, Chicot and Desha counties, with headquarters at Hamburg. Other new appointments include the following:

Dr. Julius B. Askew, Little Rock, Independence County, with headquarters at Batesville.

Dr. Max F. McAllister, Fayetteville, Miller County, with headquarters at Texarkana.

Dr. Leroy L. Fatherree, Little Rock, Craighead and Poinsett district, with headquarters at Jonesboro.

According to the report, Independence, Craighead, Poinsett, Miller and Polk counties have been newly organized on a permanent basis.

CALIFORNIA

Society News—Dr. Clarence A. Mills, James T. Heady, professor of experimental medicine, University of Cincinnati College of Medicine, Cincinnati, addressed the Southern California chapter of the American Society of Heating and Ventilating Engineers and the Los Angeles County Medical Association, August 31, on "Climatic and Weather Factors in Relation to Health and Disease and Their Application to Air Conditioning."—W. F. Washburn, Ph.D., Rochester, N. Y., discussed "Ailing Feet" before the San Francisco County Medical Society, September 14.

FLORIDA

Malaria Project Approved—The Rockefeller Foundation will finance a survey on malaria in Escambia County, with Dr. John E. Elmendorf, Jr., of the foundation staff in charge of headquarters in Pensacola. Of the \$8,000 to be spent for the first year's work, the city and county will each pay \$1,000. It is expected that the control areas will be selected on the basis of the intensity of malaria existing in the district the

adaptability of the local problem to different types of malaria control and the local interest shown in the solution of the problem Dr Elmendorf will also be director of a malaria division to be formed in the Escambia County health department

GEORGIA

Public Relations Bureau—The Medical Association of Georgia has established a public relations bureau to work in cooperation with the state departments of public welfare and health, it is reported. With offices at the association's headquarters, 38 Prescott Street N E Atlanta, the bureau will disseminate health information in a statewide educational campaign among physicians and the public

Society News—At a meeting of the Jackson-Barrow Counties Medical Society in Jefferson July 5 Dr James T Stovall Jr, Jefferson, read a paper entitled "Differential Diagnosis of Lesions of the Right Side of the Abdomen with Special Reference to Urology"—The Fourth District Medical Society was addressed at Thomaston, August 11, among others by Drs Willis P Jordan, Columbus, on "Diagnosis and Treatment of Bronchiectasis," and Weldon E Person Atlanta "Anorectal Fistula"—A symposium on allergy was presented before the Fulton County Medical Society, September 2, by Drs Arthur G Fort, Lester A Brown Jr, Abner W Calhoun, Thomas S Claiborne, Clarence L Laws, Hal M Davison, Mason I Lowance and William R Crowe Jr, all of Atlanta

ILLINOIS

Society News—The Medical News of Rock Island County made its appearance in August as the official publication of the Rock Island County Medical Society, with Dr George W Dryer as editor in chief. Dr Warren H Cole, Chicago, addressed the county medical society, September 14 on "Pathogenesis, Diagnosis and Treatment of Chronic Cholecystitis"—Dr Paul H Harmon, Chicago, discussed poliomyelitis before the McDonough County Medical Society in Macomb, July 14—The Sangamon County Medical Society was addressed in Springfield, September 2, by Drs Burton Lyman Stewart on treatment of urogenital tract infections with sulfanilamide, William DeHollander, Postoperative Pulmonary Collapse Roentgen Aspects," and George H Fleischli, "Fractures About the Elbow" All are from Springfield

Chicago

Dr Sloan Named Professor of Medicine—Dr LeRoy H Sloan, associate professor of medicine University of Illinois College of Medicine has been appointed professor of medicine effective September 1. Dr Sloan graduated at Rush Medical College in 1917

Symposium on Occupational Disease—Northwestern University Medical School is sponsoring a symposium on industrial disease and hygiene at Thorne Hall September 27-28. The following program will be presented

- Dr Samuel M Feinberg Role of Allergy in Industry
- Dr Marion B Sulzberger New York Role of Allergy in Industrial Dermatoses
- Dr Leroy U Gardner Saranac Lake N Y Some Phases of the Pathology of Silicosis
- Dr Eugene P Pendergrass Philadelphia The Healthy Chest and the Modifying Influences of Silicosis and Silicosis with Infection
- Clarence W Muehlberger Ph D Toxicology of Industrial Solvents
- Dr Alice Hamilton Boston Some Recent Developments in the Field of Industrial Solvents
- Dr Robert A Kehoe Cincinnati Industrial Lead Poisoning

Dr James A Britton, medical director International Harvester Company will conclude the afternoon's program with a round table discussion on occupational disease. At the dinner in the evening Mr O E Mount president of the board of governors, department of occupational disease at the university will preside and the speakers will be Dr Irving S Cutter dean of the medical school who will discuss "The Role of the Medical Unit in Industry," and Frances Perkins, secretary U S Department of Labor, Washington, D C, "Health in Industry"

Group to Study Sex Degeneracy—A group of neurologists and psychiatrists met in the state's attorney's office, August 27 to discuss the problem of dealing with persons belonging in the group of mental disorders not covered by the legal definition of insanity and feeble-minded who may be apprehended for some crime. The group consisted of Drs Peter Bassoe, H Douglas Singer, Clarence A Neymann, Francis J Gerty, David Slight, Paul L Schroeder, David Rothman, Lewis J Pollock, Ralph C Hamill and Harry R Hoffman. There has been a recent increase in sex crimes. Under the present statutes sex criminals not insane or feeble-minded may receive only short sentences, and they frequently repeat their crimes. A subcommittee consisting of Drs Pollock, Gerty, Hoffman, Schroeder and

Rothman was appointed to prepare a definition of the mental disorders under consideration, particularly of sexual psychopathy. It is to recommend to the committee of the whole plans for statutes which as in the case of the Briggs law of Massachusetts, would provide means for the early recognition of sexual and other psychopaths. Such laws would also provide for commitment of these persons to a hospital for observation and diagnosis as does the Colorado law of 1924 dealing with insanity as a defense, and for treatment and isolation of vicious and antisocial characters until they are pronounced cured by a suitable board of psychiatrists

INDIANA

State Medical Meeting at French Lick, October 4-6—The eighty-eighth annual session of the Indiana State Medical Association will be held at the French Lick Springs Hotel French Lick, October 4-6 under the presidency of Dr Edmund D Clark, Indianapolis and with the Orange County Medical Society acting as host. Out of state speakers will include

- Dr Sumner L S Koch Chicago Infections of the Hand
- Dr Frank J Heck Rochester Minn Interpretation of Routine Laboratory Findings for the General Practitioner
- Dr Jesse O Arnold Philadelphia Fluid Balance and Dehydration in the Prevention and Control of Eclampsia
- Dr Albert C Furstenberg Ann Arbor Mich Acute Infections of the Cervical Region and Mediastinum
- Dr John S Lundy Rochester Minn Sacral Anesthesia
- Dr Joseph Brennemann Chicago Appendicitis in Childhood
- Dr Louis A Bue Rochester Minn Diseases of the Anus and Rectum
- Dr Karl A Menninger Topeka Kan The Psychoneurotic and the General Practitioner
- Dr Bernard H Nichols Cleveland Roentgenology as an Aid to Diagnosis of Lesions in the Upper Right Side of the Abdomen
- Dr Frank H Lahey Boston Some of the Newer Developments in Thyroid Disease

The annual banquet will be held Tuesday evening. Dr Roscoe L Senseich, president of the association during 1936, will be presented with his certificate of merit and speakers will include Dr Irvin Abell Louisville, Ky, President-Elect, American Medical Association. Entertainment will include the annual golf tournament at the Hill Course Monday and the fourth annual trap shooting tournament at the French Lick Springs Trap and Skeet Club Monday afternoon. Dr Edith M Boyer Schuman, Bloomington will address the annual dinner meeting for women physicians Monday evening on "Sulfanilamide Speakers at the meeting of the woman's auxiliary Tuesday include Dr Paul A Teschner, Chicago, Bureau of Health and Public Health Instruction, American Medical Association, on "The Doctor's Wife." Dr Bernard H Nichols, Cleveland, will address the Indiana Roentgen Society October 6 at a luncheon meeting. Fraternity and class reunion luncheons will be other features of the convention

IOWA

Laboratory Services Expanded—Under provisions of a special appropriation made by the forty-seventh general assembly the following laboratory procedures are now available without cost, to all licensed physicians in Iowa, at the state hygienic laboratory Iowa City

- Wassermann and Kahn tests and at the option of the laboratory the Kline test
- Dark field examination of chancere fluid for *Spirochaeta pallida*
- Examination of smears for gonorrhea
- Sputum examination for *Bacillus tuberculosis* (limited to smears)
- Throat cultures for organisms such as *Bacillus diphtheriae*, *Streptococcus haemolyticus* and bacteria associated with Vincent's infection
- Agglutination tests for diseases such as typhoid and paratyphoid undulant fever tularemia and the Rocky Mountain spotted fever typhus group
- Blood cultures for typhoid and undulant fever
- Fecal (and urine) examinations limited to specimens for diagnosis or release and to those pertaining to special epidemiologic investigations
- Examination of milk necessarily limited to specimens in connection with outbreaks or special investigations
- Examination of the brain of animals for evidence of rabies

For laboratory services other than those listed above and of a nonroutine character, it is advised that the approved clinical laboratories of the state be consulted. If such facilities are not accessible to the physician making the request the state hygienic laboratory will render the service for a small fee which will be deposited in a reserve fund for purposes of research. Correspondence should be directed to the laboratory Medical Laboratories Building State University of Iowa, Iowa City

KANSAS

Personal—Dr Floyd C Beelman Wichita has been appointed health officer of Sedgwick County—Dr John E Attwood La Crosse, has been appointed health officer of Rush County succeeding Dr Norval W Robison Bison, who held the position four years

Annual Registration Now Due—Physicians licensed to practice medicine in Kansas are required to renew their licenses annually between July 1 and October 1 and to pay a fee of \$1

to the secretary of the board of medical registration and examination. The secretary must strike from the register of licensed physicians the names of all physicians who fail to pay their annual registration fees as required by law. Physicians whose names are so removed may be reinstated by paying the secretary \$5 and submitting to him satisfactory proof of moral fitness.

MICHIGAN

Personal—Dr Joseph W Davis, Charlotte, has resigned as health officer of Eaton County to accept a similar position in Marion County, W Va. Dr Morley B Beckett, health officer of Allegan County, will serve as acting health officer of Eaton County until Dr Davis's successor can be selected, according to the state medical journal.—Dr David Kliger has been appointed coordinator in Wayne County for the administration of the afflicted crippled children acts. Dr Kliger took office September 1 with headquarters at the juvenile division of the probate court, 1025 East Forest Avenue, Detroit.—Dr George A Hays formerly state director of the local health administration of Arizona, Phoenix, has been appointed health officer of Flint.

Clinic to Study Rheumatism—A study of rheumatism to determine the causes and if possible a cure will be undertaken immediately in a new clinic to be established and maintained at the University of Michigan Hospital, Ann Arbor by the Rackham Fund, according to the *Ann Arbor News*. Ten thousand dollars will be available annually for several years. Dr Cyrus C Sturgis, professor and head of the department of internal medicine at the university, is chairman of a special committee appointed by Dr Albert C Furstenberg, dean of the medical school, to establish the clinic and supervise its operation. Others are Drs Harley A Haynes, director of the University Hospital, and Carl E Badgley, professor of surgery. Dr Richard H Freyberg will be in charge of the research on a full time basis.

State Medical Meeting at Grand Rapids—The seventy-second annual convention of the Michigan State Medical Society will be held at Grand Rapids, September 28-30 under the presidency of Dr Henry E Perry, Newberry. The Kent County Medical Society will act as host. Scientific sessions will be held at the Civic Auditorium and hotel headquarters will be at the Pantlind Hotel. Out of state speakers before section meetings will include the following:

- Dr Alvan L Barach New York Physiologic Treatment of Congestive as Contrasted to Peripheral Circulatory Failure
- Dr Donald C Balfour Rochester Minn Cancer of the Stomach
- Dr William Wayne Babcock Philadelphia Resecting the Cancerous Colon Without Permanent Colostomy
- Dr Otto H Schwarz St Louis Prevention and Treatment of Late Toxemias of Pregnancy
- Dr Albert Graeme Mitchell Cincinnati The Thymus Gland
- Dr Howard J Parkhurst Toledo Ohio Treatment of Coccogenous Syosis

Tuesday afternoon the first general assembly will be addressed, among others, by Dr John H J Upham, Columbus Ohio. President of the American Medical Association. Included among the speakers at the various general sessions will be:

- Dr Balfour Diagnosis and Treatment of Gastro-Intestinal Hemorrhage
- Dr Ernest E Irons Chicago Pulmonary Complications in Adult Medical and Surgical Patients
- Dr John T Murphy Toledo Use of Roentgen Ray in the Treatment of Fibroid Tumors and Bleeding of the Menopause
- Dr Schwarz Cesarean Section—Its Indications and Technique
- Dr William P Healy New York Diagnosis and Treatment of Cancer of the Cervix and of the Corpus Uteri
- Dr Claude S Beck Cleveland Recent Advances in Surgery of the Heart
- Dr Oliver S Ormsby Chicago Yeast Dermatoses—Contact Dermatitis
- Dr Mitchell What I Do Not Know About Endocrinics
- Dr William L Benedict Rochester Minn Optic Neuritis Its Etiology, Diagnosis and Treatment
- Dr Paul H Holinger Chicago Acute Laryngotracheobronchitis
- Dr George A Harrop Brooklyn Diagnosis and Treatment of the Adrenal Cortex
- Dr George P Reynolds Boston Diagnostic and Therapeutic Value of the Medical Society Study of Cases
- Dr Foster Kennedy New York The Psychiatrist's Responsibility Toward the Criminally Insane and Toward Society
- Dr John F Erdmann New York Curiosities and Rarities in Surgery
- Dr Babcock Surgical Problems That Confront the General Practitioner

Wednesday evening the fifth general assembly will be designated "presidents' night." Dr Thomas Parran Jr, surgeon general, U S Public Health Service will speak among others on "The Medical Profession versus Syphilis." During the meeting of the women's auxiliary Dr Henry A Luce, Detroit, will address a luncheon session on "How to Get Along with Your Nervous Relatives."

MINNESOTA

Graduate Courses—The Center for Continuation Study of the University of Minnesota, Minneapolis, announces a series of eight graduate medical institutes to be held during the coming school year. They will begin the first Monday of each month from October 1937 to May 1938 and will last one week. Members of the staff will be selected from the faculty of the University of Minnesota Medical School, the Mayo Foundation and the extension division of the state medical association. The theme of the first course, October 4-9, will be disease of the heart. The didactic lectures and demonstrations will be given in the classrooms of the center and the bedside teaching at the University of Minnesota Hospitals Minneapolis General Hospital, Lymanhurst School for Rheumatic Children and Ancker Hospital, St Paul. Future subjects will be announced one month in advance of each institute. Any physician who is a member of his local medical society may attend. Erected late in 1936 at a cost of \$300,000, the Center for Continuation Study is used jointly by the professional schools of the University of Minnesota for intensive resident graduate instruction and contains living rooms for seventy-eight graduate students, dining hall, lounge, library, chapel, classrooms, administrative offices and parking garage. Julius M Nolte is director, and Dr William A O'Brien, associate professor of pathology and preventive medicine and public health, is a representative of the medical faculty.

MISSOURI

Society News—The Jackson County Medical Society has organized a medical business bureau with W H Bartleson as manager, according to its bulletin August 21. A change in the policy of the bulletin is announced in this issue, including a new cover and expansion of news and editorial features and a return to the use of a former name, the *Weekly Bulletin*. It has recently been known as the *Medical Journal*.

Personal—Dr William E Taylor has been appointed full time health director and instructor in bacteriology and physiology at Teachers College Springfield. According to the report, Dr Taylor who will give up his private practice, is the son of J A Taylor, founder of the Springfield Normal School, which preceded the state teachers' college.—Dr Raymond H Runde, Mount Vernon, has been appointed superintendent of the Missouri State Sanatorium at Mount Vernon, succeeding Dr William J Bryan, who resigned to become superintendent and medical director of the Municipal Tuberculosis Sanatorium at Rockford, Ill.

NEBRASKA

Annual Registration Now Due—Physicians licensed to practice medicine in Nebraska are required by law to register with the Department of Public Welfare annually, on or before October 1 and to pay a fee of \$1. A license expires if the licensee fails to register, but within the thirty days next following its expiration it may be revived by the payment of the registration fee and a penalty of \$1. If that is not done an order of revocation is issued and thereafter the revoked license can be reinstated only on the recommendation of the board of examiners in medicine and on the payment of the renewal fees and penalty then due.

NEVADA

Venereal Disease Program—Dr Byron H Caples Reno has been appointed supervisor of the program for control of venereal disease recently initiated by the state board of health.

State Medical Meeting at Ely September 24-25—The thirty-fourth annual meeting of the Nevada State Medical Association will be held in Ely, September 24-25 at the Nevada Hotel under the presidency of Dr Charles E Secor, Elko. The speakers will be:

- Dr Louis E Viko Salt Lake City Utah Present Day Methods of Treatment of Heart Disease
- Dr Donald C Collins Los Angeles The Value of Papaverine Hydrochloride in the Treatment of Postoperative Pulmonary Embolism
- Dr Joseph E Tyree Salt Lake City Lesions of the Epiphysis in Children
- Dr Howard P Kirtley Salt Lake City Clinical Studies of Sterility in Women
- Dr John M Flude Hollywood Calif Educating the Public About Cancer
- Dr Leland R Cowan Salt Lake City Factors in the Management of Malignancies of the Mouth
- Dr E Eric Larson Los Angeles Major Principles of Intestinal Surgery
- Dr John C Ruddock Los Angeles Peritoneoscopy Technique and Clinical Experiences
- Dr Byron H Caples Reno Venereal Disease Control in Nevada
- Dr Frederick T Foard San Francisco Public Health
- Dr Fred L Adair Chicago Maternal and Neonatal Care

NEW YORK

Society News—Dr Leon E Sutton, Syracuse, addressed the annual joint outing meeting of the Syracuse and Utica academies of medicine at the Yahnundasis Golf Club, September 16, on "Facial Injuries and Their Repair"—Dr Foster Kennedy, New York, addressed the Medical Society of the County of Westchester at Grasslands Hospital, Valhalla, September 21, on "Treatment of Acute Head Injury"

Dr Parsons Resigns as Commissioner of Mental Hygiene—Dr Frederick W Parsons, state commissioner of mental hygiene since 1927, has tendered his resignation to take effect October 1. Dr Parsons, who is 61 years old graduated from the University of Buffalo School of Medicine in 1901 and entered the state hospital service in 1902 as a member of the staff of the Hudson River State Hospital Poughkeepsie. He remained at Poughkeepsie until 1919 when he was appointed superintendent of the Buffalo State Hospital. In 1926 he was made medical commissioner of the New York State Hospital Commission and in 1927 commissioner of mental hygiene.

Personal—Dr Alfred J Roach has been appointed superintendent of the Broome County Tuberculosis Hospital Chenango Bridge, to succeed Dr Charles H Cole, who resigned because of ill health. Dr Roach has been assistant superintendent and medical director since 1932.—Dr John Rosslyn Earp, recently director of public health of New Mexico, Santa Fe, has been provisionally appointed medical editor in the division of public health education of the New York State Department of Health.—Drs Austin J Stillson and William C Armstrong, Windsor, recently were presented with framed scrolls by the citizens of Windsor township for their community services through many years. The presentation was made by Dr Samuel M Allerton, Binghamton, president of the Broome County Medical Society, at a community gathering August 5.

New York City

Personal—Dr Theodore Rosenthal has been appointed director of the bureau of social hygiene of the New York City Department of Health, succeeding Dr Charles Walter Clarke, who returned to his former connection with the American Social Hygiene Association. Dr Clarke was on leave from the association to organize and direct the health department's bureau.

Hospital News—The cornerstone was laid recently for the Frances Schervier Hospital and Home for the Aged at Spuyten Duyvil in the Bronx. The new institution, run by the Sisters of the Poor of St Francis, will accommodate 250 in the main building in semiprivate wards and there will be ninety-six private and semiprivate rooms in a wing. The hospital is named for Mother Frances Schervier, who founded the order in 1845 at Aachen, Germany.

Short Graduate Courses at Columbia—Two series of courses for qualified graduates in medicine are to be offered by Columbia University at Mount Sinai Hospital, November 1 to December 24 and January 17 to March 12, 1938. Subjects to be covered include general medicine, cardiology, endocrinology, gastro-enterology, allergy, pediatrics, neurology and psychiatry, gynecology, ophthalmology, dermatology, proctology, radiography, otology, pathology, physical therapy and laboratory methods. Requests for information should be addressed to the Secretary for Medical Instruction, Mount Sinai Hospital, Fifth Avenue and 100th Street, New York.

NORTH CAROLINA

Division of Neurologic Surgery at Duke—Dr Maurice Barnes Woodhall, instructor in surgery, Johns Hopkins University School of Medicine, and a member of the surgical staff of Johns Hopkins Hospital, Baltimore, has been appointed assistant professor of surgery in charge of a new division of neurologic surgery in the surgical department of Duke University School of Medicine, Durham. Dr Woodhall received his medical degree from Johns Hopkins in 1930.

Society News—Dr John H Dougherty, Asheville, addressed the Buncombe County Medical Society, Asheville, August 16, on "Water Balance" and Dr Dave M Buck Jr reported a case of sulfanilamide poisoning.—At a meeting of the Third District Medical Society, August 6, at Wrightsville Beach, the speakers were Drs Charles L Scudder, Boston, on "Fracture of the Two Weight-Bearing Bones—the Hip and the Os Calcis" Oscar L Miller, Charlotte, "Internal Fixation of Fracture of Hip", James F Robertson, Wilmington, "Review of Fractures Admitted for the Year 1936", and Richard Beverly Ranev, Durham, "Demonstration Fracture Museum".—Drs J Standing Norman, Hickory, and Abner M Cornwell, Lincolnton, among others, addressed the Catawba Valley Medical

Society at Lincolnton, July 13, on "Congenital Atresia of the Nose" and "Treatment of Sciatica by the Injection of Novocain and Normal Sodium Chloride Solution into the Caudal Canal" respectively.

OHIO

Society News—Dr Perrin H Long, Baltimore, addressed the Academy of Medicine of Cleveland, September 17, on "The Therapeutic Use of Sulfanilamide".—Dr Alfred W Adson, Rochester, Minn., will address the Youngstown Otolaryngological Club, September 29, on "Complications of Otitis Media and Frontal Sinusitis from a Neurologic Point of View."

Personal—Dr Warren C Breidenbach, Dayton, has been appointed a member of the Ohio Public Health Council to succeed Dr George D Lummis, Middletown. Dr Lummis has served since the council was created in 1917 to take the place of the state board of health.—Dr Homer H Williams, bacteriologist in the health department of Dayton since 1923, has been appointed health commissioner to succeed the late Dr Arthur O Peters.

Graduate Lectures in Lima—A program of graduate lectures will be presented in Lima, September 20-24, with Dr Carl V Weller, Ann Arbor, Mich., as the speaker. The subjects will include constitutional types in relation to disease, developmental disturbances of the face, mouth and neck, pathology of coronary occlusive disease, the thyroid gland, the gallbladder and the kidneys, parasitic worms of the North Central states, endometriosis, Antony von Leeuwenhoek and his microscopes.

OREGON

Professor of Pharmacology Appointed—Dr Norman A David, associate professor of pharmacology, University of Cincinnati College of Medicine, Cincinnati, has been appointed professor and head of the department of pharmacology at the University of Oregon Medical School, Portland, to succeed the late Dr Harold B Myers. Dr David graduated from the University of California Medical School, San Francisco, in 1931 and was appointed assistant professor and head of the department of pharmacology at the University of West Virginia School of Medicine in 1932. He was appointed at Cincinnati in 1935.

PENNSYLVANIA

Society News—The Lehigh County Medical Society held its annual picnic at the Lehigh Country Club, Allentown, August 10.—Dr David M Davis, Philadelphia, addressed the Harrisburg Academy of Medicine, September 21, on "Urinary Infections".—Dr William L Mullins, Pittsburgh, addressed the Cambria County Medical Society, Johnstown, September 9, on "Coronary Occlusion."

Pittsburgh

A Million for Diabetes Research—A trust fund of a million dollars has been given to the Children's Hospital for 'perpetual research in the causes, treatment and cure of diabetes in the youth of the Pittsburgh area,' the Pittsburgh Press reported August 25. The donor is Miss Emily Renziehausen, who for many years cared for a brother with diabetes, according to the report. The first income of the fund will be used to build an addition to the hospital to be known as the Renziehausen Memorial Ward and Clinic. In addition Miss Renziehausen has given an eleven acre farm as a site for a home for convalescent children. The fund agreement provides that any income not needed for work on diabetes may be devoted to other research work and hospital service. Drs Frederick E Kredel, Richard A Kredel and Thomas T Sheppard were named as a committee to supervise the fund, of which the Union Trust Company is trustee.

TENNESSEE

Society News—Drs Leroy E Coolidge and Robert S Cowles, Greeneville, addressed the Greene County Medical Society, August 3, on differential diagnosis of acute abdominal pain and on treatment of scarlet fever, respectively.—At a meeting of the Hamilton County Medical Society, Chattanooga, August 5, the speakers were Drs Jackson H Barnett and Jonathan J Armstrong, Chattanooga, on 'Surgical Shock' and 'Fluids Postoperatively' respectively.—The Hardin Lawrence Lewis Perry and Wayne Counties Medical Society met in Hohenwald, July 27, with the following speakers: Drs Charles C Stockard, Lawrenceburg, on "Postpartum Hemorrhage", Duncan Eyc Jr, Nashville, 'Fractures', James V Hughes Jr, Savannah, 'Ruptured Graafian Follicle', and William Battle Malone II, Memphis, 'Early Management of Traumatic Injuries, with Special Reference to Highway Accidents'.

University Opens Department of Preventive Medicine—The University of Tennessee School of Medicine has established a department of preventive medicine to open October 1, with Dr. Frank L. Roberts, Trenton, in charge. The department will be jointly supported by the university, the state department of health and the Tennessee Valley Authority. Dr. Roberts will be full time professor of preventive medicine and Dr. Lloyd M. Graves, health officer of Memphis, associate professor. An associate professor of epidemiology will be added January 1, according to a newspaper report, and later an associate professor of sanitary engineering. Dr. Roberts, a graduate of the University of Minnesota Medical School, Minneapolis, in 1922, was health officer of Gibson County from 1924 to 1928, director of local health service in West Tennessee for the state health department from 1928 to 1930 and director of health demonstrations for the Commonwealth Fund in Gibson County since 1930.

TEXAS

Personal—Dr. George T. McMahan, Burnet, has been named superintendent of a new hospital for mental disease to be built in West Texas.—Dr. Thomas J. McCamant, formerly health officer of El Paso and El Paso County, has been appointed health officer of San Antonio schools.—Dr. Thomas B. Wilson, Longview, has resigned as health officer of Gregg County to accept a similar position with the Corpus Christi-Nueces County health unit.—Dr. Gustav Mason Kahn, Galveston, has been named medical director of the American National Insurance Company, it is reported.

WEST VIRGINIA

Society News—Dr. John F. Barker, Huntington, addressed the Cabell County Medical Society, August 12 on "Sulfanilamide Therapy in Urology".—At a meeting of the Central West Virginia Medical Society in Webster Springs, August 7, the speakers included Drs. John O. Rankin, Wheeling, on "Modern Treatment of Fracture of the Neck of the Femur" and William S. Fulton, Wheeling, president of the West Virginia Medical Association, on problems of the medical profession.—The Grant, Hardy, Hampshire, Mineral County Medical Society recently voted to change its name to the Potomac Valley Medical Society, which will also take in physicians of Pendleton County.—Dr. Rexford A. Burdette, Morgantown, addressed the Monongalia County Medical Society, Morgantown, August 3, on "Lower or Basal Lobe Tuberculosis".

GENERAL

Science Exhibit at Indianapolis—The American Association for the Advancement of Science will present its annual science exhibition at the midwinter meeting in Indianapolis, December 27-30 at the Murat Theater. Application for space may be made to F. C. Brown, director of exhibits, American Association for the Advancement of Science, Smithsonian Institution, Washington, D. C.

Society News—The seventh annual convention of the Biological Photographic Association will be held in Rochester, N. Y., at the Hotel Rochester, September 23-25.—The annual meeting of the American Academy of Orthopaedic Surgeons will be held in Los Angeles at the Hotel Biltmore, Jan. 16-20, 1938. For information write Robert Lewin, Hotel Biltmore, Los Angeles.—Dr. George W. Bowles, York, Pa., was chosen president-elect of the National Medical Association at its annual meeting in St. Louis in August. Dr. Lyndon M. Hill, Atlanta, was installed as president and Dr. William P. Dickerson, Newport News, Va., was elected vice president. Dr. John T. Givens, Norfolk, Va., was reelected general secretary. The 1938 meeting will be held at Hampton Institute, Hampton, Va.

Meeting of Railway Surgeons—The forty-eighth annual Congress of Railway Surgeons will be held at the Palmer House, Chicago, September 20-22 under the presidency of Dr. William A. McMillan, Charleston, W. Va. Among the speakers will be

- Dr. Willis C. Campbell, Memphis, Tenn., Ununited Fractures of the Long Bones.
- Dr. George W. Hall, Chicago, Treatment of Syphilis of the Nervous System.
- Dr. William C. Stewart, Charleston, W. Va., Heart Disease as a Factor in Disability and Retirement.
- Dr. William Walters, Rochester, Minn., Treatment of Lesions of the Gallbladder and Bile Ducts.
- Dr. Albert H. Montgomery, Chicago, Treatment of Burns.
- Dr. Royd R. Sayers, U. S. Public Health Service, Syphilis as an Industrial Hazard.
- Dr. Casper F. Hegner, Denver, The Advantage of Surgery in Pulmonary Tuberculosis.
- Dr. Fred H. Albee, New York, The Importance of the Restoration of Blood Supply in Fracture of the Neck of the Femur.
- Dr. William H. Stokes, Omaha, A Clinical Study of Retained Intraocular Foreign Bodies: A Review of 300 Cases.

Sickness Increased in Industrial Employees in 1936—The U. S. Public Health Service in a recent study of the incidence of illness in employees of twenty-nine industrial concerns found that in 1936 there were 95.1 cases of illness lasting eight days or more per thousand men, as compared with 85.7 in 1935. Most of the increase occurred in the fourth quarter of the year and was caused by diseases of the respiratory tract, especially bronchitis and pneumonia. The 1936 rate for this group of diseases exceeded that for 1935 by 17 per cent and the average for the preceding five years by 10 per cent. The incidence of pneumonia was a third higher in 1936 than the five year average, influenza in 1936 was 22 per cent higher than in 1935, but about the same as the five year average. In the final quarter of 1936 influenza was 80 per cent higher than for the last quarter of 1935, pneumonia 20 per cent. The nonrespiratory diseases showed less variation than the respiratory group, but appendicitis showed a notable increase, from 3.8 per thousand in 1935 to 4.4 in 1936. For nonindustrial injuries the 1936 rate was 9 per cent above the frequency for 1935 but identical with the five year average. An exception to the general trend of increased illness was the tuberculosis rate, which declined from the 1935 incidence and from the average for the years 1931-1935. Other diseases that decreased in incidence were diseases of the nervous system, diseases of the heart and arteries and nephritis and all epidemic and endemic diseases except influenza.

Mississippi Valley Tuberculosis Meeting—The twenty-second annual meeting of the Mississippi Valley Conference on Tuberculosis and the Mississippi Valley Sanatorium Association will be held in Dayton, Ohio, September 22-25. The first day of the tuberculosis conference will be devoted to a "health education institute," with emphasis on school health programs. Thursday morning there will be discussions of seal sales and in the afternoon an administrative session. Friday the conference will meet with the sanatorium association and Saturday morning a meeting will be addressed by Dr. Jay Arthur Myers, Minneapolis, president of the National Tuberculosis Association, and Miss Fannie B. Shaw, New York, associate director of child health education of the national association. Speakers at the meeting of the sanatorium association include

- Drs. Charles K. Petter, Oak Terrace, Minn., and Gilbert J. Thomas, Minneapolis, Recent Advances in Our Conception of Renal Tuberculosis.
- Dr. Ralph C. Matson, Portland, Ore., Closed Method of Intrapleural Pneumolysis.
- Dr. Horton R. Casparis, Nashville, Tenn., The Part Children Play in the Tuberculosis Problem.
- Dr. George C. Turner and Loren L. Collins, Chicago, Pneumothorax in Minimal Tuberculosis.

Friday morning there will be a symposium on sanatorium administration, in which the participants will be Drs. Ernest S. Mariette, Oak Terrace, Minn., Alexius M. Forster, Colorado Springs, David O. N. Lindberg, Decatur, Ill., Harold M. Coon, Statesman, Wis., James Burns Amberson Jr., New York, and Paul P. McCam, Sanatorium, N. C.

Committee Urges Instruction in Allergy—The committee on instruction of the Association for the Study of Allergy recently made a survey of the instruction in allergic diseases in medical schools. Fifty-seven schools answered a question as to whether they had allergy clinics and, if so, how much they were used in teaching. Fourteen stated that they had none, seven of those that had clinics did not use them in teaching and four are used only for elective courses. Only about one fifth of the schools teach students how to make pollen or dust extracts, and in more than one third students are not taught how to administer extracts. In sixteen schools they are not taught how to make routine tests, and in seventeen they are not taught how to take allergic histories. Only seventeen offer elective courses to those who wish to learn more about the subject. Twenty-eight of fifty-two replies indicated that those schools had increased their instruction in allergy in the last five years. A study of the number of cases studied indicated that allergy cases represented 2.2 per cent of the total number of new cases and more than 5 per cent of the new medical, pediatric and dermatologic cases. Visits to clinics because of allergy amounted to 4 per cent of all visits and 9 per cent of all medical, pediatric and dermatologic cases. In a discussion of the information obtained in the study the committee emphasized its belief that most physicians lack knowledge of allergic diseases, that too many physicians do not recognize allergic manifestations unless they are typical, that most of the information many physicians have is obtained from literature issued by commercial firms, and that the assignment of the teaching of allergic diseases to members of the faculty who do not have a deep interest in these diseases is undesirable. Four recommendations concluded the report that the committee on curricula of the Association of American Medical Colleges be

urged to require (a) that planned instruction be included in the curriculums of all medical schools, (b) that the minimum acceptable instruction include discussions of pathology, pathologic physiology, clinical manifestations, diagnostic methods, preparation of diagnostic and therapeutic extracts, history taking, principles of specific, symptomatic and nonspecific therapy, (c) that instruction be assigned to interested teachers and (d) that such instruction be accorded the place in the curriculum that the incidence and severity of the diseases seem to justify

FOREIGN

Prize for Work in Dermatology—The French Society of Dermatology and Syphilology announces that an anonymous donor has made available a prize of 5,000 francs to be awarded every two years to the author of the best work, either printed or in manuscript form, on a subject in dermatology or syphilology representing a real advance in science. Every other time the prize will be awarded at a meeting of the society and the committee in charge will set the subject. The prize will be awarded for the first time at the general assembly of the society in May 1939 and the subject chosen is "The Processes of Sensitization and Immunization in the Epidermomycoses." Both French and foreign authors whose work has been written or translated into French are eligible to compete for the prize. Articles must be submitted to the secretary general, Dr. Pierre Fernet, 11 rue de Sontay, Paris (16), before Nov. 30, 1938.

Report of Nutrition Committee—The League of Nations Mixed Committee on the Problem of Nutrition appointed in September 1935 now has issued a detailed report. The report urges governments to adopt a conscious nutrition policy by establishing national committees to ascertain food consumption habits and nutritional status in all sections of the population. Detailed evidence of malnutrition even in the most advanced countries is given in the report, which is intended to be used as a basis for a world nutrition policy during the next few years. The committee is made up of representatives of the Technical Commission of the Health Committee of the League, the International Labor Office and the International Institute of Agriculture. The United States was represented by Elmer V. McCollum, Ph.D., Baltimore, Edwin G. Nourse, Ph.D., of the Brookings Institution, Washington, Faith M. Williams, Ph.D., of the staff of the Department of Labor, Washington, Prof. Warren C. Waite, Minneapolis, and Harold B. Rowe, of the staff of the Brookings Institution, Washington.

Government Services

Examinations for Government Positions

The U. S. Civil Service Commission announces examinations for positions in the U. S. Public Health Service (venereal disease control and industrial hygiene), in the Indian Medical Service in the United States and in Alaska, and in the Veterans' Administration. To become eligible, applicants must qualify in one of the following branches and must state in their applications the branch or branches desired: cardiology, cancer diagnosis and treatment, eye, ear, nose and throat (single or combined), urology, internal medicine and diagnosis, neuropsychiatry, pathology and bacteriology, roentgenology, surgery (general, chest and orthopedic), tuberculosis, venereal disease, industrial medicine and general practice. Applicants must not have reached their thirty-fifth birthday on the date of the close of the receipt of applications and must be in sound physical health. Applications must be received by the commission at Washington not later than October 18 or, if from Arizona, California, Colorado, Idaho, Montana, Nevada, New Mexico, Oregon, Utah, Washington or Wyoming, not later than October 21. Application forms may be obtained from the secretary, board of civil service examiners, at any first class post office from the commission at Washington or from the district office in any of the following cities: Atlanta, Boston, Chicago, Cincinnati, Denver, New Orleans, New York, Philadelphia, Seattle, St. Louis, St. Paul, San Francisco, Honolulu, T. H. Balboa Heights, C. Z., and San Juan, P. R.

CORRECTION

The Degree and Prevalence of Vitamin A Deficiency—Dr. Harold Jeghers in his paper entitled "The Degree and Prevalence of Vitamin A Deficiency in Adults with a Note on Its Experimental Production in Human Beings" in *THE JOURNAL*, September 4, page 760, erroneously included reference 18a. The paper to which this reference refers will not, Dr. Jeghers says, be published in the *New England Journal of Medicine*.

The Danger of the Domestic Use of Gasoline

Cases are recorded from time to time of the burning to death of persons using gasoline for cleaning garments. The victims are quite unaware of any danger and may be at a distance from any fire or flame. The accident occurs in this way: Gasoline vapor, being much heavier than air, falls in a still atmosphere and will be drawn by a draft toward a fire. A flash back to the cleaning receptacle then occurs, with the inevitable fire and upsetting of the burning liquid over the clothes of the operator. Fire also may be started by static electricity caused by rubbing garments, especially silks, in the cleaning process. In one case a woman was burned to death while cleaning a garment in a garden and the fire could not be traced to any source. According to the annual report of the inspectors of explosives, thirteen accidents, causing three deaths, have occurred during the year. The comment is made that this is a very high proportion, as in the landing, storing, conveying and use in automobiles of 1,400 million gallons of gasoline in the year only twenty-five accidents, involving nine deaths, have been reported.

DANGEROUS AMATEUR FIREWORKS

The inspectors of explosives also point out the danger of amateur firework mixtures, which is due not only to their sensitiveness to friction but to the quickness and force of the explosion. A chlorate and phosphorus or sulfur mixture will explode with detonative violence, smashing up the mortar and blowing fingers off the hand of the operator. The inspectors found it necessary to send out a circular to manufacturers of chemical sets, warning them not to include these dangerous substances. In one case a schoolmaster mixed potassium chlorate and antimony sulfide in an envelop. He then added phosphorus, and while he was smoothing it over with a stick of chalk an explosion occurred which injured him so severely that three of his fingers had to be amputated. The science textbooks in use at the school were obtained and it was found that they gave details about these mixtures and also suggested other experiments with explosives. The matter was taken up with the publishers and also with the board of education. In 1936 three deaths and injuries to twenty-one persons occurred in the manufacture of explosives. The total accidents due to explosives in the year was 273. Several cases of illegal manufacture of explosives were brought to light by the occurrence of explosions.

The Surgical Treatment of Angina Pectoris

In his Carey Coombs memorial lecture, delivered at Bristol, Mr. Laurence F. O'Shaughnessy discussed the pathology and treatment of angina pectoris. He said that natural compensation for occlusion of the coronary tree may be effected in several ways: 1. Anastomoses between the right and left coronary arteries may come into action when one or the other main trunk is occluded. 2. The thebesian vessels (small channels which connect all four chambers of the heart with the venous and capillary bed of the coronary tree) may act as an additional source of cardiac nutrition. 3. The natural collateral channels which connect the coronary tree with the vast vasorum of the great vessels may become more pronounced. 4. The heart may acquire a new and additional blood supply if it adheres to the parietal pericardium. The last important mechanism is available only in those rare cases in which the subject of coronary occlusion has previously suffered obliteration of his pericardial space as a result of old pericarditis, or when, following a coronary occlusion, an infarct is produced with its base on the

epicardial surface of the heart. In a special lecture delivered at the Royal College of Surgeons in January (*THE JOURNAL*, February 27, p. 738) Mr. O'Shaughnessy described the technique of his operation of cardio-omentopexy for the establishment of a collateral cardiac circulation and referred to three cases of angina pectoris or coronary thrombosis in which he had performed it. He now reported the following case.

A woman, aged 65, had suffered from angina pectoris for twelve years. The attacks became more frequent and more severe and she had been confined to bed for almost eighteen months. She was referred to the Lambeth Cardiovascular Clinic of the London County Council, of which Mr. O'Shaughnessy is consultant surgeon. On admission Oct. 1, 1936, she was obese. The heart was enlarged to the anterior axillary line. There were a soft aortic systolic murmur and a very short diastolic whiff. The blood pressure was 247 systolic, 117 diastolic. An electrocardiogram revealed complete bundle-branch block with large amplitude of QRS in leads 1 and 3. October 16, cardio-omentopexy was performed. At the end of the operation the pulse was 69 and the blood pressure 170/90. Recovery was interrupted by a paroxysm of auricular fibrillation, which began thirty hours after operation and ceased spontaneously nine and one-half hours later. Two anginal attacks occurred during the first fortnight but none subsequently. In six weeks the blood pressure returned to 240/112 and was causing symptoms. On a balanced diet it fell to 210/120. Physical signs of pulmonary collapse were present at the left base after the operation. The patient was able to get up and gradually increased her activities until she was able to climb stairs and go shopping. She had remained free from angina.

In his operations, Mr. O'Shaughnessy has found that the pericardium of man is often highly vascular compared with that of animals, perhaps because he has to develop his defenses against cardiac ischemia. Cardio-omentopexy not only brings a new blood supply into direct relation with the ischemic area and the coronary tree but also reinforces normal collaterals in the mediastinum. In the present state of our knowledge it is impossible to lay down any rigid indications for operation in cardiac ischemia. Experience at the Lambeth clinic has shown that it is practicable and comparatively safe, even under relatively unfavorable circumstances. Mr. O'Shaughnessy's patients have included a man of 72 as well as this bedridden woman of 65. He is not neglecting the obvious factor of arterial spasm in angina pectoris but maintains that spasm is significant only when coronary disease is already present. The medical staff of the clinic who select cases for operation includes Lord Dawson, president of the Royal College of Physicians, and only a small proportion of the patients sent to it are operated on. In the present stage of the work it is felt advisable to restrict intervention to the severe cases.

Epidemic of Poliomyelitis in Australia

Melbourne is suffering from a serious outbreak of acute poliomyelitis. Since the first cases were reported at the end of June, ninety-one children have been attacked and two adults, both of whom died. More than a hundred schools have been closed and special broadcasts are being given to mitigate the tedium for children, who are being kept at home for fear of infection. Country areas are demanding that children arriving from Melbourne be isolated, and Tasmania is making a similar stipulation.

Graduate Courses for Panel Physicians

The Ministry of Health is to make grants on a more extensive scale than heretofore to enable panel physicians to attend short courses of graduate study. The conditions under which a physician will be eligible for a grant are as follows: 1. Five years must have elapsed since the date of his first registrable qualification. 2. He must have not less than 300 (or in the

case of a rural practitioner 150) insured persons on his list. 3. No grant will be payable to a practitioner more than once in five years. The grant will include a fee for the course, traveling and subsistence expenses, and the payment of a whole time locum tenens when necessary.

Professor J. G. Thomson

J. G. Thomson, professor of medical protozoology, London School of Hygiene and Tropical Medicine, has died. Educated at Edinburgh University, he gained the medals in botany and physiology and was professor to the late Prof. D. J. Cunningham. He spent the first six years of his scientific career at Liverpool, where he held successive research scholarships. In 1914 he was appointed lecturer at the London School of Tropical Medicine, but during the war he was stationed in Egypt, where he specialized in pathology and protozoology at the Military Hospitals at Alexandria. On returning to England he was put in charge of the Malaria Research Laboratory at the War Office and in 1918 was appointed professor of medical protozoology at the newly opened School of Hygiene and Tropical Medicine. In 1926 he was exchange lecturer in protozoology at the School of Hygiene at Johns Hopkins University, Baltimore. In 1930 he was representative at the third International Congress on Malaria at Algiers, and in 1936 he gave at the request of the League of Nations Health Organization a series of lectures in the special course on malaria held at Singapore.

His work on the methods of enumerating malaria parasites in the blood and the study of cultural forms of the parasite are classic. His researches on blackwater fever in Rhodesia are most important, and his monograph on this disease is a standard work. He also did work on bilharziasis and other disease, when stationed in Egypt, which has advanced our knowledge. In his early days he traveled much in South America and in tropical countries, and this experience has given his work a special value. His direct approach to a subject and grasp of essential points with his common sense have contributed to the success of his writings.

Fellows of Royal College Guests of Paris Academy

In accordance with an arrangement made in 1935 between the Royal College of Surgeons and the Académie de chirurgie to visit each other every year, the fellows of the former were received as guests here July 5 and 6. The French Académie de chirurgie visited England in 1936 as guests of the Royal College of Surgeons. About forty fellows of the latter, including Sir Cuthbert Wallace, the president, attended the Paris meeting. The program for the two day stay here included a visit to the Cancer Institute in one of the Parisian suburbs, operations and demonstrations at various hospitals, a dinner at the Hotel Ritz and a visit to the chateau of Chantilly. At a meeting held on the afternoon of the first day, an address of welcome was delivered by Dr. Baumgartner, president of the Académie de chirurgie, and papers were read by Professor Gregoire on intestinal infarct, by Professor Duval on post-operative pulmonary infarct, by Professor Mondor on uterine infarct, by Drs. Brocq and Warangot on hemorrhagic pancreatic infarcts and acute pancreatic necrosis, and by Professor Binet on surgical physiology. The afternoon of the second day was devoted to the celebration of the one hundredth anniversary of the birth of Prof. Felix Terrier. Following his address of welcome, the president of the Académie de chirurgie, Dr. Baumgartner, announced that the French government had authorized him to bestow the cross of Officer of the Legion of Honor on Sir Cuthbert Wallace, president of the Royal College of Surgeons, Mr. George E. Gask and Mr. Henry S. Souttar, presi-

dent and vice president respectively of the committee that has organized these annual meetings of the Royal College of Surgeons and the Academie de chirurgie

Use of Toxoid in Staphylococcal Infections

Following the report at the June 9 meeting of the Academie de chirurgie of a case of staphylococcal infection with multiple localizations, including one in the epididymis, an active discussion took place as to the value of the toxoid in surgical cases. Dr. Rousset of Ploermel reported a case in which a man, aged 47, had a carbuncle of the neck, a perinephric abscess, a pulmonary focus and an epididymitis. No hemoculture had been made. All the various localizations, except the epididymal, were drained but the neck lesion presented such an atonic appearance that a series of injections of the staphylococcal toxoid was given every four days. After the first injection, the epididymal focus evacuated spontaneously. After a second injection, healthy looking granulation tissue appeared on the neck lesion. Complete recovery was rapid.

In the discussion, Dr. Moulouquet stated that Dr. Rousset had simply termed the case one of prolonged subacute staphylococcal infection instead of septicemia, because, although it had been impossible to have a blood culture made, staphylococci were found on several occasions in the urine. The atrium of infection had undoubtedly been the carbuncle on the back of the neck, which persisted in an indolent form for more than six months. Moulouquet agreed with Rousset that the staphylococcal toxoid was responsible for the healing of the carbuncle which had continued as a primary focus. In looking over the reports by French surgeons as to the value of the toxoid, five cases of severe septicemia (staphylococcus) confirmed by blood cultures, were found. As to the mode of administration, a minute initial dose, 0.1 cc, should be given to test the sensibility of the patient. If no reaction occurs, the dose can be gradually increased from 0.25 cc to 2 cc. Not more than five injections should ever be given. Pagniez had observed a severe shock with pallor, epileptiform movements and loss of consciousness after the eleventh injection. In spite of an absence of any toxic action in animals, the toxoid can give rise to serious reactions clinically. Although our knowledge as to how the toxoid cures certain cases of staphylococcal septicemia is still imperfect, we do know that the Ramon toxoid is a valuable agent in certain apparently hopeless cases.

Dr. Sauve believed that the variation in the results following the use of the toxoid were due to the existence of many different strains of staphylococci. He also questioned the permanence of the recovery in the case reported by Dr. Rousset. In three of his own cases, recurrence in one had been observed after apparent recovery, two years later. A third consideration is that in the cases reported by Gastinel and Reilly the first hemoculture was positive but later ones were not. He considered Dr. Rousset's case one of true staphylococcal septicemia in spite of the absence of a blood culture. Dr. Leveuf said that he was skeptical regarding the efficacy of the toxoid in staphylococcal infections. He did not agree with Dr. Moulouquet as to the benefit of giving the toxoid in the case under discussion. Dr. Monod recalled Nicolle's definition of a septicemia as including not only the presence of bacteria in the blood stream but also their constant multiplication there. Dr. Bazy believed that the staphylococcal antitoxin content of the blood ought to be estimated in every case in which the toxoid is used. Dr. Sauve, in reply to Dr. Monod, said that he agreed with him as to the interpretation of negative cultures. The discharge of bacteria into the blood stream is intermittent in cases of septicemia, hence a blood culture may be negative at one examination and positive at another. In closing the discussion, Dr. Moulouquet, who had presented the case for Dr. Rousset, maintained that the toxoid was clearly responsible for the recovery in this severe staphylococcal infection.

Report on Magnesium Alloy Bone Splints

At the June 16 meeting of the Academie de chirurgie, a critical analysis of a monograph on magnesium splints in fractures, by Dr. Verbrugge of Antwerp, Belgium, was read by Dr. Menegaux of Paris, to whom the monograph had been assigned for review. As justification for the use of absorbable bone splints, Dr. Verbrugge cited the fact that not only was it necessary to remove steel-vanadium splints in 6 per cent of the cases in Lambotte's service but such an operation is very difficult and at times impossible to carry out. In addition, in children, such splints when placed near the epiphysis interfere with bone growth. Splints of magnesium alone were not found sufficiently resistant, so a splint composed of 92 per cent magnesium, 8 per cent aluminum and a small amount of manganese was employed. In five rabbits and one dog, the upper end of the tibia was splinted. Gross examination at variable periods revealed only a moderate periosteal and cortical thickening, and medullary condensation. The splint was then used in thirty-five clinical cases, in thirty-one of which healing occurred by primary union and in four following fistula formation of short duration. There is a local elevation of temperature and a zone of hydrogen gas formation (as seen radiographically), at first subperiosteal and later intraosseous. In twenty-five cases there was no abnormal degree of osteoperiosteal reaction and consolidation was present at the end of four weeks. In seven cases, nearly all fractures of the tibia, the results were unsatisfactory because of inadequate fixation of the splint and consequent imperfect immobilization and excessive callus formation. In six fractures near joints the splint did not interfere with movement. In fifteen epiphyseal or juxta-epiphyseal fractures the metal was rapidly absorbed and did not retard bone growth.

In a second series of animal experiments, the tibia of ten rabbits was splinted with the Dow metal (magnesium-aluminum) and ten other control rabbits with a thin steel splint. The latter did not give rise to any reaction, whereas the Dow metal splint caused important reactions strictly localized around the splint in the form of bone resorption and periosteal thickening. In commenting on the results of Verbrugge's experimental work, the reviewer, Menegaux, criticized the lack of microscopic examination of the first rabbit series and that, in the clinical cases, the majority were of the epiphyseal variety with but little displacement. The local reactions, such as gas and fistula formation, were also objectionable from the surgical standpoint.

Unfavorable results, such as sequestration of a large area of the cortical portion of the tibia, were reported by Berard and Creyssel in 1935, following the use of a resorbable magnesium alloy splint. Other reports were cited by Menegaux, showing that magnesium is more toxic than gold, iron, nickel and silver and less so than copper and aluminum. Menegaux believed that it was inadvisable to employ splints of magnesium and its alloys. The use of nonabsorbable steel bone splints is being generally adopted, according to various recent reports.

Acute Pulmonary Tuberculosis in Adolescents

At the June 11 meeting of the Societe medicale des hopitaux, two cases were reported by Troisier, Bariety and Nico, which show that even after candidates for admission to universities or nursing schools have passed a thorough physical examination, including an epidermal tuberculin test, they can develop an acute adult form of tuberculosis when their environment changes from that of rural districts to that of a large city. Both patients were young women in whom the roentgenographic examination of the lungs and the epidermal tuberculin test had been negative when they were admitted respectively to the University of Paris and to the school for nurses of a large Paris hospital. One died of a tuberculous meningitis following an acute ulcerocaseous type of pulmonary tuberculosis without preceding mediastinal adenopathy. The other died as the direct

result of the pulmonary infection. In both, the epidermal tuberculin test, previously negative, became positive. In the discussion, Rist said that such cases would be seen more often in the future in proportion to the increased use of the tuberculin reaction in adults. There would also be less difference between the roentgenographic appearance of lesions due to primary infection and that due to reinfection. He reported the case of a young woman with a negative epidermal reaction who had come from the country districts to enter the school of nursing in one of the Paris children's hospitals. A month after she began ward service, evidences of pulmonary tuberculosis appeared. The epidermal tuberculin reaction, previously negative, suddenly became positive, ten weeks after she began her nursing work. Not infrequently the clinical picture was similar to that of an attack of influenza at the onset, as in the cases reported by Troisier. Etienne Bernard said that he had seen acute pulmonary tuberculous lesions in young adults, which appeared to be primary infections. At the present time, based on the roentgenographic appearances, one cannot distinguish between such primary infections and reinfections.

Influence of Milk on Growth and Metabolism

The question of what influence the heating process exerts on homologous and on heterologous milk has been repeatedly studied but there has been no unanimity of opinion on the subject. Catel, professor of pediatrics at Leipzig, recently undertook a clinical and experimental investigation of this problem. From feeding experiments of short and long duration with homologous milk two principal observations were elicited. 1. By sterilization of homologous milk the natural immunity of human and animal nurslings is reduced, a circumstance made manifest by increased morbidity and mortality. 2. A diet of sterilized homologous milk leads to obvious impairment of growth, under certain conditions to complete arrest of growth. For example following the feeding of premature infants with raw mother's milk sterilized at the nursery, a decline in the rate of growth ranging from 14 to 77 per cent with a mean of 44 per cent was observed. Accordingly, raw homologous milk attains a higher nutritive value than heated milk. (By nutritive value is meant, according to Friedberger, simply the utilization of the nutriment in relation to the preparatory, that is to say, the warming, process. This utilization finds expression in the curves of weight and growth.) Further experiments and calculations (which concerned the use of raw and of autoclaved goat's milk in the rearing of young goats) showed that the utilization value of raw milk is from three to ten times greater than that of autoclaved milk. Since it seemed logical to seek the cause of this impairment of growth following heated milk diet in a disturbed metabolism, metabolic experiments were performed with goats. It was observed that (1) the nitrogen balance remains positive but the absorption of nitrogen is plainly reduced, (2) radical changes take place in the mineral metabolism (marked storage of chlorine, negative calcium balance, manifest diminution of the phosphorus balance) and also in the blood serum and in the bony tissues the calcium and phosphorus values were reduced. It is possible by the addition of substances containing vitamins to effect a resumption of growth and completely to normalize the metabolism. The briefer feeding experiments with heterologous milk in both the raw and the heated states disclosed that after placing goats on a diet of sterilized cow's milk the increases in weight were greater than after feeding with raw milk. On the other hand the injurious effects of the sterilized milk were plainly perceptible in an increased susceptibility to illness, notably diarrhea and in several instances a fatal tetany. Feedings of autoclaved cow's milk generally resulted in complete

arrest of growth and death from cachexia within a matter of days, weeks or months. By proper addition of even the most minute quantities of vitamin-containing substances it was in most instances possible to compensate for the disturbances of growth.

The general implication of the foregoing experimentation for human physiology is that human milk in particular ought to be fed the nursing only in the raw state. If human milk is preserved for storage in depots, it should be submitted to only such a process as will in no way impair its natural character. A method of brief heating appears to offer the most plausible solution of a problem that is of major importance from both a clinical and a social point of view.

Contagious Diseases and Aviation

Recently for the first time the minister of the interior and of aviation has issued regulations designed to combat the spread of contagious disease by aerial navigation. The airport medical officer is authorized, if circumstances so warrant, to conduct a medical inspection of the passengers and crew of an aircraft both before the takeoff and after the landing. To avoid needless delays, these medical inspections are to be carried on in conjunction with the usual administrative formalities (customs inspection and so on). Excluded from ordinary air travel are all persons affected with cholera, typhus, plague or smallpox, as well as all persons suspected of harboring any of these diseases. Travelers who come under this ban may be permitted by the medical officer to continue on in a special plane. Persons suspected of transporting infections as well as bacillus carriers and continuous disseminators of bacteria also can be excluded from flight. Quarantine measures also have been made more strict. Letters and other paper matter are not subjected to any sanitary inspection, and parcel post and other mailed packages are inspected by the medical officers only if such material has been shipped from a region of endemic cholera and if it consists of fresh foodstuffs. If special epidemiologic conditions exist, aircraft may be assigned to special landing fields. The pilot of the plane should furnish any information on the hygienic conditions that may be requested of him. In order to prevent the spread of other communicable diseases the authorities of each airport have the right, on the basis of the professional opinion of the medical officer, to forbid the takeoff of any persons who present symptoms of the mentioned diseases. If no physician is present, the airport official can postpone the departure of a suspected person till such time as a medical opinion on his condition can be formulated.

VIENNA

July 31, 1937

Congress of Roentgenologists

During the second week of July the second congress of the Austrian Society of Roentgenology met in Vienna with Professor Dr. Kienbock the presiding officer. There were 720 Austrian specialists as well as some 300 foreign colleagues who were attracted to Vienna by the first Short Wave Congress, which was to follow the meeting of the Austrian society. The congress began with the usual formalities. Minister Resch of the national bureau of health acted as official governmental representative, and the government made a further contribution to the congress by honoring the founder of roentgen therapy, Prof. Dr. Leopold Freund, with the high title of "Hofrat" for his many services.

The more important themes were (1) early diagnosis by means of roentgen and infra-roentgen rays and (2) roentgen therapy of inflammation. A summary of the principal speakers and their topics follows. Dr. Lenk discussed "tomography," a new diagnostic technique based on cross sectional representation of the body in layers. Dr. Blühbaum of Cracow described inflammations of the cervical portion of the vertebral column, which often

give rise to severe neuralgias in the region of the brachial plexus. These conditions are first diagnosed by means of x-ray visualization, sciatica is prominent among them. Professor Sgalitzer stressed the great difficulty encountered by the roentgenologist in differential diagnosis of inflammatory and tumorous processes of the internal organs. Only after observations and comparisons with the clinical data have been repeated over a considerable period can a correct diagnosis be established. This is especially true of disease processes in the intestine, lungs and brain. In many instances the inflammation can be obliterated by simple roentgen irradiation and a previously undetected coexistent neoplasm becomes plainly discernible.

Dr Fleischer, docent, discussed the x-ray visualization of pulmonary alterations which may appear in the vicinity of tuberculous foci. It is known that these processes are not necessarily tuberculous but may be only secondary sequels of the primary manifestations. Dr Herrnhiser of Prague discussed the same theme. In recent years, he said, it has been established that in the study of shadows in the hilus pulmonis more diagnostic significance attaches to the structure than to the size and shape. The foregoing factors are most important in the diagnosis of childhood tuberculosis, which is frequently localized in the hilus. Dr Kautsky spoke on bronchography, a technic which he finds especially valuable for the diagnosis and therapy of bronchiectasis. Of interest was the report of Ruckenstein of Innsbruck on the x-ray visualization of dilatation and diverticulum in the region of the esophagus.

L. Strauss, engineer, demonstrated a new apparatus which he calls the "telecord," by means of which each cardiac phase can be photographed in sequence. The device can be attached to any x-ray apparatus.

Dr Zdansky spoke on the differential diagnosis of gastric carcinoma as opposed to catarrhal or ulcerous gastritis. Observations over a period of years of cancer in which cure has been effected attest the importance of diagnosis in the early or precancerous state. Drs Presser and Pape emphasized that not infrequently the discrepancy between the clinical observations and the x-ray observations is decided in favor of the roentgenologist only by surgical operation. Dr Altschul of Prague discussed the limits of x-ray diagnosis of bone disease. The time at which examination takes place is important, as in the initial stages bone disease is but rarely demonstrable by x-rays. The early diagnosis of head injuries was discussed by Professor Schüller. Despite positive determinations (foreign bodies within the cranium, bone fractures and so on) the initial subjective symptoms are as often as not quite slight and therefore misleading. Such patients stand in grave danger unless submitted to x-ray examination. In severe traumas of the head the portable apparatus is most serviceable. Dr E. G. Mayer stressed the importance of roentgenography in disorders of the mastoid and pyramidal processes.

Dr Leb of Graz discussed the early diagnosis of gallbladder disease. Formerly a cholecystitis was assumed if the gallbladder was not filled by the contrast medium. The author has, however, in more than 200 cases introduced the contrast fluid by intravenous injection (not orally, as is customary). He was able, by means of this more exact technic, to detect inflammatory lesions in the gallbladder when the shadows of the organ appeared normal in other types of visualization.

The second principal theme was roentgen therapy of inflammations. The leading paper was read by Dr Wieser. Professor Freund stressed the marvelous prophylactic influence of roentgen irradiation on recurrent inflammations. Professor Dr Wintz discussed the roentgen therapy of inflammatory disorders of the female genitalia. There are virtually but two types of procedures: irradiation of the foci of inflammation proper with small doses and irradiation of the ovaries with larger doses. The last named procedure induces a dormancy in ovarian function (temporary castration) and secondarily a recession of the inflammatory process. In acute mastitis the

inflammation can be brought to cure through a roentgen-produced dormancy of lactation. The observations of Professor Wintz were verified by those of Dr Gajzago of Budapest, who had achieved similar successes in the treatment of phlebitis.

Dr Palugyay of Vienna has observed favorable results of roentgen irradiation in osteomyelitis. In its early stages the disease can be cut short and quickly eradicated by mild dosage. In the advanced stages mild doses are ineffectual, larger doses however, induce a quicker casting off of sequestrums. In paronychia, too, in the simple as well as in the osseous and articular forms, one can, according to Dr Spitzenberger, attain results by roentgen therapy that compare favorably and may even be superior to those obtained by surgery. The roentgen therapy of disturbances due to spur formation on the soles of the feet was highly recommended. Although irradiation does not cause the spur to disappear, it heals the inflammatory processes for which the spur is responsible.

Windholz advocated roentgen therapy in chronic tonsillitis. Although the rays do not effect a total obliteration of the tonsils as in tonsillectomy, they do lead to satisfactory and seemingly permanent results. This observation was corroborated by Frank, who treats tonsillar abscesses solely with roentgen rays.

Dr Hammer particularly recommends roentgen therapy in neuritis and neuralgia. It is more effective than any other type of treatment for these disorders. The influence on inflamed nervous tissues seems to be specific.

Even this brief enumeration of the most important papers shows how this congress, although planned as a small, local Austrian affair, came to assume an international complexion through the presence of so many prominent roentgenologists from Germany, Italy, Czechoslovakia, Hungary and Poland.

Society Meetings

At a meeting of the Accademia medico fisica of Florence recently Professor Focosi reported four cases of metallic foreign bodies lodged in the posterior segment of the eye. The anterior segment was normal and the refractive media were transparent. The foreign bodies in all cases were removed through the sclera by means of Volkmann's giant electromagnet. The localization of the metallic particles was determined by ophthalmoscopic or x-ray examination of the eye. The scleral incision was proportional to the size of the body, to prevent injuring the choroid. The operation gave satisfactory results in all cases. The speaker concluded that the removal of foreign bodies through the sclera is a procedure which is preferable to that of removing them through the anterior chamber.

Professor Volterra said that the methods actually used for determining the aromatic substances of the blood do not give satisfactory results. The colorimetric reactions, done on the blood deprived of proteins, result in the determination of many aromatic substances of phenolic nucleus aside from that of the phenols in the blood. The reaction is nonspecific, especially because of the presence of amidoles. Distillates, obtained by indirect distillation in a steam current, contain also substances that disturb the reaction. Better results are obtained by resorting to the xanthoproteic reaction of Parenti and Pekelis, with slight modifications. Normal blood contains free and conjugated phenols in a noticeable amount. An exact chemical determination as to the amount of phenols in the blood cannot be made by any method. The method described and used by Volterra, however, gives clinically satisfactory results in studying the metabolism of aromatic substances.

The gruppo cardiologico italiano met recently in the hall of the Clinica medica of the Milan University to discuss chronic myocarditis. Professor Condorelli discussed this subject from

a clinical point of view. He criticized the modern opinions of those who regard chronic myocarditis as a syndrome of circulatory insufficiency or due to extramycocardial heart diseases. There is no doubt that the myocardium may be involved in both pathologic conditions and that the diagnosis of the conditions of the myocardium in circulatory insufficiency or extramycocardial heart diseases is of great importance. Chronic myocarditis, however, is a myocardial disease of chronic evolution independent of circulatory insufficiency. The specific agent of rheumatism frequently involves the cardiac muscle diffusely. Nonspecific myocardial lesions, such as degeneration and myofibrosis, are caused either by coexisting rheumatic coronaritis or by atheroma of the coronary arteries, which may complicate the disease. In the diagnosis of the conditions of the myocardium of patients suffering from hypertension, the presence of hypertrophy is a sign of importance in showing a diminished functional capacity of the heart. Besides the physical symptoms and x-ray signs, the alterations of the electrocardiogram, especially of the S and ST deflections, are of diagnostic value. The disturbances of atrioventricular conduction show ischemic lesions of the bundle of His from coronary sclerosis. The speaker stated that the clinical diagnosis of myocardial sclerosis can be made early in the development of the disease, before establishment of the phenomena of decompensation, and can be followed by an early treatment of the disease.

Dr. Caporali, in a lecture before the Turin Società di Chirurgia, spoke on the surgical treatment of impotence. His operation for impotence is done by the following technic: spinal or sacral anesthesia, incision of the skin at the back of the penis, passage of a nontraumatic needle carrying a thread of catgut from one to the other cavernous body, moderate traction of both ends of the catgut and knotting in order to have the dorsal vein of the penis compressed. The patient is placed in the jackknife position, a urethral sound of Bemique's type is passed into the urethra, the incision starts at a point 10 cm from the anal margin, and after a course of 5 cm it is bifurcated to form an inverted Y. By this incision one approaches the spongy body, which is covered by the bulbocavernosus muscle, at the end of which the ischio-cavernosus muscle is located. With a nontraumatic needle threaded with catgut the ischio-cavernosus muscles of both sides are approximated in front of the bulbocavernosus muscle, to make local compression. The bulbocavernosus muscles are also approximated by the same technic. Because of the fact that the nerve supply of the region is abundant, the operation has to be carefully done to prevent injuring the nerves.

Marriages

DONALD WILLIAM FAWCETT, Starkweather, N. D., to Miss Rosemary Barbara Tallent of Menominee, Mich., June 26.

GEORGE EDWARD HALL, Toronto, Ont., Canada, to Miss Lola Ruth McDonald of Bronxville, N. Y., June 26.

ANDREW MARSHALL JAMISON JR., Spartanburg, S. C., to Miss Amelia Albergotti of Orangeburg, June 5.

WILLIAM LESLIE HEITER, Mobile, Ala., to Miss Elizabeth Agnes Manson of Jacksonville, Fla., June 2.

NICHOLAS LUCIA, Braidwood Ill., to Miss Elizabeth J. Yeats of York, Pa., at Collegeville, Pa., June 6.

ARCHIBALD R. JUDD, Glen Gardner, N. J., to Dr. MARGARET DILL MILLER of Philadelphia, July 16.

JOSEPH L. LILIENTHAL JR., New York, to Miss Katherine Arnstein of San Francisco, June 25.

ALEXANDER O. BIRGERSON, Chicago, to Miss Eleanor B. Mueller of Hinsdale, Ill., July 31.

HARLEY A. HAYES, Ann Arbor, Mich., to Mrs. Grace Lyons at Ionia, July 3.

HENRY N. HARKINS, Chicago, to Miss Jean Trester of Hobart, Ind., June 19.

Deaths

Arthur Walters Rogers, Oconomowoc, Wis., Rush Medical College, Chicago, 1895, past president of the Waukesha County Medical Society and the Milwaukee Academy of Medicine, in 1927 president and for many years chairman of the council of the State Medical Society of Wisconsin, and in 1934 awarded the gold seal of the society, member of the American Psychiatric Association and the Central Neuropsychiatric Association, for many years director and owner of the Oconomowoc Health Resort, now known as the Rogers Memorial Sanitarium, of which he was physician in charge, aged 67, died, August 27, of coronary occlusion.

Harry Ver Brike Brown, Glendale, Calif., Bennett College of Eclectic Medicine and Surgery, Chicago, 1902, formerly vice president of the Los Angeles County Medical Association and past president of the Glendale Branch, member of the state board of medical examiners, for many years a member of the board of trustees of the Glendale Union High School District, acting as president for one term, and also served as a member of the board of trustees of the Glendale Public Library, aged 62, died, June 25.

John Thomas Joseph Bird, Los Angeles, University of the City of New York Medical Department, 1886, member of the Medical Society of the State of New York, formerly clinical professor of medicine at the New York University College of Medicine, aged 76, died, June 26, in the Hospital of the Good Samaritan, as the result of an injury received in a fall while at Yosemite National Park, Calif.

Harry Gilmer Walcott, Dallas, Texas, Baltimore Medical College, 1901, fellow of the American College of Physicians, emeritus professor of gastro-enterology at the Baylor University College of Medicine, associate professor of physiologic chemistry at his alma mater, 1901-1902, served during the World War, aged 58, died, June 2, in the Medical Arts Hospital.

George Womock Sitman, Baton Rouge, La., Tulane University of Louisiana Medical Department, New Orleans, 1892, member of the Louisiana State Medical Society, parish health officer, medical superintendent of the Greenwell Springs (La.) Sanatorium, aged 67, died, June 16, in Roseland of chronic interstitial nephritis, pneumonia and arteriosclerosis.

R. E. Lee Smith, Doyle, Tenn., University of Tennessee Medical Department, 1886, member of the Tennessee State Medical Association, past president of the Knox County Medical Society, formerly superintendent of the Eastern State Hospital, Knoxville, aged 72, died, June 7, in the Knoxville (Tenn.) General Hospital.

Herbert Spencer Van Kirk, McKeesport, Pa., University of Pennsylvania Department of Medicine, Philadelphia, 1899, member of the Medical Society of the State of Pennsylvania, past president of the city board of health, on the staff of the McKeesport Hospital, aged 61, died suddenly, June 6, of coronary thrombosis.

Benjamin Thane, Wahpeton, N. D., University of Minnesota Medical School, Minneapolis, 1917, member of the North Dakota State Medical Association, served during the World War, health officer, contract physician to the Wahpeton Indian School Hospital, aged 50, was electrocuted by his own x-ray machine, June 17.

Reginald Malcolm Ballantyne, Manlius, N. Y., Syracuse University College of Medicine, 1913, physician to the county penitentiary, served during the World War, past president of the board of education, aged 49, died, June 30, when the automobile in which he was driving was struck by a trolley car.

Julian L. De Loney, Detroit, Meharry Medical College, Nashville, Tenn., 1905, member of the Michigan State Medical Society, formerly professor of internal medicine at the University of West Tennessee College of Medicine and Surgery, Memphis, aged 55, was shot and killed, June 24, by a patient.

George Coleman Skinner, Washington, D. C., Rush Medical College, Chicago, 1894, formerly surgeon in the U. S. Public Health Service reserve, and later connected with the Veterans Administration, served during the World War, aged 67, died, June 21, in the Veterans Administration Facility.

George Edward Smith, Fredonia, N. Y., University of Buffalo School of Medicine, 1886, member of the Medical Society of the State of New York, past president of the Chautauque County Medical Society, formerly coroner, aged 74, died, June 18, of myocarditis and cerebral hemorrhage.

Charles Oscar Caswell, Portland, Maine, Medical School of Maine, Portland, 1900, member of the Maine Medical

Association, for many years head of the science department of the city high school, aged 70, died, June 22, of cerebral hemorrhage and hypertensive heart disease

Henry Ansel Vincent, Wellington, Kan., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1900, member of the Kansas Medical Society, served during the World War, aged 61, died suddenly, June 9, of acute dilatation of the heart

Florence Augusta Sherman, Albany, N. Y., Woman's Medical College of the New York Infirmary for Women and Children, New York, 1891, formerly assistant state medical inspector for the state department of education, aged 76, died, June 20, in Watertown, of nephritis

Lloyd Charles Lane ♂ Oklahoma City, University of Oklahoma School of Medicine, Oklahoma City, 1929, aged 32, on the staffs of the Oklahoma City General Hospital, Wesley Hospital and St Anthony Hospital, where he died, June 28, of a sinus infection

Orrin Hays Swayze ♂ Yazoo City, Miss., Tulane University of Louisiana Medical Department, New Orleans, 1893, formerly county health officer, for many years member of the board of trustees of the city schools, aged 66, died, June 13, of cerebral arteriosclerosis

Vaughan Le Roy Sprenkel ♂ Allentown, Pa., Jefferson Medical College of Philadelphia 1931, on the staff of the Sacred Heart Hospital, aged 31, died, June 18, in the Jefferson Hospital, Philadelphia, of cerebral hemorrhage and thrombocytopenic purpura

William James Shaw, Rome, Ga., Atlanta Medical College, 1895, member of the Medical Association of Georgia, past president of the Floyd County Medical Society on the staff of the Harbin Hospital, aged 69 died, June 21, of chronic myocarditis

George Dalton, Malden, Mo., Missouri Medical College, St. Louis, 1889, member of the Missouri State Medical Association, aged 84, died, June 24, in a hospital at Little Rock, Ark., of hemorrhage of the stomach and carcinoma of the pancreas

Frank Pierce Gray, San Francisco, Cooper Medical College, San Francisco 1895, member of the California Medical Association, formerly assistant professor of diseases of women and children at his alma mater, aged 84, died, June 28

William Riley Parker, Dixon, Ill., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1901, member of the Illinois State Medical Society, died, June 25, in a local hospital, of cerebral hemorrhage

Edwin Clyde Ramer, Memphis Tenn., University of Tennessee College of Medicine, Memphis, 1928, member of the Tennessee State Medical Association, aged 35, died, June 29, in the Methodist Hospital, of cerebral hemorrhage

Frances Wason Potter, Medford, Mass., Woman's Medical College of Pennsylvania, Philadelphia, 1891, member of the Massachusetts Medical Society, aged 82, died, June 24, of arteriosclerosis and cerebral hemorrhage

Everette Lewis Powell, Farrisville, Texas, University of Louisville (Ky.) Medical Department, 1902, St. Louis College of Physicians and Surgeons, 1904 aged 62, died, June 24, in the John Sealy Hospital, Galveston

William N Spohn, Brownsville, Texas, Kentucky School of Medicine, Louisville, 1897 member of the State Medical Association of Texas, aged 67, died, June 10, in the Mercy Hospital, of gastric hemorrhage

John Newton De Shazo, Center Cross, Va., Medical College of Virginia, Richmond, 1900, member of the Medical Society of Virginia, member of the county board of supervisors aged 61, died, June 26

William Cecil Burnaman, Washington, Kan., Lincoln Medical College of Cotner University 1908, member of the Kansas Medical Society county coroner, aged 52, died, June 23, of coronary thrombosis

Alonzo L Carpenter, Joplin Mo., University Medical College of Kansas City, 1897, formerly city physician, aged 68 died, June 25, in the Freeman Hospital, of injuries received in an automobile accident

Mary Augusta Camp, Red Hook N. Y., Woman's Medical College of the New York Infirmary for Women and Children New York, 1893, aged 80, died, June 17, of chronic nephritis and myocarditis

Nathaniel Van Wert Wright, Baltimore Baltimore University School of Medicine, 1901, Southern Homeopathic Medical College, Baltimore, 1902, aged 59, died suddenly, June 19, in Lewes, Del

James T Tipton, Mountain Home, Ark., Memphis (Tenn.) Hospital Medical College, 1891, member of the Arkansas Medical Society, aged 72, died, June 4, of heart disease and cirrhosis of the liver

Joseph Vanden Berg, New York, Columbia University College of Physicians and Surgeons, New York 1904, member of the Medical Society of the State of New York, aged 60, died, June 23

Herbert Wilson Long ♂ Newark N. J., Bellevue Hospital Medical College, New York, 1894, on the staff of St Michael's Hospital, aged 65, died, June 10, of cerebral embolism

Edward Everett Collins, Premont, Texas, Vanderbilt University School of Medicine Nashville, Tenn., 1890, served during the World War, aged 76, died, June 28, in a hospital at Legion

Franklin De Wight Ayers ♂ Sabula, Iowa, Baltimore University School of Medicine, 1892, aged 70, died June 23 of chronic myocarditis, cholecystitis and prostatic hypertrophy

Clinton Quincy Dodd, Santa Monica, Calif., John A. Creighton Medical College, Omaha, 1910 member of the Nebraska State Medical Association, aged 49 died recently

William H Steele, Griffin, Ga., Atlanta College of Physicians and Surgeons 1900, member of the Medical Association of Georgia aged 67, died, June 23, of cerebral hemorrhage

Albert Marion Hoyer, Akron, Ohio, Starling Medical College Columbus 1891, aged 79, died June 28, in the City Hospital, of pyelonephritis and prostatic hypertrophy

St Elmo Davenport, Atlantic City, N. J., College of Physicians and Surgeons, Boston, 1908 school and city physician, aged 58, died, June 28, of mitral regurgitation

Jeremiah Maher, Los Angeles, Rush Medical College Chicago, 1882, past president of the Alameda County Medical Society, aged 88 died, June 14, of arteriosclerosis

Fletcher F Craig, Fort Worth, Texas, Fort Worth School of Medicine, Medical Department of Texas Christian University, 1909, aged 53, died, June 28, of nephritis

Robert Bates Hunt, Boston Harvard University Medical School, Boston, 1912, served during the World War, aged 51, died, June 22, in the Faulkner Hospital

William Florence Sheridan, Pittsburgh, Jefferson Medical College of Philadelphia, 1871, aged 89, died, June 3, of myocarditis and essential hypertension

Frank Guy Blanchard, Woodville, Ohio, Western Reserve University Medical Department, Cleveland, 1888, aged 77, died June 26, of coronary thrombosis

Amos Hiram Winslow, Toledo, Ohio, University of Michigan Homeopathic Medical School, Ann Arbor, 1879, aged 84, died, June 14, in a local hospital

William Alonzo De May, Fort Collins, Colo., Kansas City (Mo.) Medical College, 1891, aged 80, died, June 22, of diabetes mellitus and pneumonia

Charles Russell Smith ♂ Tioga, Pa., University of Pennsylvania Department of Medicine, Philadelphia, 1898, aged 66, died, June 1, of lobar pneumonia

Walter M Boylan, Boyne City, Mich., Michigan College of Medicine and Surgery, Detroit, 1900, aged 65, died, June 24, of bronchopneumonia

Amos Leuty, Morris, Minn., Drake University Medical Department, Des Moines, Iowa, 1898, aged 68, died, June 24, of coronary thrombosis

George Millard Clifton ♂ Norman, Okla., Metropolitan Medical College Chicago, 1900, aged 60, died, June 22, of coronary thrombosis

Walter Livingston Coulthard, Vancouver, B. C., Canada, University of Toronto (Ont.) Faculty of Medicine, 1894, aged 64, died, June 6

William Ernest Borley, Mishawaka, Ind., Detroit College of Medicine, 1894, aged 67, died, June 21, of heart disease at Twelve Mile

Thomas Wellesley Peart, Hamilton, Ont., Canada University of Toronto Faculty of Medicine, 1909, aged 48, died, June 4

William Thomas Burns, Toronto Ont., Canada, University of Toronto Faculty of Medicine, 1900, aged 63, died, June 3

Jerome Cornell Fleischman, St. Louis, (licensed in Missouri in 1905), aged 56, died, June 27, of heart disease

Gustave Kempf, Detroit, Detroit College of Medicine, 1895, aged 64, died, June 27, of pulmonary tuberculosis

Correspondence

THE HISTORY OF SYPHILIS

To the Editor—I have just read the Special Clinical Article in THE JOURNAL of August 21 by a distinguished syphilographer (Cole, Harold N Congenital and Prenatal Syphilis, THE JOURNAL, Aug 21, 1937, p 580) This contains a section titled Historical Review, from which I quote the following

Torella 1498 Vella 1508 and Cataneus 1516 had the idea that a mother's syphilis was transferred to the child in its passage through the birth canal or later from infected milk or infected mammae Fallopius body physician of Pope Alexander VI and of Pope Julius II, noted that wetnurses were infected from syphilitic babies and in 1504 gave the first clinical description of the syphilitic fetus

Now Gabriel Fallopius was born in 1523 and died in 1562 Pope Alexander VI was pope from 1492 until 1503, when he died, and Julius II was pope from 1503 to 1513 How Fallopius could have been physician to these popes long after they had died, and how he could have written about congenital or prenatal syphilis in 1504, or some nineteen years before he was born, is beyond my comprehension but can doubtless be explained by those who believe that the treponematoses named syphilis by Fracastorio in 1530 first invaded Europe and Asia from the island of Haiti in 1493

Incidentally I returned yesterday from a 6,000 mile journey, during which I had the privilege of visiting a library containing a rich collection of rare and valuable books and manuscripts, some of which I was able to study and copy Among other material I had photostated a good clinical description of prenatal syphilis dating to 1363 In fact, I already had some passages of this nature belonging to a period a little over 100 years earlier

R C HOLCOMB, MD, Upper Darby, Pa

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES THEY DO NOT, HOWEVER REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS BUT THESE WILL BE OMITTED ON REQUEST

IDE COLOR TEST FOR SYPHILIS

To the Editor—I have recently received a circular with regard to the Ide Color Test for syphilis Such a simple and convenient test would be very valuable What is its present status as to accuracy?

MD, Burlington Iowa

ANSWER—Sobel Ide and Tamao Ide reported on their test in the *Journal of Laboratory and Clinical Medicine* 21 1190 (Aug) 1936 No significant comparative studies with well established tests have as yet appeared in the literature hence it is impossible to comment at this time as to the dependability of this test

SALT TABLETS FOR HEAT—POSSIBLE OVERDOSAGE

To the Editor—What information can you give me on the use of salt tablets in excessive heat? What dangers are there in overdosing in early cases of arteriosclerosis and/or nephritis with potential edema?

MD New York

ANSWER—The use of salt tablets to combat the ill effects of heat has become an almost standard procedure in hot industries During very hot weather the majority of all larger manufacturing establishments resort to this practice A worker engaged in active physical duties on a hot summer day may perspire as much as 6 liters, although the average is lower The saline content of perspiration is such that as much as 20 Gm of mineral material may be lost from the body in a single twenty-four hour period This mineral loss has proved to be the cause or contributing cause of muscle cramps, excessive fatigue and gastro-intestinal upsets The consumption of water alone or oatmeal water or dextrose water will not allay

the physical difficulties resulting from mineral losses So great is the loss of chloride through profuse sweating that it is almost impossible to replace total loss fully through the consumption of salt tablets or salted fluids Workers are encouraged to take one tablet (usually 0.65 or 1 Gm of sodium chloride) with every drink of water Seldom do workers consume more than ten tablets a day The average number is nearer five If the high number of ten tablets is daily consumed, this represents not more than 10 Gm of sodium chloride, which does not exceed the average loss of salt through perspiration on a hot summer day Naturally, considerable salt is taken into the body along with foods, but the combined intake rarely exceeds perspiration losses In the absence of foolhardy acts of workers who occasionally ingest a handful of salt tablets as an act of bravado, it is not known that any harmful results will arise from the use of salt tablets in industry, in homes and elsewhere The desideratum of course is to keep the salt replacement at a level or near to the salt losses through excretions and secretions In early cases of arteriosclerosis or nephritis, with potential edema, no apprehension as to ill effects is warranted so long as the salt intake is maintained on a replacement basis in the body, which is rarely exceeded in the hot industries or during hot summer months through the use of from five to ten salt tablets daily

BRASS POISONING

To the Editor—I should appreciate receiving detailed information concerning the subject of brass poisoning—signs, symptoms diagnosis and treatment.

V N FELDMAN MD Holyoke Mass

ANSWER—Ordinarily the term brass is applied to an alloy of copper and zinc Frequently, however, the term is applied to other metallic materials in which copper is the chief component Some brass may contain lead to as high a percentage as 50 Nearly all brass contains at least traces of lead as an impurity Likewise, arsenic may be present as an impurity in quantities sufficient to produce arsenic poisoning Therefore the term "brass poisoning" is an anomalous one and any chronic disease resulting from exposure in brass manufacture is likely to be either lead or arsenic poisoning The copper component of brass seldom gives rise to any occupational disease, although copper may not be regarded as entirely innocuous Molten copper, like many other metals, may give rise to metal fume fever Green perspiration and greenish discoloration of the hair may be associated with exposure to copper, but such conditions do not constitute genuine diseases Copper at times leads to a dermatitis, which as an occupational disease is relatively unimportant On the other hand, the zinc component of brass may lead to a clear cut occupational disease of acute nature In the making of brass, the melting point of the zinc is so much lower than that of copper that it is necessary to boil the zinc in order to melt the copper This leads to the evolution of appreciable quantities of zinc oxide in the atmosphere Workers inhaling this zinc oxide may develop a variety of metal fume fever which in different trades is termed "brass poisoning" "brass workers' ague," "zinc chills" or "foundrymen's chills" The probability of this disease naturally is in proportion to the extent of exposure Winter weather with enclosed work places favors the occurrence of the disease This is also true of wet, snowy weather New workers are prone to acquire the disease until inured Older workers, absent from the work place, lose their tolerance and may develop difficulties Commonly the disease does not arise during the work day and during exposure but first appears at night, after exposure on the preceding day The attack may be characterized by a severe chill and marked thirst These manifestations commonly give way to a period of profuse sweating, association with some degree of prostration, distaste for food, and indolence The experienced workman comes to know that he may return to work on the following day, without marked discomfort, perhaps only to suffer from another attack during the following night Associated with the zinc chills there appears to be a predisposition to respiratory infection, so that some few individuals may lose time from employment on this account No chronic form of the disease is known and repeated attacks lead to no direct manifestation of impairment other than those associated with lack of sleep, lack of food and frequently the ill effects of undue alcoholism, since the thirst connected with these attacks favors high alcoholic intake Gastro-intestinal upsets are a frequent concomitant of this form of brass poisoning There is no known specific treatment, but preventive measures carried out in the plant, such as the wearing of respirators or the procurement of proper ventilation, may ward off attacks The attack itself calls for no specific treatment In industries apart from brass founding, such for example as galvanizing the zinc oxide produced, combinations with other vapors, such

ns sulfuric acid, from pickling vats, leading to the formation of zinc sulfate, may occur. Exposure to such a zinc compound may give rise to dissimilar and more serious manifestations than those described for zinc chills.

OPHTHALMOPLÉGIA AND GASTRIC UPSETS IN CHILD WITH POSITIVE WASSERMANN REACTION

To the Editor—I have a boy aged 6 years under my care who was in good health up to 1934 when he began to have attacks of pain in the stomach without vomiting for two or three days followed by evidence of oculomotor nerve disturbance (i. e. drooping of the right eyelid and strabismus of the right eye) for three or four days. This cycle was repeated regularly every three months almost to the day. The father's Wassermann and Kahn reactions were found to be 4 plus. The mother's on two separate occasions were entirely negative. The paternal grandfather died of unknown cause in an insane asylum. The child's Wassermann reaction was 4 plus. Physical examination of the child was negative either for acquired or for inherited evidence of syphilis. The eye symptoms clear up entirely within three or four days. Vision accommodations are entirely normal at intervals. Treatment has consisted of sulfarsphenamine intramuscularly 0.2 Gm per kilogram (the child is uncooperative in treatment intravenous therapy being impossible) once a week for six weeks followed by a bismuth compound intramuscularly for six weeks with a four weeks rest period. One of these courses has been given. The expectant time of disturbance arrived during the course with no stomach symptoms but with an eye disturbance lasting only two days. The Wassermann reaction at the end of the course was negative. Is the outlined course of treatment adequate or would a continuous type of therapy be advisable? Please advise as to drugs. Would mercury chloride be preferable to bismuth?
M D Pennsylvania

ANSWER—The evidence offered is not sufficient to warrant a diagnosis of gastric crisis. It would seem advisable to have a spinal fluid examination, using a general anesthetic if the child is noncooperative. The eyegrounds also should be examined. The history of recurring ophthalmoplegia in association with the gastric upsets is quite unusual. The use of an arsphenamine preparation for intramuscular administration is advisable in a child of this type. However the development of blood dyscrasias from the use of sulfarsphenamine has been encountered frequently enough to make its use attended with some risk. Bismuth arsphenamine sulfonate might be used in its place, followed by the bismuth course as suggested or even by mercury injections. If the spinal fluid is positive, more intensive measures may have to be adopted, such as intraspinal therapy or malaria therapy. The child should have at least three courses of injections of an arsphenamine with courses of bismuth or mercury compounds interspersed according to the continuous system of treatment, before the more intensive measures are adopted.

SOFKURD MILK

To the Editor—What is SofKurd mineral exchange milk? How does it compare with ordinary pasteurized milk in digestibility and nutritive value?
M D Ohio

ANSWER—SofKurd Milk is a trade name for a pasteurized milk from which a portion of the ionizable calcium has been removed. This is effected by passing the milk over "sand" consisting of one of the zeolites. These are hydrated silicates of aluminum and of sodium, potassium or calcium. Compounds of this type containing sodium and potassium exchange these elements for some of the calcium of the milk, which is allowed to flow over them. The procedure is similar in some respects to a method of softening water. If suitable proportions of sodium and potassium are used in the zeolites, the treated milk contains these elements in practically unchanged ratio. Part of the calcium shifts from the milk to the zeolite and along with it goes some of the phosphate by a mechanism that is not well understood. The ratio of calcium to phosphorus in the milk, however, is not changed by this treatment. The chief chemical difference between SofKurd Milk and ordinary pasteurized milk is that the former contains 20 per cent less calcium and phosphates. The originators of the method (Lyman, Brown and Otting *Indust & Engin Chem* 25 1297 1933) showed that the removal of part of the ionizable calcium prevented the formation of a clot by rennin. This milk also forms a soft curd when treated with pepsin and hydrochloric acid. The significance of soft curd qualities has been discussed in a recent report of the Council on Foods (*THE JOURNAL*, June 19, p 2122) with the conclusion that milk yielding a soft friable curd in the stomach is well tolerated and more readily (but not necessarily more completely) digested in the stomach than milk producing a hard curd. It should be noted that the determination of the curd tension of "SofKurd mineral exchange milk" by the well known Hill method gives high results unless the coagulating agent is pepsin and hydrochloric acid. This is because the Hill reagent (pepsin plus HCl) adds much more calcium than has been removed by the zeolite treatment. The

curd tension observed with pepsin and hydrochloric acid as the coagulant is usually around zero and in this respect the milk resembles breast milk. Hess, Poncher and Woodward (*Am J Dis Child* 48 1058 [Nov.] 1934) carried out a balance experiment with an infant 80 days old who was fed this type of milk. Throughout the experiment the infant was in positive calcium balance and retained a slightly greater amount of calcium (and therefore a greater proportion of the calcium of the food) when liquid zeolite-treated milk was used than when ordinary milk was fed. In vitro studies indicate that the proportion of ultrafiltrable calcium is greater in 'base exchange' milk, which may explain the high proportion of calcium reported to have been retained by the infant on that type of milk. Rogers, Pavey and Williams (*Ohio State M J* 30 441 [July] 1934) used SofKurd Milk as a complementary food for the newborn and recorded that fifty infants fed this type of milk made better gains and suffered fewer losses than fifty babies fed untreated milk. These reports, which are favorable to SofKurd Milk, can hardly be regarded, however as conclusive proof of the superiority of this product over ordinary boiled milk as a principal food for infants. More extensive clinical investigations would be desirable to establish its nutritive value in the feeding of infants. It seems rational to suppose, however, that any milk which yields a soft curd would be of value in the feeding of older children and of persons who do not easily tolerate ordinary pasteurized milk.

EFFECTS OF SYMPATHECTOMY IN HYPERTENSION

To the Editor—Will you please furnish me with information concerning the results of celac ganglionectomy and lumbar sympathectomy with respect to the following points: 1 In an early essential hypertension of two years duration in a man aged 35 with a blood pressure of 150 systolic 110 diastolic what is the immediate effect? 2 Does the diastolic pressure return to its original level after the initial fall? If so what is the cause of this secondary rise? Is it from replacement of paralyzed smooth muscle with contracting fibrous tissue? 3 Does the pressure continue to rise past the preoperative level? 4 What are the possible untoward results from these operations immediate and late? 5 Are any functions other than the vascular affected? 6 In experimental animals with normal blood pressure does such an operation result in arteriosclerosis of the splanchnic vessels and a secondary rise in pressure above normal?
M D Ohio

ANSWER—1 There is some doubt as to whether extensive sympathectomy combined with first and second lumbar ganglionectomy is indicated. In the first place one should be sure that the man had essential hypertension. This can be determined by hourly readings over a twenty-four hour period and by blood pressure readings taken during immersion of the hands in ice water. If the patient has true hypertension the systolic pressure will rise from 20 to 50 mm of mercury. Furthermore, the operation would not be advisable unless the systolic and diastolic pressures drop to normal under the administration of sodium amylal, and unless the pressures drop to normal under the administration of sodium ethyl (1 methyl butyl) thio-barbiturate. In the event extensive sympathectomy (which includes resection of all three splanchnic nerves combined with first and second lumbar ganglionectomy performed bilaterally with a ten day interval between the operations) is carried out the immediate effect would result in a return of the pressures to normal or subnormal readings.

2 The immediate pronounced drop is undoubtedly due to the marked vasodilatation that follows extensive sympathetic resection. The subsequent rise to a normal level is probably due to the maintenance of muscular tone by a pressor substance floating within the blood stream. It is doubtful that the contracting fibrous tissue is capable of producing this rise. It is known that the pressures fail to fall following sympathectomy when sclerotic changes are present. Therefore it is fair to assume that the drops in pressure are undoubtedly due to the vasodilatation that takes place when the central nerve impulse has been interrupted.

3 No, if the case has been properly selected. If a patient has an advanced sclerosis, the pressure will continue to rise in spite of sympathectomy.

4 There may be dryness of the skin below the somatic segment section, with excessive sweating above the level. In men there is a loss of ejaculatory power, but this does not disturb the potentia coeundi or libido.

5 Yes, some patients may have diarrhea for a limited period. 6 Apparently no animals have been studied long enough to prove or disprove the point.

Some authorities believe that sympathectomy for hypertension has no sound foundation and has only served the purpose of destroying a large and important system of nerve fibers to obtain varied and nonuniform responses. The question has been raised as to whether the operation, even though it does

alter blood pressure, has actually changed the course of the progressive pathologic process in true essential hypertension. The eyeground studies in one series of patients certainly showed no improvement in the vascular disease or in the morbidity.

THALAMIC SYNDROME

To the Editor—A man aged 70 sitting on a bench Oct 24 1936 felt weak and collapsed and had to be carried to his home. He did not lose consciousness. He complained of headache and tingling and numbness of the right side of the body. Physical examination revealed a hemianesthesia of the entire right half of the body with a definite line of demarcation. There was muscular weakness on the affected side but no motor paralysis. The eyes reacted sluggishly to light and in accommodation. The right corneal reflex was gone the tongue protruded well without deviation. There was no distortion of the face. The heart rate was 84 regular and of good quality. The blood pressure was 212 systolic 110 diastolic. The lungs were clear. The abdomen was flabby and somewhat distended the reflex on the right was hypoactive. The knee jerks were bilaterally diminished with a suggestive Babinski on the right and no ankle clonus. The right side of the body was insensitive to pin prick temperature or deep pressure. The Wassermann reaction was negative. The urine at the first examination showed albumin ++ and a few granular casts but on a later check up was clear. The blood nonprotein nitrogen was normal. A diagnosis of hypertension arterio sclerosis and left sided cerebral hemorrhage in the area of the thalamus the posterior portion of the internal capsule was made. A neurologic consultation was held. Nursing care with absolute rest in bed was prescribed. Glyceryl trinitrate $\frac{1}{150}$ grain (0.4 mg) and sedatives caused marked improvement in his condition. There was a gradual return of sensation first pin prick then temperature and lastly ability to distinguish the form and shape of objects felt. His blood pressure ranged from 180/200 systolic and 98/108 diastolic. He was able to get up from bed within the month and gradually get up and about the house. However there appeared marked paresthesias—a sensation of burning coldness sweating and shooting like pains on the right side of the body being most marked in the right upper extremity. These have persisted since and in the past week they have been so pronounced as to cause him again to become bedridden. It has also affected him mentally for he has become despondent and gloomy giving way readily to crying spells. Sedatives such as bromides and amylal analgesics aminopyrine salicylates nitrites iodides and lastly narcotics have been of no avail. Local therapy to the extremities consisting of dry and moist heat also have given no benefit. I have sought the advice of a neurologist and medical men but have been unable to obtain information that has been of aid. Any suggestion as to possible therapy for relief of the paresthesia burning and coldness will be greatly appreciated.

MAX B. FERSHMAN MD Bronx N Y

ANSWER—The patient no doubt has what is described as thalamic pain as well as a thalamic syndrome. The pain and the emotional state mentioned are typical of involvement of that structure especially when they occur in conjunction with or follow a hemiparesis, hemianesthesia and hemianopia. Often there is considerable pain with loss of pin prick sensibility over the painful regions. This is known as *analgesia dolorosa*. The pain and paresthesias sometimes become intractable. Fortunately, in most of the cases the pain ultimately disappears with the return of partial thalamic function. Until then one may have to resort to morphine, codeine or strong hypnotics. If, however the pain does not subside, posterior commissure section or chordotomy can be done in the cervical cord.

FRENUM OF UPPER LIP

To the Editor—A child aged 11 months has a separation of the upper central incisors due to hypertrophy of the frenum of the upper lip which is attached to the roof of the mouth. At what age should this muscle be cut and at what place? Should the teeth be wired now or should one wait until the permanent teeth appear?

MD Arkansas

ANSWER—In general the best time for operation on the frenum labii superioris is between 5 and 6 years or between 9 and 10 years. Separation of the central incisors either temporary or permanent is not in itself an indication for operation. The median suture between the intermaxillary bones normally persists in the anterior portion until quite late in life. The central incisors, therefore, both temporary and permanent normally erupt with quite a wide space between. The permanent centrals are normally brought in contact by the pressure of the erupting laterals and canines.

There is a wide range of variation within normal limits in the structure and attachment of the frenum. Usually at birth or some time afterward it is attached at the crest of the alveolar process. As the alveolar process grows downward and forward carrying with it the temporary incisors, the attachment of the frenum should be left behind. It occasionally happens that the frenum extends over the crest of the alveolar process and is attached to the fibrous tissue of the incisal papilla on the palatal slope. In such cases the attachment is not left behind on the labial surface of the process but extends between the incisor teeth as a pad or mat of fibrous tissue, which prevents the

central incisors from coming together. This condition cannot usually be positively determined before the fourth or fifth year. When operation is indicated this dense mat of fibrous tissue should be dissected out from between the teeth and removed the wound being closed by two or more sutures in the gum tissue.

When operation is delayed until the ninth or tenth year the teeth should be moved together by a mechanical appliance first and then the appliance removed, the teeth will separate in a few days. The operation is then to be performed, the tissue dissected out and the appliance replaced and the teeth immediately brought together so that in healing the connective tissue fibers will unite from tooth to tooth as they should. This band, extending from the mesial surface of one central to the other, normally holds these teeth in contact and unless this attachment is formed immediately after the operation the teeth will eventually separate. Operation before the completion of the temporary denture is seldom if ever indicated.

ORDINARY OR ENTERIC COATED GLANDULAR PRODUCTS

To the Editor—1 Are glandular products such as thyroid ovarian pituitary or adrenal when prescribed in ordinary capsules destroyed by the acid present in the stomach? 2 What is the opinion at present on enteric coated medication? What chemical is used and what proof is there that the capsules pass unchanged through the stomach?

ROBERT D. KANE MD Elmhurst N Y

ANSWER—1 Of these endocrine products it is only thyroid that is definitely known to be active when given orally. Its activity is not appreciably destroyed by the digestive juices and it need not be given in enteric coating. The others have no clearly demonstrated value when given orally whether in ordinary or in enteric capsules. 2 Enteric coating is accomplished by phenyl salicylate, keratin, shellac or mixtures of these, or by gelatin hardened with formaldehyde. X-ray examination after the swallowing of opaque (e.g., barium sulfate containing) capsules yields the most obvious proof as to the location of disintegration. When an enterically coated capsule containing sodium iodide and methylene blue is swallowed, marked delay in the appearance of the iodide reaction in the saliva indicates that the capsule probably did not disintegrate in the stomach, while lack of appearance of greenish color in the urine would indicate that the capsule did not disintegrate at all. The sifting of the stools would, of course, also demonstrate lack of disintegration.

LARGE INGUINAL RINGS AND DEVELOPMENT OF HERNIA

To the Editor—What attitude should a physician examining factory employees take regarding large external inguinal rings? I find men with no hernia but rings that will admit a finger for a full joint (size $7\frac{1}{2}$ hand) and some rings nearly two fingers across. Are these patients more likely to develop hernias than the normal tight ringed persons?

MD Michigan

ANSWER—Erdman (Nelson Loose Leaf Surgery, vol 4, p 610) stated that the enlargement of the external ring, which was found in 22 per cent of 2,000,000 drafted men, according to the report of the surgeon general, may be an important determining factor in the occurrence of primary direct hernia. Gorton (Compensable Hernia, *J Indiana M A* 23:521 [Nov.] 1930) believed that hernia of weakness which may be due to congenital weakness of the abdominal muscles, or atrophy following disease in the absence of a preformed sac, is rare.

Some believe that the so called hernia of weakness may be either direct or oblique. The latter type occurs lateral to the inferior epigastric vessels and outside the cord. It is much more common than is generally realized.

It is probable that with an unusually large external inguinal ring in the absence of a preformed sac, there is a tendency to the development of the so called hernia of effort. This belief is further strengthened by the observation that there is often an associated weakness of the deeper layers of the abdominal wall together with an imperfect development of the external oblique fascia.

While adequate support from all layers of the inguinal region, even if weakened might be strong enough to withstand ordinary intra-abdominal pressure the absence or weakness of the external oblique fascia may be sufficient to permit herniation, particularly under effort.

A number of persons who were refused work by company physicians because of an unusually large external ring have been operated on. In a fairly large percentage there was a definite weakness in Hesselsbach's triangle and in some an incompletely obliterated peritoneal process which could not be determined before operation.

INFECTIONS OF HANDS IN MEAT HANDLERS

To the Editor—I am called on at times to treat infections of the hands of butchers and others who handle meat. They seem to be the result of infected cuts and scratches. I have been told that mutton is the cause but I have had instances in which no mutton was handled. In one instance it followed a small scratch on the thumb made by a spicule of beef bone. This acted in some respects like erysipelas but there was little systemic reaction just a dusky area of redness which spread down the thumb and across the palm. The redness was deepest where the saw and cleaver would bruise the hand. Some cuts will fill with pus and resemble a pyocyanus infection. What is the nature of these infections? Allergic? Streptococci? Is it the meat itself or a subsequent pollution? One man stated that smoked meat never bothered him but that fresh meat was a frequent cause.

THEODORE BAKER MD Blairsville, Pa

ANSWER—The infections referred to are doubtless due to inoculation of open wounds with pathogenic organisms of varying virulence. Meat is an excellent culture medium for bacteria of all sorts, just as is milk and every other form of perishable food. The hands of butchers are constantly exposed to bacterial contamination and it is only logical that when they receive cuts the open wounds should frequently become infected. The type of infection and the wound secretion, just as in other cases, depends essentially on the type and virulence of the organism and the patient's resistance. Since meat is usually kept at comparatively low temperatures, the virulence of the organisms on its surface is likely to be diminished. On the other hand, some of the most violent and rapidly spreading infections that one sees in general hospital practice may be due to trivial injuries from a spicule of bone that has caused a penetrating wound of a finger tip.

As a matter of prophylaxis there is nothing more effective than frequent washing of the hands with warm water and soap during the course of the day's work.

MINE GASES AND THEIR EFFECTS

To the Editor—Will you kindly furnish me with information concerning mine gases and their effects on the human body.

E F SHEPPARD MD Jenkins, Ky

ANSWER—Solely for the purposes of this brief discussion, mine gases may be divided into two groups (1) those arising from natural agencies and (2) those produced by dynamite firing and fires. In the former may be found carbon dioxide ("black damp"), although this gas is more often in the second category as a component of "after damp," methane ("fire damp") and hydrogen sulfide ("stink damp"). The popular terms "black damp" and "after damp" do not strictly apply to carbon dioxide, but instead to a mixture of carbon dioxide with nitrogen and other gases commonly produced as a result of explosions. Of the three gases mentioned, carbon dioxide and methane (sometimes ethane as well) act only as asphyxiants. Hydrogen sulfide is highly toxic, causing symptoms in any concentration that may be measured. As little as 0.05 per cent may produce death. In high concentrations this gas leads to quick death from actions on the higher nerve centers. In lower concentrations eye irritation leading to corneal ulcers and inflammation of the eustachian tubes and respiratory tract are characteristic features. This gas as well as methane in certain proportions is highly explosive.

In the latter group may be found the carbon dioxide-nitrogen mixture and hydrogen sulfide and, in addition, carbon monoxide ("white damp") and various oxides of nitrogen. The action of carbon monoxide is too well known to require discussion here. The oxides of nitrogen, of which the peroxide is perhaps the most dangerous, lead insidiously to pulmonary edema, inflammation of the respiratory tract and pneumonia. The slow burning of explosives is far more productive of dangerous gases than their actual explosion. Some or all of the gases mentioned may arise from coal fires, coal dust explosions and gas explosions as well as from the burning or firing of explosives.

COLON BACILLUS PROSTATITIS AND VAGINITIS

To the Editor—How common is colon bacillus prostatitis and urethritis in the male and vaginitis in the female? Kindly outline a successful course of treatment for both of these conditions.

YEN PUI CHIANG MD Lihue Kauai Hawaii

ANSWER—Colon bacillus prostatitis is a common condition, as about 10 per cent of prostatic cultures will show the colon bacillus. It almost invariably accompanies infection of the urinary tract caused by the colon bacillus. Sulfanilamide has been used with success in the treatment of colon bacillus prostatitis and urethritis. If the patient is an adult of average weight, 5 Gm may be given daily for one or two days, then 4 Gm for one or two days, followed by 2.5 Gm daily for from seven to ten days. This dosage should be immediately reduced,

or even discontinued, if toxic symptoms or untoward reactions develop. It must be remembered that acidosis sometimes follows the administration of sulfanilamide. Other undesirable effects, such as jaundice and urticaria have been reported. Certain studies indicate that blood changes may follow prolonged administration of sulfanilamide. These include methemoglobinemia, sulfhemoglobinemia, granulocytopenia and even hemolytic anemia. It is advisable, therefore to examine the blood in cases in which there is extensive use of sulfanilamide.

Colon vaginitis is a rare disease even though colon bacilli are commonly found in the vagina. Before such a diagnosis can be made, the presence of cervicitis, Trichomonas infestation and mycotic vaginitis must be ruled out. There is no specific treatment. One per cent gentian violet and a 0.5 per cent solution of acriflavine in glycerin or phenylmercuric nitrate 1:1,500 solution by instillation followed by douches of 1:20,000 can be tried. Wool tampons saturated with merthiolate 1:2,000 are often of value. It must always be remembered that vaginitis is resistant to treatment until cervicitis has been corrected.

ELECTRIC ARC WELDING

To the Editor—Is there a minimum distance advised for spectators or workmen working around arc welding operations without protective goggles or does this depend primarily on the susceptibility of different individuals?

W S CRAWFORD, MD Tulsa Okla

ANSWER—If all electric arcs were the same size and the environment surrounding the arc were constant, it is probable that a fixed minimum distance might be determined beyond which little or no damage would be likely. Light and heat waves are forms of radiant energy appearing in waves of varying lengths. The damaging rays arising in arc welding are ultraviolet, infra-red and visible light rays, which are the source of glare. At the point of formation these rays are concentrated, but obviously they become diluted as the distance from the point of origin increases. Thus the quantity of such rays affecting the eye would be much less at 200 feet than at 20 feet. It is believed that there is a minimum distance of beginning safety for spectators or workmen in arc welding operations, unprotected by goggles or otherwise, but this distance is probably theoretically different for every single arc and depends, among other factors, on the quantity of arc produced, the general level of illumination in the room or other space where arc welding is carried out, and the amount of glare produced.

Studies made by the Medical Department of the U S Navy using a thermopile device have been directed to this problem of the distribution of radiant energy around welding operations. The office of the surgeon general of the navy is a likely source of extended information in this matter.

For practical purposes, workmen are little concerned in the dangers of arc welding if the distance from the arc is more than 200 feet, under ordinary circumstances.

EPIDEMIC CATARRHAL JAUNDICE?

To the Editor—I have been having numerous cases of what I thought was catarrhal jaundice. The cases are similar. Ordinarily the patient appears for treatment jaundiced. There is no pain in the upper right quadrant or other gallbladder symptoms of sufficient severity to account for the jaundiced condition. In a few days that condition clears up and the patient is then in apparently normal condition. I should like to have your opinion as to what is or may be the cause of this condition so that if possible, I may trace it down and eliminate it.

CHARLES E VESTLE MD Lansing Kan

ANSWER—The question omits details that would be of value in arriving at a solution. Were there fever, malaise or other signs of acute infection at the onset of the jaundice? Were the stools acholic and did bile pigment appear in the urine? Was there an estimation of the concentration of bile pigment in the blood?

Generally speaking, jaundice is obstructive, toxic or hemolytic. Infectious jaundice is fundamentally obstructive and will be so considered in this discussion. If these were cases of true jaundice it would seem that they must be obstructive, because toxic or hemolytic jaundice would persist over a longer time. Indeed it is difficult to see how any true jaundice would disappear "in a few days."

The term catarrhal jaundice is used to designate the jaundice resulting from duodenitis with swelling of the distal end of the common bile duct as well as the jaundice resulting from cholangitis that involves the bile ducts all the way into the liver.

When the inflammatory reaction is confined to the duodenum and common duct, the jaundice is likely to be of relatively short duration. The symptoms of acute infection are usually

present fever, malaise and muscle pain. This condition not infrequently is epidemic and affects a community in a fashion similar to an influenza epidemic.

Specific infectious jaundice, resembling Weil's disease, has occurred in American communities. The specific spirochete can usually be found and the course is longer than the course described in these cases. This disease may be transmitted from person to person.

The possibility of the skin being stained by a substance other than bile must be considered unless an elevation of bile pigments in the blood and urine has been demonstrated.

A hypercarotenemia from overindulgence in certain fresh vegetables may produce a yellow stained skin.

Certain chemicals, notably trinitrophenol and certain sulfur derivatives, produce a stain in the skin resembling jaundice.

If, as it seems probable, these cases are "epidemic catarrhal jaundice," the epidemic will be self limited.

DRUGS FOR PARALYSIS AGITANS

To the Editor—A patient, aged 31 with paralysis agitans has shown improvement under treatment with 6 grains (0.4 Gm) of stramonium daily. 1 What is the maximum dose of stramonium and over how long a period may this be given without fear of untoward effects? 2 Do the powdered leaves possess any advantage over the fluidextract? 3 What are the relative merits of stramonium and scopolamine in the treatment of this disease? 4 What drugs besides these two are of value, and what are the dosages?

M D, Indiana

ANSWER—1 The dose of stramonium as well as of the other drugs of the belladonna series used in paralysis agitans is "dose enough" to accomplish the result without excessive discomfort. The dryness of the mouth and skin and the dilatation of the pupil are sufficiently distressful to make it unlikely that a sufficient dose will be taken to do any real harm.

2 It is not known that the powdered leaves possess advantage over the fluidextract, but it is known that sometimes one tincture of stramonium acts better than a tincture of another lot, so that the question may well be raised whether there might be differences in the extraction of the drug or in the drug itself. The use of the powdered drug would eliminate any doubt as to the possible incomplete extraction of active principles or their alteration during the process of extraction.

3 It is a curious fact that patients with paralysis agitans may find one of these drugs of similar action preferable to the other. Thus there are some patients who seem to get most benefit from scopolamine hydrobromide.

4 Atropine may succeed in cases in which scopolamine and stramonium fail. The same principle governs the method of using atropine that is employed in apportioning the dosage of the other agents of this series in this condition. Thus Benhamou, Fournes and Cuvous (*Paris med* 2 484 [Dec 14] 1935) recommend atropine sulfate in a solution of 0.5 Gm to 100 cc, a drop, therefore, corresponding to 0.25 mg ($\frac{1}{240}$ grain) of atropine. The schedule starts with one drop three times a day, at breakfast, in the middle of the day and in the evening. From one to two drops is added each day until the amelioration of the symptoms does not increase. After from seven to eight days the dosage is progressively diminished drop by drop until the motor spasms recur. It is then continued at the minimal dose that produces optimal results. A daily dosage as high as from 100 to 140 drops (from 25 to 35 mg) of atropine may be reached without the occurrence of toxic symptoms.

TEST FOR ALCOHOL IN BLOOD

To the Editor—In THE JOURNAL Dec 26 1936 page 2145 appears an alcohol blood test by Widmark used by Berlin police. Is this test reliable? If so where can I find how to do this test?

M PAUL TRAVERS M D Miami Fla

ANSWER—The Widmark test for determining the concentration of alcohol in the blood is reliable within a fraction of 1 per cent. It requires, however, a considerable chemical technique and is rather time consuming. All information dealing with this test appears in the German literature. Widmark's original contribution appeared in the *Biochemische Zeitschrift* 131 473, 1922. There are numerous references to the test in the German literature subsequent to this. Two of the recent ones are as follows:

Koller Josef Zur Technik der quantitativen Alkoholbestimmung im Blut nach der Methode von Widmark *Deutsche Zeitschrift für die gesamte gerichtl. Med* 19 513 1932
Kuntz H R Bemerkungen zur Technik der Blutalkoholbestimmung nach Widmark für reichen Untersuchungen *ibid* 24 273 1935

A modification of the Widmark test, much simpler, less time consuming, and accurate within clinical limits is described by

J C Ables in the *Proceedings of the Society for Experimental Biology and Medicine* (34 346 [April] 1936) under the title "A Simple Method for the Determination of Ethyl Alcohol in Blood."

RUPTURE OF LIVER

To the Editor—Would you kindly send me information regarding the mortality, the prognosis and the number of cases of recovery following operation for rupture of the liver due to trauma.

M D, New York

ANSWER—According to Deaver and Ashhurst (*Surgery of the Upper Abdomen*, ed 2, Philadelphia, P Blakiston's Son & Co, 1921, p 598) the mortality in cases of rupture of the liver not treated operatively is probably about 80 per cent. Tilton (*Ann Surg* 41 27, 1905) considers the mortality in cases in which operation is performed about 60 per cent. Undoubtedly there are many minor ruptures of the liver that recover without operation. In cases in which the hemorrhage is subcapsular, the need for immediate operation is less pressing. Moynihan (*Abdominal Operations*, ed 4, Philadelphia W B Saunders Company 2 236, 1926) Ochsner and DeBakey in *Christopher's Textbook of Surgery*, Philadelphia, W B Saunders Company, 1936, p 1283) believes that instant operation is advisable in suspected cases. The mortality is definitely increased in delayed operation.

SOLUTION OF POSTERIOR PITUITARY IN TREATMENT OF HERPES OF EYE

To the Editor—Will you kindly advise me regarding the therapeutic effect of double strength solution of posterior pituitary in treating herpes and dendritic ulcer of the cornea. Has this drug any healing properties or does it merely relieve the pain? In *Gifford's Ocular Therapeutics* page 125 it is intimated that solution of posterior pituitary should be given for the pain only but says nothing as to its healing or curative effects.

C L CHAMBERS M D Des Moines, Iowa

ANSWER—The use of solution of posterior pituitary is not advised in the treatment of dendritic ulcer of the cornea (herpes simplex) but only for herpes zoster ophthalmicus. In this condition it seems to affect the pain alone and none of the other signs of the disease. If the cornea is involved, other local treatment will be necessary. The only mode of general treatment that affects the course of herpes zoster seems to be the use of convalescent serum or whole blood of convalescents in large quantities. Serum from patients who have recently had varicella seems to be of almost equal value if zoster serum is not available.

RAYNAUD'S DISEASE

To the Editor—A woman aged 42 has Raynaud's disease. At present the fingers and toes get white to purplish, painful and numb. From laboratory tests all defects of the body are being cared for and she feels somewhat improved. What suggestions have you?

M D California

ANSWER—In some instances Raynaud's disease is not particularly harmful since it does not progress. In most instances there is a tendency to gradual progression characterized by increasing ease with which attacks of discoloration of digits are induced, by recurrent infections about the fingernails, by small, painful ulcerations on the ends of the fingers, or by scleroderma.

Sympathectomy, with which neurosurgeons have had a wide experience, is uniformly successful when performed for Raynaud's disease involving the lower extremities. This uniformity of success is lacking to some degree in operations on the sympathetic nervous system for Raynaud's disease affecting the upper extremities. However, in the hands of an experienced neurosurgeon the probabilities of complete cure or significant amelioration are good.

It is probable that this patient should have a sympathectomy. The subject is reviewed and references are made to other articles by Allen and Brown in their article on Raynaud's Disease in THE JOURNAL, Oct 29, 1932, page 1472.

VITAMIN B AND HAIR COLOR

To the Editor—Please give me references to reports on the use of the B vitamins in restoring natural color to gray hair.

ISIDOR F SHAPIRO, M D Bronx, N Y

ANSWER—Claims that any of the vitamins restore gray hair to its normal color should be regarded with suspicion. Search of the recent literature of vitamins gives no ground for such a claim. According to R A Peters (*The Vitamin B Complex*, *Brit M J* 2 903 [Nov 7] 1936) the symptoms of vitamin B₁ deficiency may be loss of appetite, edema, palpitation, breathlessness, especially when there is defective removal of blood lactic acid after exercise, neuritic conditions and painful muscles.

Deficiency of vitamin B is believed to be an important factor in the causation of pellagra. The lack of vitamin B₆ causes dermatitis in rats. Other parts of the vitamin B complex may play a part in the causation of pinta disease of children, black tongue in dogs, some heart conditions and some forms of cataract.

TUBERCULOUS EPIDIDYMITIS AND COITUS

To the Editor—A man 44 years of age married by renal tuberculosis with unilateral epididymitis and orchitis of several weeks duration. His temperature is normal and there is little pain at present. He has been advised to abstain from coitus but states that he is nervous and irritable and that in spite of the advice he has had intercourse once or twice and feels much better for several days afterward. How much harm will this do him? Is there danger of coitus causing a bilateral involvement?
M D Colorado

ANSWER—It seems unlikely that the patient will do himself harm by having coitus once or twice a week especially since he feels better for several days afterward. In cases of tuberculosis of one epididymis there is always the possibility of involvement of the opposite side. The second epididymis becomes involved in about 40 per cent averaging about two years after the onset of the tuberculosis in the first epididymis so that bilateral involvement may take place either with or without coitus. Therefore it seems justifiable to grant permission for coitus.

ARGYRIA FOLLOWING NEOSILVOL NOSE DROPS

To the Editor—What is the possibility of development of argyria following prolonged use of neosilvol in the form of nose drops? I can find no reference to this subject in the literature I have consulted.

M D North Carolina

ANSWER—In their summary of generalized argyria Gaul and Staud (Clinical Spectroscopy, *THE JOURNAL*, April 20, 1935, p 1387) state that "argyria developed in 65 per cent following pharyngeal and intranasal applications and in 35 per cent following peroral administration. The duration of the local and systemic treatment varied from one month to eleven years. Neosilvol was used in 20 per cent, collargol in 22 per cent, and argyrol in 55 per cent of the cases." In a table they give references to fifteen articles citing neosilvol as the cause of generalized argyria.

STERILIZATION AND PRESERVATION OF COCAINE SOLUTION

To the Editor—Please tell me the proper way to make a sterile solution of cocaine for use as a local anesthetic in the eye and how long it will remain sterile if not contaminated.

M D Ohio

ANSWER—Cocaine solutions may be sterilized in the autoclave at 15 pounds for fifteen minutes without interfering seriously with their effect. Such solutions when kept sterile can be used for two to three weeks and probably longer. With solutions for instillation which are opened frequently it is best to add 40 grains of boric acid crystals to the ounce to prevent mold and bacteria. The solution prepared in this way remains clear and retains its effect for several months.

CONTACT LENSES

To the Editor—A recent magazine article described the use of contact lenses in place of ordinary glasses. This article appeared in *Collier's* for June 26. I have been requested by a patient to get some information on this subject. What is the current opinion as to the safety of such lenses?

LEWIS BOOKER M D New Castle Del

ANSWER—There is a thorough review of the question of contact glasses in the June issue of the *Archives of Ophthalmology* by Mr T E Obrig of New York. Among those who have had experience with contact glasses it is believed that there is less danger of injury to the eye by breakage than from ordinary spectacles.

IS THERE A MALE CLIMACTERIC?

To the Editor—Is there a male climacteric and is it attended by physical and nervous phenomena? What therapy is available?

M D Pennsylvania

ANSWER—Although the term "male climacteric" has been used by several writers, the accuracy of the term is doubtful. The female climacteric represents the definite cessation of a function accompanied by certain phenomena which vary in intensity and the entire clinical picture may take a few years and does not start or terminate at the same time in different women. In the male, however, there is no such definite cessation of function. One man may lose his sexual vigor at 30 and another man may continue to be sexually vigorous beyond 70. It is true that as a rule between 55 and 60 the sexual

vigor declines and also around this time the prostate may give trouble, but these symptoms do not necessarily appear, whereas the menstrual function in the female must stop at some time, generally between 45 and 50. It seems no more logical to speak of a male climacteric than it would be to call the ages between 5 and 10 the measles period because many children get measles at this time.

FRENUM OF UPPER LIP

To the Editor—Will the removal of the frenum of the upper lip at its attachment between the central incisors prevent too large a space between the central incisors in babies and will it cause a narrowing of this space? Would you consider this an accepted surgical procedure?

E P WEIN M D Clinton Iowa

ANSWER—Removal of the frenum of the upper lip, at its attachment, is of benefit in narrowing the space between the central incisors. However, this procedure is not advisable until the permanent upper lateral incisors have erupted. When these teeth erupt, they often force the central incisors together. If, however, after the lateral incisors have erupted, the space between the central incisors is still too wide, removal of the attachment of the frenum to the periosteum is an acceptable procedure.

SYPHILIS IN PREGNANCY

To the Editor—The answer under Syphilis in Pregnancy (*THE JOURNAL* August 7 p 451) contains a serious mistake which deserves correction. It states that a positive Wassermann reaction on the cord blood specimen is a reliable criterion of syphilitic infection of the new born infant. Modern literature is filling up with corrections of this old misconception. A positive Wassermann (or other reliable serologic test for syphilis) on the cord blood or on venous blood of the new born infant may and very often does simply reflect the presence of syphilitic reagents transmitted from the Wassermann positive mother to her infant in utero. This transmitted reaction may persist for several weeks or months. One way of evaluating it is to titrate the strength of the reaction a falling reaction presumably indicating such a passive transfer of reagents from the mother. A rising titer would indicate probable syphilitic infection of the infant.

Not all laboratories are equipped to carry out such a titration. In that case reliance should be placed on physical examinations, roentgenograms of the long bones and a persistence of the positive serologic reaction. According to a personal communication from Dr Christie of Harriet Lane Home Johns Hopkins Hospital a definitely positive serologic reaction at four months probably indicates syphilis. One should add that even the best and most sensitive tests on the serum are not always positive on a single examination but certainly they are when the infant has clinical signs of congenital syphilis.

One should emphasize the point that the washing out of the early positive transmitted reaction does not necessarily preclude the later development of a true positive reaction and clinical signs of syphilis. Therefore an apparently uninfected infant born of a syphilitic mother should be kept under observation for at least one year.

JOHN V DAVIES M D Boston

ERGOTAMINE TARTRATE IN MIGRAINE

To the Editor—In Queries and Minor Notes (*THE JOURNAL* August 7 p 450) you recommend the hypodermic use of 1 mg of ergotamine tartrate. Relief afforded by the hypodermic injection of ergotamine tartrate (1 mg) at the onset of a seizure would be of further diagnostic value. Having had experience in the use of the drug I should like to call your attention to the fact that the injection of such a quantity might prove distinctly dangerous. It has been our custom never to inject at a single time more than 0.5 mg (1 cc) of ergotamine tartrate (gynecten); the usual initial dose being 0.25 mg. May I take the liberty of referring you to Lennox and von Storch, Experience with Ergotamine Tartrate in 120 Patients with Migraine (*THE JOURNAL* July 20 1935 p 169 and von Storch, *New England M J* 217:247 [Aug 12] 1937).

I am in the process of preparing a study of the dangers and accessory effects concerned in the use of ergotamine tartrate in the treatment of migraine in a series of patients treated for from three to five years. In brief large doses of ergotamine tartrate may be given over a long period of time if the following precautions are rigidly observed: not more than 0.5 mg at a single hypodermic injection nor more than two such injections in twenty-four hours; 0.25 mg always to be used as the initial dose when introduced intravenously, not more than five 1 mg tablets to be used by mouth followed by two per hour to a total of eleven. Contra-indications are coronary disease, obliterative vascular disease, hypovitaminosis (C) active infection and hepatic disease.

T J C VON STORCH M D Neurological Unit Boston City Hospital Boston

EOSINOPHILIA IN PERIARTERITIS NODOSA

To the Editor—In *THE JOURNAL* August 7 p 453 in Queries and Minor Notes is a reply to a question regarding eosinophilia in which mention is made of various diseases that may cause eosinophilia. No mention is made of periarteritis nodosa. About 12 per cent of the cases reported have shown an eosinophilia in one case of 77 per cent. I recently had a case with a total leukocyte count of 20,000 with 50 per cent eosinophils. Textbooks on hematology do not include it as a cause of eosinophilia. Biopsy of a tender area in the calf muscles or deltoid should be done.

Book Notices

A Brief Outline of Modern Treatment of Fractures By H. Waldo Spiers, A.B., M.D., Professor of Orthopaedic and Fracture Surgery, College of Medical Evangelists, Los Angeles, California. Second edition. Cloth. Price \$2. Pp. 137 with 114 illustrations. Baltimore: William Wood & Company, 1937.

The author states in his preface that the book "aims to illustrate the fundamentals in bone surgery and to touch only the high spots in their practical application. Modern textbooks are so filled with illustrations and demonstrations of operative technic, with the discussion of so wide a variety of methods, that the average student or intern is frequently at a loss to know what it is all about." In the main he has adhered to this theme, and the little book has much solid meat in it and should be of use to senior students and those preparing for state board examinations and the like. With such a clear statement as to the purpose, it is strange to find inserted various detailed accounts of operations such as the Watson-Jones approach to the hip joint but with it no reference to where the original article may be found. Bibliographies would be valuable in this book to enable the reader to refer readily to the article cited. The first chapter is devoted to a consideration of fracture problems in general. The statements of the author are necessarily dogmatic and in many spots are plainly taken from lectures to students. The very terseness of the author's statements lose certain of their effectiveness because the reasons back of the assertions are not given, e.g., no mention is made of peroneal paralysis and ulnar paralysis although warning is issued against pressure over the head of the fibula and the internal condyle of the humerus. No mention is made of the much talked of prone position in transporting persons who have sustained fracture of the spine. Exception can be taken to such a loose statement as "fibrous ankylosis is present in all joints which have been immobilized for any great length of time," particularly when the rest of the paragraph clearly shows that the author is well aware of the true pathology of the type of stiff joints that he is discussing. Another statement "The popularity of open reduction of fractures is probably based on the fact that to an extent at least the fee will be proportionately larger," is entirely uncalled for and except in rare instances is untrue and has no place in such a book. It takes no great flight of the imagination to see how this may be seized on by unfriendly lawyers and other persons to use against the medical profession. Likewise the statement "In this day of scientific treatment of fractures it is almost criminal neglect to fail to check up the results of reduction by x-ray films" is a two edged sword and surely the very evident necessity of such a procedure could have been couched in more fitting language. The remaining chapters are devoted to special types of fractures and, considering the pages at the author's disposal, are well done. His brevity in discussing such an important condition as ankle fractures might be criticized. The statement that the rather rare but potentially vicious trimalleolar fracture accompanied by posterior displacement of the foot usually required operation to replace the posterior tibial marginal fragment can be questioned for it is generally agreed that such an operative procedure is but seldom required. The author is evidently a staunch supporter of Bohler's methods. The last chapter, devoted to fractures of the mandible is evidently inserted in this edition to make for completeness and which opens with the advice that patients so afflicted are best

handled by the oral surgeon. All in all here is a useful little book, and the fact that there has been a demand for a second edition may mean that further opportunity for improvement will be afforded the author.

Methodik der Hormonforschung Band I Schilddrüse Nebenschilddrüse Nebennierenrinde Nebennierenmark Pankreas Von Dr. phil. Christian Bomskov. Paper. Price 54 marks. Pp. 716 with 231 illustrations. Leipzig: Georg Thieme, 1937.

The author of this treatise has endeavored to include in one book all the essential methods of investigation on the glands of internal secretion. There are detailed reference in this first volume to the thyroid, parathyroid, adrenal cortex, adrenal medulla and pancreas. The result is encyclopedic. A vast amount of information not elsewhere accessible in convenient form is gathered here. This includes details of anatomy, surgical technic (including forms and dosages of anesthetics for various laboratory animals), methods of handling and administering extracts to animals, blood histology and blood chemistry of different species, histologic technic, methods of recording physiologic changes, methods of extraction and purification of glandular extracts, methods of controlling hydrogen ion concentration including tables of indicators, detailed consideration of the physiology of each of the five glands mentioned with reviews of the literature, tables of patents on glandular products and a thousand other items too numerous to mention. It is therefore a useful reference book. But it has a serious fault common to many compilations of this type. The good and the bad are included indiscriminately and quite uncritically. No adequate effort has been made to weed out unsatisfactory methods or to sift carefully the literature on glandular physiology. The errors of fact and judgment in this volume are plentiful. The section on the adrenal cortex being an especially unfortunate example. Many typographic errors occur also. Bomskov's work may therefore be recommended only to experienced investigators in endocrinology, who will find a wealth of useful material but will not be misled by the abundant nonsense that has inadvertently crept in. The book is profusely illustrated with excellent reproductions of photographs and drawings.

Annual Reprint of the Reports of the Council on Pharmacy and Chemistry of the American Medical Association for 1936 with the Comments that have appeared in The Journal. Cloth. Price \$1. Pp. 104. Chicago: American Medical Association, 1936.

This small annual volume is indispensable to the library of physicians, pharmacologists and others who need to keep abreast of the latest developments on the frontiers of medical progress. It gives the details of the Council's consideration of products which have been found unacceptable as preparations for use in rational therapeutics and its reports on those which show promise but are not yet ready for general acceptance.

Among the reports on out-and-out unacceptable products are Amends Solution and the "Igol" products, iodine preparations marketed under misleading or unacceptable claims, the latter under an uninformative proprietary name, Androstine Ciba, claimed to be a testicular extract and found to be an irrational combination of inactive preparations marketed with unwarranted and misleading claims, Gadomont, a preparation of cod liver oil in a wax base with zinc oxide, benzoic acid and phenol, proposed for use in the treatment of burns, cuts and minor skin irritations, found unacceptable as being an unoriginal product of insufficiently declared composition marketed under a coined proprietary name with unwarranted therapeutic claims, and indirectly advertised to the public, the "Carasyl" preparations, which are essentially mixtures of psyllium flour, karaya gum and fig flour, marketed with unsubstantiated therapeutic claims under a proprietary name.

In 1934 the Council sponsored an exhaustive report on bacteriophage therapy which pointed out that in view of the present status of knowledge, no such preparations could be accepted for New and Nonofficial Remedies. In this volume of the collected Council reports the Council declares the "Phagoid" preparations, a line of bacteriophage products, definitely unacceptable because they are offered to the medical profession with unscientific, unwarranted claims thus encouraging physicians to use in a routine way medicaments the therapeutic value of which has not been established and because the preparations conflicted in other ways with the rules of the Council.

This volume includes a preliminary report on Trichophyton and Oidiodermis—trichophyton preparations marketed by Lederle Laboratories, Inc. This report is a sequel to the preliminary report on Trichophyton Extract issued in 1932, which postponed consideration to await development of further clinical evidence on trichophyton therapy. Also included in this volume is a report on the unacceptability of two trichophyton preparations, Dermatocol and Dermotricofun, distributed in this country by Ernst Bischoff Co., Inc., under the stated proprietary names without sufficiently declared composition and with unwarranted therapeutic claims.

Other preliminary reports are Refined and Concentrated Antipneumococcal Serum Type VII—Lederle, Present Status of Tetrachlorethylene (since accepted for N N R), Smallpox Vaccine (From Chick Chorio-Allantoic Membrane)—Lilly, and Use of Trichloroethylene for General Anesthesia.

A short report in this volume relegates to the therapeutic scrap heap the following, which formerly stood accepted: Filicic Acid and Related Substances, Ipecac Principles and Preparations, Manganese Compounds, Betanaphthyl Salicylate, Thorium Salts and Preparations, and Silver Citrate.

Important general reports are those on Injection Treatment of Hernia and Nomenclature of Endocrine Principles. Under the latter are included reports on the nomenclature of corpus luteum hormone, the estrus-producing compounds and the "male hormones." This valuable report enhances the prestige of the Council as a leader in the field of scientific nomenclature.

Studies in Sibling Rivalry. By David M. Levy, M.D. Research Monographs No. 2, American Orthopsychiatric Association. Lawson G. Lowrey, M.D., Editor. Paper, Pp. 96 with 12 illustrations. Menasha Wisconsin. George Banta Publishing Company, 1937.

This work consists of two studies, originally published in the *American Journal of Orthopsychiatry*. They are presented primarily as an experiment in methodology in which the play activities of children, under controlled conditions, are used to study "principles of motivation in social relationships." The first paper, on the use of play technique as experimental procedure, presents statistical summaries of studies in sibling rivalry. A standardized play situation is used. The child is exposed to a play with dolls in which a brother or sister doll observes a new baby nursing at the mother's breast. The author summarizes the activities observed in response to this hostility-provoking situation and presents the details of the dynamic patterns noted. More particularly he notes distinctive primitive patterns of hostility and definite modifications of these of the nature of atoning for, undoing or denying the effects of the hostile acts.

The second paper is a more detailed study of the patterns of hostility observed in the sibling-rivalry experiments. The subjects were twelve 3 and 4 year old children. Here the author summarizes and graphically charts the precise reactions of the children to the controlled play situation. In addition to the uninfluenced responses of the children, he also observes the effect of offering a direct stimulus toward manifestations of hostility. The activities of the children in attempting to prevent the carrying out of hostile actions, the exact forms and methods whereby hostile acts are carried out, the efforts to make restitution, and the methods whereby the child defends himself against the possible consequences of his hostile behavior are minutely recorded.

It is demonstrated that the dynamics of behavior is essentially the same through the entire series of cases. While details of the pattern vary somewhat, they remain consistent for a given child in repeated experiments. These differences are not accidental but are determined by the child's previous responses in actual sibling-rivalry situations and by other features of his psychic life. The child, at the age of 3 years, already manifests reactions to his hostile tendencies of the nature of checking or controlling them. If the hostile feeling is released, it follows the pattern typical for the child following which "self-redeeming" behavior is manifested.

The author discusses the possible therapeutic effect of exposing children to the opportunity for manifestation of hostility afforded by the experiments. He is able to show that certainly immediate effects of the experiment can be observed, usually of the nature of freer expression of hostility on the part of the child. A favorable change in relationship with the real mother

and baby is observed when there has been free release of hostility in the repeated experiments. It is not demonstrated, however, that lasting effects are achieved as a result of the experiments. Some of the children were under active psychotherapeutic treatment other than that connected directly with the experiments.

These studies are of first importance chiefly on account of the demonstration of an objective use of play in the study of the mental life of the child. Stimulated by psychoanalytic experience, the interpretation and meaning of the behavior are derived by direct observation of the repeated sequences. Dr. Levy definitely points a way that should yield fruitful results in the hands of investigators who can be as discriminating as he is in these studies.

What It Means to Grow Up. A Guide in Understanding the Development of Character. By Fritz Kunkel, M.D. Translated by Barbara Koppelman Compton and Hulda Nebuhr. Cloth. Price \$2. Pp. 180. New York & London: Charles Scribner's Sons, 1936.

Kunkel outlines simply and directly the dynamics of the development of personality types and enumerates the basic determinants in the formation of various behavior patterns. The book identifies critical situations in growth and stresses the necessity of the individual facing them to alter his personality structure in the direction of maturity. Maturity, Kunkel states, is gaged by the development of "tension capacity," the possession of which differentiates adult behavior from immature reaction patterns. Tension capacity, which in everyday life is synonymous with courage, enables one to ignore egocentric drives and achieve objective attitudes. A person who lacks this faculty adheres to selfish patterns and is unable to meet menacing life situations satisfactorily. In the last chapter a discussion of the critical growth period from childhood to maturity is well treated. The suggested philosophy of life is constructive and is founded on tangible principles. In emphasizing the part played by early experiences in shaping reaction patterns, the book recalls the extreme attitude of the behavioristic school of Watson. A nontechnical terminology is employed throughout. If only as a popular reformulation of generally accepted principles, the book should prove interesting to parents, teachers and those concerned with child guidance.

Le traitement du diabète infantile par l'insuline. Par M. E. Aubertin, professeur à la Faculté de médecine de Bordeaux. Association Française de Pédiatrie. Neuvième Congrès des pédiatres de langue française tenu à Bordeaux les 23, 29 et 30 Mai 1936. Paper. Pp. 67. Bordeaux: Imprimerie M. Durand, 1936.

This is an excellent summary not only of the use of unmodified insulin in juvenile diabetes but of the dietary treatment and course of the disease. It is divided into four parts, consisting of a discussion of dietary treatment, indications and use of insulin, the accidents of insulin, the indication for insulin therapy in the course of special conditions and end results in treatment. The author believes that practically all cases of juvenile diabetes should be treated with insulin and with a quantitative diet, which prevent the progression of the disease and its complications. He discusses all the dietary forms of treatment, including an unusually good discussion of Stolte's diet. He refers to Allen's experiments of producing degeneration islets by overfeeding and the experiments of La Coste and Saric, who, by undernutrition and insulinization of normal persons, produced a depression of endogenous insulin output. He concludes that a middle course in the treatment of diabetes is indicated, namely, that the carbohydrate should form from 35 to 40 per cent of the total calories, the protein 15, 12 and 10 per cent, according to age, and the fat from 45 to 50 per cent. The calorie value of the diet begins at the age of 1 year with 1,000 calories, and to this he adds 100 calories each year. He points out that the four unusual accidents of insulin administration are infections, hypodystrophy, anaphylaxis and edema. He discusses hyperinsulinism in detail and the fatal cases reported in the literature. In the third part the infrequent occurrence and the treatment of infantile diabetes is discussed, and the treatment during infections and surgery. Tuberculosis he finds, is a rare complication and hypochlosterolemia an index of poorly controlled diabetes. Cataracts, arteriosclerosis and hepatomegaly are the sequels of failure to control the disease. He concludes with a discussion of preventable causes of death. The work may be highly recommended to all students of the subject.

Toe Casting and Liquid Rubber Technic By William H. Woolf, Pod G Instructor in Podiatry, The First Institute of Podiatry, New York. Edited by Maurice J. Lewi, M.D., President, The First Institute of Podiatry. Cloth. Price \$1.50. Pp. 88 with 73 illustrations. New York: Harriman Printing Company, Inc. 1937.

This little book was written by a chiropodist and edited by a physician. The subject is laboratory technic. It presents the methods by which one can make models of toes, arches, bunions, corns and other minor distortions of the foot. It reveals the way liquid rubber can be utilized in the preparation of corn splints, bunion shields, hammer toe protectors and arch supports. Traction bunion splints can also be made. These liquid rubber appliances are easy to keep clean and can be used a long time. The use of liquid rubber in chiropody will gradually supplant the present leather and felt appliances for foot comfort. It requires some practice to make good models by casting and also practice to use the liquid rubber successfully. It takes too much time for any one but a laboratory technician or appliance maker. The making of these rubber appliances will appeal chiefly to chiropodists and it is for them that this volume was written. The use of liquid rubber has merit and time will improve the technic of preparation and its usefulness.

Diagnóstico dos aneurysmas da aorta torácica Por Geraldo de Andrade, docente livre de clínica médica da Faculdade de medicina do Recife. J. Aguiñaldo Lins, director do Instituto de Radiologia do Hospital Portuguez Recife. Bibliotheca medica brasileira. Monographias. Serie II. Vol. IV. Faprilkoid. Pp. 329 with 93 illustrations. São Paulo: Companhia Editora Nacional. 1936.

This book reports the results of a large clinical and anatomopathologic study of aneurysms of the thoracic aorta, including the ascending, transverse and descending portions. The first and second chapters deal with etiology, pathogenesis and differential diagnosis. Special reference is made to the incidence of aneurysm in relation to age, sex, geographic region and type of work, and on the role of either physical or psychic trauma and constitutional (especially cardiac) malformations. This is followed by chapters on the value of certain objective signs in diagnosis, such as the presence of anisocoria, the Argyll Robertson pupil, exophthalmos, Horner syndrome, pallor, congestion of the face, the technic and significance of palpation, and the effects of aneurysms of the thoracic aorta on the radial pulse, the heart rhythm and the arterial and venous pressures. The detailed aspects of the book are illustrated by the presence of chapters on auscultation and x-ray examination of the lungs, the role of pain in diagnosis, and the symptoms of aneurysm, which take up four chapters. The x-rays, especially with regard to differential diagnosis, are discussed exhaustively. The bibliography covers eight pages. The book is well prepared, and the printing and the illustrations are neat and clean. The book should be of use to cardiologists, internists and syphilologists.

Wundheilung Von Prof. Dr. Wilhelm Lohr, Direktor der chirurgischen Klinik des Städtischen Krankenhauses Magdeburg Altstadt. Paper. Price 21 marks. Pp. 234 with 141 illustrations. Leipzig: Johann Ambrosius Barth. 1937.

The aim of this book is to emphasize the importance of the nutrition therapy of wounds, and especially of local vitamin therapy by means of cod liver oil, which was introduced by the author over six years ago as a result of his twenty year study of the systemic reaction of the body to wound metabolism. In tabular form the author shows that many therapeutic diets are greatly deficient in the minimal vitamin requirement, particularly of B and of C. This is especially true for the peptic ulcer diet, various dyspepsia diets, the Karell diet and the ketogenic diet. As healing and defense against infection demand an increased supply of vitamins, it is probable the author believes, that the vitamin deficiency of these diets must be corrected to secure optimal therapeutic results. To remedy this defect he adds yeast to milk in his clinic and employs a diet rich in vitamin C in all acute febrile as well as chronic infections (typhoid, tuberculosis, pneumonia, gastro enteritis, wounds). Whenever there is doubt as to the proper absorption of vitamin C on account of unfavorable conditions in the digestive tract, he gives it parenterally. The oil soluble vitamins A and D, he employs whenever possible by local application, although even internal administration of cod liver oil hastens

the healing of wounds. He employs with asserted good success, in addition to the Leube diet, 20 Gm. of unrefined cod liver oil four times daily, the last dose at bedtime. The oil is administered either in lemon juice or in apple sauce. Lohr points out that commercial cod liver oil is sterile and that experiments have shown that the best results are obtained by mixing it with petrolatum of a melting point near the body temperature. The addition of cholesterol has proved irritative. He injects from 3 to 4 cc. of pure cod liver oil into chronically inflamed joints with alleged good results. Another item in wound therapy on which the author lays great stress is the closed plaster-of-paris cast, which he applies to all wounds after filling the unsutured wound with cod liver oil ointments. Photographs showing remarkable results with this method are reproduced. He treats in the same manner the large defects left after surgical extirpations and operations, e.g., osteomyelitis and even gas gangrene. He also recommends cod liver oil ointments in burns, no matter how extensive, including those due to x-rays. He ascribes his good results largely to the absolute immobilization secured by his method and avoidance of chemicals, drains and gauze. The author feels emboldened by his results and those of others to suggest that his cod liver oil-plaster-of-paris dressing may make mutilating debridement a thing of the past. To all surgeons the perusal of this book is recommended as a lesson of the *vis medicatrix naturae*. Unfortunately, the author does not see fit to give the exact formula of the salve that he employs even though he lays great stress on its correct preparation, referring the reader to a special salve made by a manufacturer who is "expert" in this field.

Materia Medica including Pharmacology and Therapeutic Hints By S. Chatterjee, B.Sc., M.B., Pharmacology Department, Calcutta Medical Institute. Cloth. Price 6s. 6d. Its. 4/. Pp. 391. Calcutta: Medini Publishers. 1935.

This book is designed primarily for the use of students at the Calcutta Medical School. It is a brief treatise of materia medica and pharmacology in outline form. It contains much essential information, which is readily available because of the size of the book. It is obvious, of course, that a book of this nature cannot serve as a textbook but should prove useful when reference to the more salient features of drug actions, toxicology and therapeutics suffices. A classification of drugs similar to the therapeutic index in *Useful Drugs*, extended to cover the details of the uses, is included in the book along with the usual tables on foods, incompatibilities and abbreviations. Under "Drugs Acting on the Generative Organs" there is a subheading "Direct Aphrodisiacs"—strychnine, camphor, alcohol, opium, cannabis indica and cantharides, and under "Indirect Aphrodisiacs"—drugs that cause general improvement of health—"iron, arsenic, strychnine and glandular products." The index is followed by advertising pages, which include the promotion of some rather unusual preparations. The first is "Hewlett's Mixture"—Mist Pepsinae Co c Bismutho (similar to the British Pharmaceutical Codex preparation *Mistura Bismuthi Composita cum Pepsino*), which is indicated to be "useful in all forms of dyspepsia, pyrosis, gastric pain, vomiting and for alleviating pain in cases of ulcer and cancer of the stomach." Other advertisements include "Gametoxan," said to be diethanol dihydroquinamine uranyl hydrochloride, "Neotropin"—no formula given, and "Sulfarscnol"—the latter without any indication that it is a brand of sulfarsphenamine. The book is intended primarily to promote the rational use of drugs common to the practice of medicine in Calcutta and it is therefore rather surprising to find so many advertisements for patent medicines.

For Peace and Good: A Handbook of Contemporary Politics By Joseph Tiberius Trenchard, Ph.D. Cloth. Price \$2.50. Pp. 174. New York: Economists Incorporated. 1937.

Although the blurb on the jacket says that the author "is recognized as one of the best informed consulting economists" there is little in the book to indicate that he has a knowledge of even the most elementary principles of any recognized school of economics. The work is essentially one of the utopian schemes which seem to have come forth constantly since the time of Plato. He rewrites the constitution of the United States and proposes a complete reorganization of the American system of government. In spite of the announcement that a

middle course between communism and fascism is to be taken, the author rejects most of the essentials of democracy and follows the pattern of the totalitarian states. He would regulate hours and wages, limit free education to the common school, bar married women from industry, introduce a system of health insurance, and impose a bachelors tax. The final touch is furnished by the reproduction of a form letter such as every one writing to the President receives, as if it were a presidential recommendation.

Über einige neue Arzneimittel II. Von P. Wolff. Sonderabdruck aus dem Schweizerischen medizinischen Jahrbuch 1937. Paper. Pp. 87. 114. Basel: Benno Schwabe & Co. [n. d.]

The steady increase of diabetes mellitus among civilized nations and the extensive search for a prolonged acting insulin brought forth protamine zinc insulin for the treatment of the diabetic patient. In this book the existing literature on insulin and its longer acting substitutes is thoroughly reviewed. Any one acquainted with the subject knows how difficult this task is. This monograph, which appeared in the Swiss medical year book, can be highly recommended to research workers and clinicians who wish to be informed on the various aspects of insulin therapy. Its special usefulness lies in the extensive bibliography.

Manual of Public Health Laboratory Practice. By J. R. Currie. Henry Mehan, Professor of Public Health, University of Glasgow and Contributors. Cloth. Price \$6.75. Pp. 378. With 169 illustrations. Baltimore: William Wood & Co. 1936.

The author distinctly wants it understood that this manual is written primarily for medical graduates. The subjects include chemistry, bacteriology, protozoology, helminthology and meteorology. It is written with directness, so that there is little waste space. Because of the difference in English pure food laws, many of the food analyses might not apply to American equivalents. The author does not expect physicians to be trained chemists and hence this material is condensed and all discussions are brief, much that is considered to be outside the realm of the ordinary public health officer being dispensed with. There are, however, much information and many illustrations which a doctor called on to assume part time public health duties would find of assistance. While not meeting any urgent need in this country because of legal and geographic variations, this is an eminently practical book.

Bernhard Bang. Selected Works. Edited by Vald Adersen. Professor at the Royal Veterinary and Agricultural College, Copenhagen. Paper. Pp. 560. With illustrations. London: Oxford University Press. Copenhagen: Levin & Munksgaard. 1936.

The Danish veterinary pathologist Bernhard Bang died June 2, 1932, in the eighty-fourth year of his life. Shortly before his death Professor Bang was asked to publish in the chief languages a selection of his most important scientific works, which had secured for him a world-wide reputation. The negotiation had not been completed when Professor Bang died. The present volume was edited by Professor Adersen under the sponsorship of the Rask-Ørsted Foundation. The works included in the present selection of Professor Bang's extensive literary productions have been divided into three groups, in each of which they are arranged in chronological sequence. The first group comprises Bang's investigations on a series of important animal diseases (infectious abortion of cattle, actinomycosis, mastitis in cattle, infections caused by the bacillus of necrosis, endocarditis in swine, erysipelas, chronic bacterial enteritis in cattle, and abortion due to tuberculosis). The second group comprises Bang's investigations on tuberculosis of the udder and on tuberculous milk. The last group comprises a selection of Bang's works on tuberculin and its employment in combating tuberculosis in cattle. Bang's comprehensive literary productions are characterized by an extraordinary degree of simplicity, clarity and conciseness. All students of diseases of animals transmitted to man will profit greatly by a perusal of this volume, particularly as relates to Bang's investigations of those diseases which brought him well merited acclaim: infectious abortion of cattle (Bang's disease), tuberculosis and actinomycosis. Many of the papers are published in the English language; others are written in French or German. The fundamental contribution of Bang in his discovery of the causation of contagious abortion of cattle provided other investigators

with the knowledge that led to the later discovery by Evans of the etiologic unity of this disease in cattle and brucellosis (undulant fever) in human beings.

Surgical Anatomy. By Grant Vassle, M.B. M.S. F.R.C.S. Assistant Surgeon, Guy's Hospital, London. Third edition. Cloth. Price \$6.50. Pp. 468. With 153 illustrations. Philadelphia: Lea & Febiger, 1937.

Compendiums of anatomy must be brief, concise, accurate, and above all lucid. This small volume possesses all these qualities in a form sufficient to satisfy most persons. Written mainly for the intern and last year medical student, it will fill their needs as well as any other short anatomic reference book. The author strikes a satisfactory balance between anatomy and clinical application and at the same time does not stifle his immature reader with voluminous detail. Illustrations are ample in most cases to describe the text; they are well labeled and fully summarized. While in no sense a substitute for an anatomy book, this volume will serve admirably to refresh the memory on the relation of bodily structure to surgical problems.

Childbirth Yesterday and Today. The Story of Childbirth Through the Ages to the Present. By A. J. Rongy, M.D. F.A.C.S. Attending Obstetrician and Gynecologist, Lebanon Hospital, New York City. Cloth. Price \$2. Pp. 192. With 20 illustrations. New York: Emerson Books Inc. 1937.

This book describes the way in which women of the primitive ages, and those in various civilized countries, coped with the problems of pregnancy and childbirth. In the discussion on childbirth among primitive people is included tribal customs and traditions, and an insight is given into the way in which childbirth was regarded by the Hebrews, Egyptians, Greeks and Romans. Successive chapters discuss the glory and weaknesses of the midwife, history of child care, and history of childbirth. The chapter on the reign of superstition reveals the source of many of the mysterious customs that arose from ignorance and tradition. Finally birth control and the present day problem of maternal mortality are presented. Those interested in obstetrics and maternal mortality will find much of interest in the book.

Lehrbuch und Atlas der Haut und Geschlechtskrankheiten. Von Dr. Karl Zieher, o. o. Professor und Vorstand der Universitäts Klinik und Poliklinik für Haut- und Geschlechtskrankheiten in Würzburg. Textband. Tafelband. In two volumes. Fourth edition. Cloth. Price 56 marks. Pp. 684. With 171 illustrations. 196. With 378 illustrations. Berlin & Vienna: Urban & Schwarzenberg. 1937.

One of the most valuable features of this textbook is the series of drawings in black and white by Freytag. These illustrations are admirably done. The colored plates also, which are from Jacobi's historic atlas, are masterpieces of their kind. The text, for so large a volume, is rather sketchy and incomplete. The section on syphilis, pages 382 to 566, probably is best. The suggestions regarding treatment are practical. Apparently the author has great confidence in mercury as a spirocheticide. Malarial therapy in syphilis is discussed, but heat treatment does not receive the attention that its value merits. About 10 per cent (seventy pages) of the first volume is devoted to the history, symptomatology and treatment of gonorrhea. The index is comprehensive.

Diabetes. A Modern Manual. By Anthony M. Shindler, Jr., M.D. Chief of the Diseases of Metabolism at the St. Agnes Hospital, Philadelphia. Introduction by Morris Fishbein, M.D. Editor, Journal of the American Medical Association. With a foreword by George Morris Pier, M.D. B.S. M.D. Professor of Medicine, Graduate School of Medicine, University of Pennsylvania. Whittlessey House Health Series. Morris Fishbein, M.D. Editor. Cloth. Price \$2. Pp. 240. With 5 illustrations. New York & London: Whittlessey House. McGraw-Hill Book Company Inc. 1937.

This manual on diabetes is one of a series for the patient and the physician. It is well written, in a style easy for a patient to read. Any intelligent person can easily grasp the subject matter. It offers much also to the physician in general practice, who can well afford to read it. The summaries at the end of each chapter help to outline quickly the main points and should be of much help to the busy practitioner. Any one who knows its contents can practice diabetes in a rational manner. The book includes some of the most recent work in this subject and is therefore a handy compendium. A whole chapter is devoted to questions asked by the patient and the answers to them, which practically cover the subject. It is not a reference work but a practical manual.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Hospitals Degree of Care to be Exercised by a Hospital—An operation was performed on the appellee in the appellant hospital under spinal anesthesia. Prior to and during the operation an opiate, pantopon, was administered to the patient. Following the operation, the patient was returned to his room where, after an interval of approximately forty minutes during which time the attending physician was present, he was left in the care of a hospital nurse. Subsequently, about eighty minutes after the operation, the nurse left the room for five minutes to make some entries on a chart. During her absence, the patient fell from bed and fractured a thigh bone. In this suit against the hospital, the patient alleged that his injury was attributable to the negligence of the nurse in leaving him unattended. The jury returned a verdict for the hospital, but the trial court granted a new trial because it concluded that it had erroneously instructed the jury. The hospital then appealed to the Supreme Court of Alabama.

An instruction, said the court, was not erroneous which told the jury that, even if it constituted bad judgment on the nurse's part to leave the patient alone in the room, a finding for the patient would not be justified if the jury was reasonably satisfied from the evidence that the nurse did nothing more than any reasonably prudent, careful, skilled and diligent nurse would have done under the same or similar circumstances. It did not predicate negligence only on acts of commission and ignore acts of omission. The instruction clearly stated that, if the act of leaving the room was no more than any reasonably prudent, careful, skilled and diligent nurse would have done under like circumstances, the patient could not recover damages. But, said the court, an instruction was palpably erroneous that told the jury "unless you are reasonably satisfied from the evidence that the servants, agents or employees of defendant, in and about the treatment of Mr. Galloway, used the same degree of care, skill and diligence as used by hospitals generally in this community, then you cannot find for the plaintiff." This instruction told the jury not to find for the patient unless there was no negligence on the part of the hospital's employees. It was in direct contradiction of other instructions and at variance with the pleadings and all the evidence presented under the issues. This instruction, the court said, obviously did not express what was intended by counsel, and was given by the trial court through oversight.

The trial court instructed the jury that the hospital was required to exercise "the same degree of care, skill and diligence as used by hospitals generally in this community." The patient apparently contended that a greater degree of care was required, relying on the case of *Birmingham Baptist Hospital v. Branton*, 218 Ala. 464, 118 So. 741, in which it was said that a hospital was required to exercise "that degree of care, skill, and diligence used by hospitals generally in that community and by the express or implied contract of the undertaking." Broadly speaking, said the court in the present case, that care which persons of common prudence exercise under like conditions is the degree of care recognized by the courts throughout the country. This implies a care having regard to the conditions of the particular case and to the fact that the subjects of nursing are sick people. A hospital is liable for want of ordinary care, whether for incompetence of a nurse or failure of duty by a fully qualified nurse. The added expression in the *Birmingham Baptist Hospital* case and by the express or implied contract of the undertaking is unquestionably correct and pertinent, said the court in framing an inclusive statement of the law applicable to all cases. It does not, however, impose a greater degree of care, skill and diligence than that "used by hospitals generally in that community" unless there is some evidence of an express or implied contract imposing a higher obligation than that implied from the admission of a patient. There was no such contract in the present case. The

hospital, continued the court, is not an insurer of the safety of a patient nor is the doctrine of *res ipsa loquitur* applicable to a case of this type.

The fact that undergraduate nurses are, by the practice of hospitals generally, put in charge of patients following operations in which anesthetics have been employed is not evidence of a want of ordinary care. Such practice must be left to the judgment of those specially qualified by experience and learning. If reasonable and ordinary care and skill are not employed in protecting the patient, the hospital is liable for the consequences, whether the employee in charge is a graduate or an undergraduate nurse. Under the evidence it was a question for the jury to determine whether or not the patient, to all reasonable appearances, had become sufficiently oriented to his surroundings for it to be safe to leave him alone for a few minutes.

Since the trial court did erroneously instruct the jury, its action in granting a new trial was affirmed.—*South Highlands Infirmary, Inc. v. Galloway (Ala.)*, 171 So. 250.

Medical Practice Acts Lectures on the Healing Art, with Incidental Demonstrations, not Practice of Medicine—Hurley, being unlicensed, conducted a school of healing and incidental thereto gave class demonstrations of the application of the theory of healing he taught. Briefly, the central thought of his theory was that if the human body was restored or adjusted to the "center of gravity" and kept so the physical ills of mankind would largely cease. In demonstrating his conception of what would restore the center of gravity, Hurley would cause one of the class to present his nude back to the view of the remaining members of the class and to stand in relation to a plumb line suspended from the ceiling in line with his spinal column, so that departures of the body from gravity would be observable. In promoting restoration of the center of gravity of the body toward its normal, he would lightly touch the subject "on the muscle known as gluteus maximus, on the buttocks," and on other muscles, which he claimed would cause relaxation and induce return to normal. The whole result, he claimed, would be that ills having seat in abnormal distortions of the body, which he said exhausted the category of ailments, would yield to restore gravity. He did not treat individual cases nor did he treat other than in classes, he made no examination as to the physical condition of pupils entering or desiring to enter his classes and did not inquire of them as to whether they were suffering from any ailment. He made no diagnosis in any instance and assured all that his purpose was to teach a technic calculated to eliminate that which he claimed was the cause of all ills. He was convicted under an information which in separate counts accused him of practicing medicine and chiropractic, respectively, without a license. He appealed to the Supreme Court of Colorado.

Hurley, in the opinion of the Supreme Court, was engaged in the practice neither of medicine nor of chiropractic. He did not diagnose and gave no treatment to individuals. A person who does not diagnose does not practice medicine. He taught but one thing—the correct pose of the body and its beneficial effect on general health. He did not profess to cure this man of that disease, but all men of whatever ailment they suffered by imparting one principle of universal application. Furthermore, the practice of chiropractic is defined in Colorado as "the Science of locating and removing interference with nerve transmission." Hurley did nothing within that statutory definition. Nothing that Hurley did, said the court, was inimical to public health, safety, morals or general welfare. To forbid such teaching or to visit criminal prosecutions and penalties because of it would encroach not only on the teacher's right to engage in a lawful activity but on the rights of those who may wish to pursue the outlined course.

Considering the fact that in scientific professional and legislative conception the schools of medicine and chiropractic are wholly different, continued the court, it is inconceivable that Hurley violated both statutes. His acts were in contravention of one or the other statute, or of neither, but not of both. The verdict of guilty returned on either count was equivalent to a verdict of not guilty on the other count. The two verdicts of guilt were at the same time verdicts of not guilty. They were inconsistent and repugnant. Each negated the other.

The trial court, in the opinion of the Supreme Court, should have directed a verdict in favor of Hurley. The judgment of conviction was accordingly reversed—*Hurley v People (Colo)*, 63 P (2d) 1227

Malpractice Limitation of Actions, Suit Based on Tort, Not on Contract—The plaintiff instituted suit against the defendants, two physicians, Feb 18, 1932, alleging that in December 1928 she was suffering from an illness due to some ailment of the uterus, that she verbally employed the defendants to diagnose and treat the condition, that they accepted the employment and agreed to use proper care and skill in diagnosing and treating her ailment, that they treated her until March 1, 1929, when they were discharged and another physician was employed, and that the defendants improperly and unskilfully treated her with radium and certain cauterizing agencies and medicine. The trial court overruled the defendants' demurrer to the evidence and they appealed to the Supreme Court of Kansas.

The sole question before the court was whether the action could be classified as one for damages for breach of an oral contract, to which a three year statute of limitations applied, or as one for damages for malpractice, to which a two year statute of limitations applied. If it were an action for damages for malpractice, it was agreed that the statute had run before the institution of the action and that the trial court should have sustained the demurrer. The evidence, said the Supreme Court, tended to show that the defendants were unskilful and negligent in their diagnosis, that under methods well known they could have determined whether the patient had cancer, but the methods were not used, that they were also unskilful and negligent in their treatment, and that bad results followed. Under this evidence it was clear to the court that the gravamen of the action was malpractice irrespective of any allegation or testimony tending to show a contract for treatment. The action, therefore, sounded in tort and the two year statute of limitations applied. The trial court should have sustained the demurrer. The Supreme Court accordingly directed the trial court to render a judgment for the defendants—*Coulter v Sharp (Kan)*, 64 P (2d) 564

Malpractice Liability for Negligence of Hospital Nurse—An operation was performed on the appellee at the appellant hospital, during which the patient suffered a "collapse." The operating physician, after directing that the patient be removed to her room and that a saline solution be injected, apparently left the hospital and was not thereafter connected with the case. Another physician, whose connection with the case is left in obscurity by the record injected the saline solution, during the course of which injection a hospital nurse "without proven directions therefor" placed an unshielded light globe on the patient between her forearm and breast and covered it with a towel. Severe burns resulted for which the patient sued the hospital. From an adverse judgment, the hospital appealed to the Supreme Court of Oklahoma.

The hospital denied liability on the ground that the two physicians, not it, were responsible for the nurse's negligence. An operating physician, said the Supreme Court, during an operation is responsible for the acts of the attendants and nurses, although they are employees of the hospital. Likewise an operating physician is responsible for the negligence of nurses and attendants when he accompanies and attends the patient and directs treatment after the operation. But for a hospital thus to escape responsibility for the negligence of an employee in caring for a patient after an operation, it must appear that the operating physician "actually exercised supervision and control over the servants" of the hospital at the time of the negligence or lack of care. In the present case the patient was burned after the departure of the operating physician. The hospital insisted that the presence of the other physician in the room when the patient was burned relieved it of liability for the negligent act of the nurse. But, said the court, there was no evidence that this physician was employed by the patient to attend her at the hospital or that he had any authority from the patient to exercise any supervision and control over the servants of the

hospital so as to relieve the hospital from liability. Furthermore, a physician who is working over a patient after an operation to save him from heart failure is not responsible for the negligence of a nurse who burns the patient, it being clear that where an immediate emergency requires all of the physicians' attention, he must leave details to the nurse. *Marchand v Bertrand*, Rap Jud Quebec, 39 C S 49, found in Quebec Official Law Reports, vol 39, p 49, 1910, 60 A L R 152. Again, a physician is relieved from liability for the negligence of nurses and attendants furnished by a hospital when such negligence is not known or discoverable by the physician in the exercise of care and skill by him. *Harris v Fall*, 177 F 79, 27 L R A (N S) 1174

The hospital also contended that the patient had recovered a judgment against the operating surgeon and the physician who administered the saline solution and that that case was determinative as to the absence of liability on the part of the hospital for the negligence of the nurse. The court, however, refused to consider that judgment as determinative of the hospital's liability because the hospital was not a party to the prior case and because in that case it could not have well been determined whether the hospital had complied with its contract to provide plaintiff competent servants, ordinary care and protection.

For the reasons stated, the judgment in favor of the patient was affirmed—*Floever Hospital v Hart (Okla)*, 62 P (2d) 1248

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Electrocardiography in Small Children.—The Glendys use the following modifications in electrocardiographic studies in children. Sanborn red wax paste was used as the contact material in applying the electrodes, which were placed on the dorsum of the forearms, on the anterior fleshy portion of the left lower leg and at the cardiac apex to record the chest lead, the leg electrode being left in place as the indifferent electrode. The sites of application, after being cleansed with alcohol, were rubbed gently with a small amount of red wax paste and a dab of paste the size of a small pea was smeared on each electrode before it was put in place. The electrodes on the extremities hold firmly in place when the metal ring on one end of the retaining strap is placed over the central post of the electrode at its base and the loose end carried round the extremity and adjusted to the proper snugness by sinking the sharp point of the post into the elastic webbing. Similarly, in applying the electrode to the chest, one of the larger openings at one end of the rubber strap is placed over the base of the central post of the electrode, the strap is then carried round the chest and the electrode made fast by placing one of the many small holes over the tip of the post.

Prognosis in Rheumatic Fever.—Leonard studied the relationship of age to susceptibility and resistance in rheumatic fever in 500 patients who had sustained one or more known attacks of rheumatic fever. Just as first attacks of rheumatic fever show a sharp decline in frequency preceding the age of puberty, so also do recurrent (second or third) attacks show a decline during or just after the same age period. Factors responsible for this decline will probably remain unknown as long as the pathogenesis of rheumatic fever remains obscure but two influences were evinced which seem to contribute to it. One of these is that since there is a sharp decline in primary attacks before puberty there will be a sharp decline in recurrent attacks during the years immediately following, for recurrent attacks are more apt to follow a primary attack. However, this is not entirely responsible for the improvement noted at puberty, for another contributing factor is apparent in the analysis of groups of patients who had sustained their first attacks at different periods of childhood. A gradual decrease in susceptibility occurs, which covers the ten year period following the ages of 7 to 9 years. These two factors then, and possibly others, chance to coincide at about the age of puberty to cause a distinct lessening of the number of recurrences. The recognition of this improvement at the age of puberty is of some value in prognosis.

- Pathogenesis of Cortical Necrosis of Kidneys in Rabbits Following Injection of Staphylococcus Toxin. J. H. Glynn, Montreal.—p. 593

Clinical Acute Nephritis.—Bell includes under the term "clinical acute nephritis" all cases of acute renal disease that exhibit a definite impairment of renal function indicated by retention of nitrogenous products, decreased ability to excrete phenolsulfonphthalein, inability to form a concentrated urine, loss of large amounts of protein in the urine, bleeding from the parenchyma of the kidney and severe oliguria or anuria. The 110 cases of acute nephritis that were available for study were subdivided into groups in accordance with the structural changes in the kidneys. There were thirty-one cases of uncomplicated acute glomerulonephritis and twenty cases in which the nephritis was associated with another disease. In the normal glomerulus and in subclinical glomerulonephritis it may be seen that all the capillaries of the lobules are completely invested with a basement membrane, but in clinical glomerulonephritis the capillaries within the lobule become fused together and their inner basement membranes split to form the characteristic intracapillary fibers. The lesions are all intracapillary. In five cases uremia was due to numerous massive lesions of the embolic type, in the absence of endocarditis. Eleven cases are reported in which the principal symptoms were septicemia, hematuria and uremia. This is called the hemorrhagic type of glomerulonephritis. Albuminuria, hematuria and edema of renal origin are evidences of glomerular injury. Tubular disease is evidenced by oliguria and anuria. In rare instances acute uremia is due to multiple thromboses of small renal arteries.

Occasionally tubular nephritis is due to other causes than mercury bichloride poisoning. The acute uremia following transfusion with incompatible blood is due chiefly to obstruction of the collecting tubules by casts of hemoglobin. There is a group of cases in which uremia seems to be partly of extrarenal origin and partly due to distention of the convoluted tubules with minor degenerative changes in their lining cells. In purely extrarenal uremia the kidneys are normal and the azotemia is due chiefly to dehydration and to increased destruction of protein. Decrease of blood chloride is apparently not a cause of azotemia. The azotemia of diabetic coma is due in part to tubular injury in some instances.

Pneumoperitoneum in Treatment of Pulmonary Tuberculosis—The pregnant tuberculous woman suggested to Trimble and Wardrip the possible value of pneumoperitoneum in pulmonary tuberculosis, which reproduces the mechanical effects of pregnancy. The amount of elevation of the diaphragm even during the latter months of pregnancy may be only from 2 to 3 cm, but it is apparently sufficient to be of benefit to pulmonary lesions. If the amount of elevation caused by pregnancy is of value, one can be quite certain that the amount obtained by the use of pneumoperitoneum will also be helpful because as much as two or three times this amount can be obtained. The greatest degree of collapse has been obtained by the use of pneumoperitoneum in conjunction with phrenic nerve paralysis. With the addition of subphrenic pressure by pneumoperitoneum, the paralyzed leaf of the diaphragm may rise sufficiently to reduce the volume of the lung to as little as one third of its original volume. The amount of diaphragmatic rise varies with the individual, but a rise to as high as the third interspace anteriorly on each side has been noted from pneumoperitoneum alone. The elevation of the diaphragm was a little greater with the patient in the upright position also if the patient was on one side constantly the uppermost hemidiaphragm was more affected. Consequently, when pneumoperitoneum is used in conjunction with phrenic nerve paralysis, the patient is kept on his good side. This, of course, is contrary to the procedure when a patient is placed at postural rest or on a bolster. The technic of pneumoperitoneum is very

similar to giving pneumothorax refills. To date three far advanced cases have been made sputum negative. Cough and sputum have frequently been diminished and the patient made more comfortable. Cavities that have failed to close by any other available procedure have been closed by pneumoperitoneum. This is particularly true of basilar cavities. In one case it was effective in closing a large subclavicular cavity which had been present for two years. The beneficial psychologic effect on these patients for whom previously there was little to offer has been marked.

Nature of Cardiovascular Disturbances—To determine whether cardiovascular disturbances in nutritional deficiencies exist as a clinical problem, Weiss and Wilkins investigated the records of some 900 patients suffering from various types of nutritional deficiency, including general malnutrition, chronic alcoholism with or without polyneuritis, pellagra, neuritis of pregnancy and diabetes. There were eighty-five cases in which cardiovascular dysfunction of varying severity could not be ascribed to the usual etiologic factors. Because all instances in which organic lesions of the cardiovascular system existed were eliminated and because many of the cases were observed by physicians not experienced in cardiovascular problems, the number selected must be considered minimal. This conclusion is corroborated by the fact that within a period of two years the authors have personally studied thirty-five patients from a total of 5,506 admissions to two general medical services in this hospital. The observations here presented are therefore based on a total group of 120 cases. The cardiovascular disturbances caused by nutritional deficiencies do not form a rigid clinical syndrome. Right and left ventricular failure, arteriolar dilatation and increased blood flow peripheral circulatory collapse and shock, singly or in combination, have been observed. The onset of the disease may be sudden or gradual. Patients with the severe form of the disease show a tendency to fever, to bronchopneumonia and to acute fatal circulatory collapse. Under therapeutic measures such as rest, cardiac drugs, diets rich in vitamin B₁ or crystalline vitamin B₁, all the cardiovascular disturbances usually revert to normal. The clinical symptoms and signs, the blood chemistry, the myocardial changes, the hemodynamics and therapeutic responses correspond to those described in "beriberi heart" in the Orient. The disease as observed in Boston, however, is characterized by more varied and more generalized involvement of the cardiovascular system. Vitamin B₁ deficiency plays a primary part in the precipitation of the disease. Alcohol also is a significant factor, not only because it supplies calories without vitamin B₁ but also because its metabolic effect is similar to that of a pure carbohydrate. The rate of response to vitamin B₁ in "alcoholic" and "nonalcoholic beriberi" varies. The arteriolar system shows a more rapid change than the heart. The cardiovascular disorder usually disappears before the polyneuritis. The condition described bears pertinently on the clinical behavior and the mortality rates of alcoholic and nonalcoholic patients with vitamin B deficiencies (beriberi and pellagra). It may explain the poor reaction of these patients to increases in metabolic rate, such as occur in febrile infections, in hyperthyroidism or under surgical operations.

Exudative Discoid and Lichenoid Chronic Dermatitis
—Sulzberger and Garbe observed nine cases of distinctive exudative discoid and lichenoid chronic dermatitis. The condition has been confined to men of the Jewish race, appearing during the fourth or fifth decade of life. The onset of the dermatosis has usually been sudden, the generalized eruption was sometimes preceded by a circumscribed dermatitis which was irritated by treatment. The foreground of the picture is dominated by pruritus—by the intractable and uncontrollable itching with its nocturnal accentuation and its frequent veritable crises. The general health remained to a great extent unimpaired throughout, if the transitory loss of weight and the irritability and fatigue are accepted as presumably due to the severe subjective sensations and to the ensuing sleeplessness. The most characteristic objective lesions were sharply demarcated oval and discoid plaques showing rapid variations in consistency and appearance: these plaques were at times flat and scaly, elevated and edematous or oozing and crusting; they would speedily pass through many of the clinical stages considered characteristic of eczematous lesions. The brief oozing surfaces of the plaques and particularly the delicate and often punctate crusts (status punctosus) allowed one to infer that exudation and at least histologic vesiculation had been present. The oozing yielded more or less rapidly to topical therapy or underwent spontaneous involution recurring however either spontaneously or after bouts of scratching and irritation. In all nine cases the more persistent lesions in the form of certain circumscribed disks and plaques as well as certain diffusely affected areas seemed at times to be definitely infiltrated and at these times the picture was suggestive of a premycotic eczema or of some other leukotic dyscrasia. Although no part of the skin could be considered entirely immune to the discoid and oval lesions there was an obvious preference for extensor, as compared with

flexor, surfaces and the perimamillary areas, the anterior and posterior aspects of the axillary folds, the scrotum, the circumoral region, the bridge of the nose, the abdomen and the scapular areas. On the trunk, the long axes of the oval lesions showed a consistent tendency to follow the lines of cleavage. Besides these disks and oval plaques all the patients presented the lichenoid phase and the phase resembling the premycotic stage of mycosis fungoides. Marked cutis anserina and diffuse follicular involvement with often persistent somewhat follicular papules like those of lichen planus were observed in all but one case. Other manifestations which compelled attention were the frequent and often persistent erection of the nipples in seven cases, the edema and swelling and even the complaint of "soreness" of the mamillae and perimamillary areas (seven cases). The usual methods of therapy and superficial application of unfiltered roentgen radiation in the usual dose seemed only to aggravate the condition. Except in one case, removal of certain evident foci of infection was not followed by cure or even by any definite alteration in the course of the disease. On the other hand, hospitalization and certain other changes of environment repeatedly resulted in marked improvement in all but one case. Histologic observations did not enable them to characterize the disease clearly, nor did they permit the classification of the cutaneous lesions as those of any known definite dermatologic entity. In none of the cases were there changes diagnostic of dermatitis herpetiformis, of lichen planus or of mycosis fungoides, of other leukotic dyscrasias or of any other dermatologic entity. The only permissible conclusion seems to be that the process was exudative and inflammatory, favoring the blood vessels, being most severe in the upper layers of the cutis and in the papillary bodies and being accompanied by eczematoid changes in the epidermis.

Smallpox Vaccine in Treatment of Recurrent Herpes Simplex—Foster and Abshier treated thirty-five patients for frequently regular recurrent herpes simplex, by vaccination with variola (smallpox) vaccine. Each patient was vaccinated approximately four times at intervals of two weeks unless a take was noted in which case the reaction was allowed to subside before the treatment was continued. Among this group five takes were noted. The majority gave reactions of immunity which subsided after the interval of two weeks. A follow up after two years showed that in four there had been slight recurrences and in one, no result. This gives a 14 per cent ratio of recurrence. Treatment was not attempted in patients with concomitant diseases, such as pneumonia, known drug eruptions or herpes menstrualis. Treatment with vaccine is suggested as an effective means of combating a comparatively insignificant yet troublesome eruption.

Cerebriform Nevus Resembling Cutis Verticis Gyrate—Hammond and Ransom report two cases of cerebriform nevus of the scalp resembling cutis verticis gyrate which constitute a condition distinctly different, both clinically and pathologically, from all the other types of cutis verticis gyrate. Since this condition presents so few features in common with cutis verticis gyrate, they suggest that it be removed from this classification and designated as cerebriform nevus of the scalp. In the literature and textbooks this convoluted nevus is referred to as cutis verticis gyrate when it occurs on the scalp but as nevus cerebriformis or cerebelliformis when it occurs elsewhere on the surface of the body. Cutis verticis gyrate should be considered only a descriptive term (Madden) and it should be generally understood that several different pathologic processes in the scalp may result in the formation of convolutions and furrows. In any patient exhibiting cutis verticis gyrate, a careful differential diagnosis should be made to determine the underlying cause so that appropriate treatment can be recommended. The authors believe that Masson has shown rather conclusively that a nevus represents a proliferation of the chromatophores, tactile corpuscles and nerve cells, forming the end apparatus of the sensory nerve filaments of the skin. There seems to be little doubt of the relationship of the nevus to the neurofibroma. The results of the histopathologic study in the two cases reported support Masson's concept of the neurogenic nature of the nevus. The differences of opinion among different writers as to the most satisfactory form of treatment of a nevus is noted. The methods of therapy range from the application of the electric needle, solid carbon dioxide, cautery, caustics, radium and liquid air to electrolysis, roentgen irradiation, endothermy, electrodesiccation and electrocauterization. It is believed that the best form of treatment is complete surgical excision.

Cevitamic Acid Content in Milk—Reedman determined the cevitamic acid content of milk from four breeds of dairy cows. The acid content varied little between breeds or among the animals of the same breed and, further, little variation was noted in the stages of lactation or with the age of the cattle. The cevitamic acid content of milk was found to decrease gradually on storage. Samples of raw milk cooled immediately to 5 C and stored in the dark retained approximately 75 per cent of the original value after forty-eight hours. Added cevitamic acid behaved similarly. Only reduced cevitamic acid

is found in fresh raw milk stored in the dark. It would seem that cevitamic acid oxidase is absent, or present in very small amounts in milk. Milk pasteurized thirty minutes by the holder method retained more than 70 per cent of the original vitamin C content. Buttermilk, whey, powdered whole milk and evaporated milk contain a small amount. Raw skimmed milk averages 25 mg of cevitamic acid per hundred cubic centimeters, while skimmed milk powder may contain as much as 267 mg per hundred grams if dried by the just drum method. It is true that milk alone will not supply sufficient vitamin C in the diet, but it is equally true that it would not normally be required to do so. As an average, a pint of milk may be said to contain 10 mg of cevitamic acid after pasteurization. The nutritional value of milk is practically unchanged by properly conducted pasteurization.

- *Skin Tests with Bacterial Products in Arthritic and Nonarthritic Individuals E F Traut, Chicago—p 501

Skin Tests with Bacterial Products—Traut made intradermal injections of whole bacteria and the supernatant broth of their forty-eight hour cultures into patients with chronic rheumatoid arthritis and into allergic and nonallergic controls. Previous observations of increased tendency of arthritic patients to react to streptococci or their products were confirmed. Hemolytic streptococci again gave the most marked and most frequent reactions. The increased cutaneous sensitivity was limited to streptococci. The staphylococci and gram-negative organisms did not similarly affect the skin of arthritic patients. None of the observations justified the assumption of a specific

organism. A history of hay fever, asthma, urticaria or eczema profoundly affects the results of tests with the supernatants of broth cultures. The number of positive tests is directly proportional to the content of irritant, nonspecific substances. This nonspecific irritant factor renders valueless skin tests of an individual with unstandardized autogenous bacterins or other autogenous bacterial products not previously standardized by tests on control individuals.

Determination of Acetone in Blood and Urine—The reagents that Abels uses for determining acetone in the blood and urine are a 5 per cent solution of sodium bisulfite in water, Nessler's solution, a 1:1 dilution by volume of sulfuric acid and a standard acetone solution. A stock solution containing 0.1 mg per cubic centimeter of acetone is prepared and checked gravimetrically by the method of Van Slyke. The standard solutions used are made by a 1:10 dilution of this, so that 1 cc contains 0.01 mg. This should be prepared daily. The apparatus consists of a 50 cc Erlenmeyer flask and a tightly fitting cork. Suspended from the under surface of the cork by means of a pin (6 cm long) is a cotton pencil (dental roll). The pin is stuck first through the cotton plug and then into the cork. The urine is made acid to congo red with 1:1 sulfuric acid, and 0.5 cc is pipetted onto the cotton roll. In the case of the blood, no previous acidification is necessary, and the 0.5 cc sample may be used directly. Five-tenths cc of the 5 per cent sodium bisulfite solution is spread over the bottom of the flask and the cork is carefully and firmly inserted so as to allow the blood or urine sample to suspend about 1 cm over the level of the bisulfite. The flask is heated in a boiling water bath for fifteen minutes and, when cool, the cork and cotton roll are removed, 1 cc of water is added and then 1 cc of Nessler's solution, bringing the total volume to 25 cc. The solution is poured into a test tube (6 inches by one-half inch) and the amount of turbidity is compared with the standard set. The standards are prepared at the same time in similar test tubes from 0, 0.002, 0.004, 0.01 mg of acetone, water to 1 cc, 0.5 cc of 5 per cent sodium bisulfite, and 1 cc of Nessler's solution. The full development of the turbidity takes fifteen minutes, during which time the tubes should be shaken occasionally. If exposed as little as possible to the light, they keep for about twenty-four hours. When abnormal amounts of acetone are suspected in the blood or urine, a stronger set of standards containing 0, 0.005, 0.01, 0.05 mg of acetone should be prepared.

Variations in Lipemia of Normal Subjects—Man and Gildea determined the serum cholesterol, phosphatides, fatty acids and generally the total protein, albumin and globulin content of six women and four men between 24 and 45 years of age at intervals throughout a total length of time of from three months to four years. The intervals between blood studies were irregular in four persons, were of two weeks duration throughout three months in two men and two women,

and then were prolonged to approximately one month in one man and two women. Such timing of the blood studies has permitted investigation of the level of serum lipids in relation to the season of the year, to the menstrual cycle of women and to the constancy of lipemia after intervals as prolonged as one and one-half years in two subjects, two and one-half years in one man and four years in one woman. There was a wide range in the serum cholesterol, lipid phosphorus, titrated fatty acids and total protein of any one person. The minimal and maximal serum cholesterol varied by as much as 31 per cent, lipid phosphorus by 23 per cent, titrated fatty acids by 37 per cent and proteins by 14 per cent. Differences in lipids were not related to changes in hemoconcentration when serum proteins were employed as a criterion of blood volume. Variations in lipids were not related to slight changes in body weight. In women the course of serum cholesterol could not be correlated with the menstrual cycle, and, moreover, changes in the cholesterol of men exceeded those in women. No definite trend in serum lipids in relation to the season of the year could be traced from person to person.

Growth Factor in Summer Milk—Kohler and his collaborators attempted to demonstrate the identity factor found in grass juice with known vitamins. A series of supplements was fed to rats receiving mineralized winter milk ad libitum. Growth was stimulated by daily supplements of 3 Gm of fresh grass, 3 cc of grass juice, 0.6 Gm of dried oat grass, 0.2 Gm of rice bran or 0.2 Gm of liver extract. The known essential food factors as well as flavine, choline, goat milk factor and alcohol-ether precipitate factor have been eliminated from consideration as being the active principles by the inferior responses to growth produced by daily doses of 2 drops of cod liver oil, 1 cc of orange juice, 0.5 Gm of brewers' yeast, 0.25 Gm of dried bran and 1 Gm of defatted wheat germ. Increased growth of rats on mineralized winter milk receiving a supplement of grass or grass juice over that of controls receiving no supplement is accompanied by an increase in the consumption of milk. Fresh or carefully dried tissues of green plants con-

tain a substance (or substances) which is the limiting factor for growth of rats on mineralized winter milk. The activity of the tissues of fresh plants may be demonstrated by use of the expressed juice. The daily dose of juice necessary to produce optimal growth is 0.1 Gm on the dry weight basis. Other supplements produced slight increases in growth over the controls. Von Wendt has published work which indicates that the seasonal variation in the nutritive quality of milk is of importance in human nutrition in territories in which milk and its products are the chief articles of diet.

Interpretation of Normal Blood Pressures and Pulse Rates in Routine Physical Examinations. H. G. Armstrong—p. 456.

Shock—Makel declares that to save life not only must shock be recognized when the classic symptoms are present, but conditions causing, and signs indicating, the probability of secondary shock must be known and proper prophylaxis given. Once shock has developed, treatment must be instituted without delay. "The critical level of blood pressure once reached it will not rise again without assistance. The best guide as to the procedure to be followed is the degree of shock present as determined by depression of the blood pressure. Mild shock responds quickly to measures directed toward increasing body heat, the relief of pain and free oral administration of fluid and avoidance of movement. In severe shock the indication is to increase immediately the diminished blood volume. The intravenous administration of physiologic solution of sodium chloride to which dextrose is added usually results in an immediate restoration of the blood pressure. The most effectual means of restoring a diminished blood volume is transfusion of blood. In the domain of surgical technique there is need of greater gentleness in handling the tissues and of more painstaking care in eliminating every factor contributing to shock. The use of powerful mechanical retractors, the neglect of hemostasis, the unnecessary bruising of organs and traction on them are all too common. The surgeon should shrink from needless trauma as he would from the conscious introduction of infection. Food and water deprivation and exposure to cold increase the ease with which shock can be produced. Prolonged anesthesia may greatly exaggerate the condition. Treatment may be summarized thus: removal of all contributing causes. These are not only associated with physical trauma but include psychic and nervous aberrations. Drugs and agencies to stimulate and maintain blood pressure should be used.

Lateral Pyelogram as an Aid in Diagnosis of Perinephric Abscess. Preliminary Report. J. G. Menville. New Orleans—p. 37.

Local Use of Quinine in Ophthalmology—During the last six months Robinson has used quinine bisulfate in solutions and ointments (2 per cent) in the treatment of catarrhal conjunctivitis and has found its results most gratifying. In fifteen cases so treated, the conjunctival infection decreased by one half within two days, on the average. Exudates from such eyes examined microscopically after one week were found to be sterile. The average case cleared up in from seven to ten days. The disease process was longer in being brought under control when the solution was used. The use of a 2 per cent quinine bisulfate ointment along with the use of atropine as a postoperative treatment in ten cases of pterygium has greatly reduced scarring when compared with the records of cases in which such treatment had not been used. Similar results were observed in a number of postoperative cataract cases in which the intracapsular method with a corneal suture was employed. Ethylhydrocupreine hydrochloride in solutions of from 0.5 to 1 per cent has been used in seventy-five cases of pneumococcal conjunctivitis, proved with the microscope, during the last year and in less than 3 per cent of these cases the drug did not halt the condition. Ten patients with hordeola after removal of the dead hair and evacuation of the exudate were placed on 0.5 per cent ethylhydrocupreine to be used thrice daily and in no case was there any sign of conjunctivitis seen at any time. Although ethylhydrocupreine and quinine as ocular therapeutic agents are still in their experimental stage, the author states that both drugs are highly beneficial in their effects on infectious microorganisms of the conjunctiva and the repair of ocular adnexa, and that they act synergistically with each other and are not hampered by the use of their supposed antagonistic drugs such as mercury, iodides, bromides, lead, zinc, copper and ammonia, and that the two drugs may be combined over long periods without producing injury to any of the ocular adnexa.

*Infantile Eczema. H. A. Foerster. Oklahoma City—p. 260.
Treatment of Gonorrhea in the Male. D. W. Branham. Oklahoma City—p. 262.

Infantile Eczema—Foerster declares that the following conditions must be ruled out before one has the true atopic variety of infantile eczema: dermatitis, seborrhea, infectious eczema, fungus infection and contact dermatitis. When these conditions or types of eczema are eliminated then and only then is one qualified to call the case one of atopic or true infantile eczema. The treatment of (atopic) infantile eczema is usually of a dual nature, that is, local soothing measures and that which is directed toward finding the cause. The three most important things to test for are milk, egg and wheat as these are the basis of most infant diets. An infant genuinely sensitive to cow's milk cannot take boiled, acidified or any form of canned cow's milk without keeping the eczema flared up. The author advises putting these infants on a goat's milk formula. Breast-fed infants are usually egg sensitive, the condition being transmitted through the mother's milk. Eggs should be eliminated from the diet, care being taken that the

infant or mother does not get traces of egg in cake, bread, custard, pretzels and the like. Often milk sensitive infants are barley sensitive, and many of the soya bean milk preparations contain barley, this may be the explanation of failure of soya bean milk substitutions to help the eczema. Atopic infants, if followed closely, all have an allergic background, and one can expect from 50 to 75 per cent to continue to develop new sensitivities as they grow older and as more foods are added to their diet, they progress to the stage of neurodermatitis and later pass into the asthmatic and hay fever category. Therefore it behooves one to follow these cases carefully from year to year and to be cautious with regard to a too favorable prognosis.

*Amebic Abscess of Liver J R Young and L J Bristow Anderson—p 164

Amebic Abscess of Liver—Young and Bristow review the cases (twenty-five) of amebic abscess of the liver that have occurred among the last 34,994 admissions. Of the patients admitted for primary pathologic changes of the liver 37 per cent, or one in three, had amebic abscess. A past history suggestive of amebiasis was obtained in only thirteen patients, and only six had a diarrhea on admission to the hospital. The relatively high incidence of persons who have an amebic abscess of the liver with no antecedent history of a dysentery is explained by the fact that slight amebic infections limited to the right half of the intestine may not produce diarrhea, while the same degree of infection in the left half may produce symptoms, and the nearer the rectum is approached by the infection, the more pronounced are symptoms produced. Only five patients had received emetine previous to the present illness. If used oftener, amebic abscesses would be less frequent. From the histories, as nearly as could be determined the average duration of symptoms was more than twenty-one weeks, the extremes being eighteen months for the longest and two weeks for the shortest. In reviewing the symptoms as presented, pain and/or tenderness in the region of the liver and fever occurred in all cases. Pain in the upper right quadrant associated with an enlarged tender liver and a sallow, muddy skin should make one suspicious of amebic hepatitis, whether or not the patient gives a history of a past diarrhea. The other most frequently noted symptoms were loss of weight and vomiting in fifteen cases, chills in thirteen and sweats in ten, while seven patients gave the history of having pain in the right shoulder. All the patients had a secondary anemia. Stool examinations are helpful only when positive, and a negative stool by no means rules out amebiasis. Roentgenoscopy is one of the most important and reliable diagnostic aids, especially fluoroscopy, where

elevation and fixation of the right leaf of the diaphragm is a constant occurrence. The treatment of amebic abscess of the liver consists of specific therapy, closed drainage (aspiration), open drainage or a combination of these methods. As soon as the diagnosis is made or suspected, 0.065 Gm of emetine daily for from six to ten days is given. If the patient is not relieved, the abscess should be emptied by aspiration. If aspiration is not done or is not successful, open drainage of the abscess by the transpleural or abdominal approach is indicated depending on where the abscess is "pointing." No matter what method of drainage is used emetine should be given to every patient having abscess of the liver.

Aseptic Ureterosigmoidostomy—Foley devised an aseptic method of uretero intestinal anastomosis. It is definitely aseptic in respect of both fecal and urinary soiling. It involves use of a new snare or guillotine instrument within the intestinal lumen but imposes no technical elaborations or difficulties. The ligated end of the ureter, pushing a small invaginated tent of intestinal submucosa before it is inserted into the snare. The two structures are held in the grip of the snare while the ureter is embedded in the intestinal wall by suture and the abdomen is closed, all of which is accomplished without even a suture needle penetrating the lumen of either intestine or ureter. Later with supply of a cutting current to the instrument the snare amputates within the intestinal lumen the ligated end of the ureter and the invaginated tent of intestinal submucosa covering it thus establishing the uretero intestinal communication. The new instrument has been called a ureteral transplanter.

 *Three Clinical Types of Ringworm Due to Trichophyton Gypseum. Eleanor Silver Dowling and H Orr—p 298
 Neuropathic Eczema. E Ramel—p 307

Ringworm Due to Trichophyton Gypseum—Dowling and Orr set out to estimate the prevalence of Trichophyton gypseum in Alberta and to describe the clinical varieties of ringworm it may produce. Trichophyton gypseum was identified by the gross appearance of the cultures and by the size and shape of the spores, particularly the macroconidia. During 1935 and 1936, tissue from about 200 patients was examined in potassium hydroxide solution for fungal infection and, from the tissue containing fungi, cultures were obtained whenever possible. It was found that the commonest dermatophyte was Trichophyton gypseum, which was responsible for 67 per cent of the ringworm. Sixteen cultures of dermatophytes were obtained which were identified with certainty as Trichophyton gypseum. Of the sixteen isolates, seven of them were derived from lesions of the arm, five from chronic, scaly, sometimes vesicular lesions of the skin of the feet and four strains were derived from deep-seated inflammatory lesions—one from kerion of the scalp and three from pustular, boggy, granulomatous-like lesions of the beard. Only seven of the sixteen strains resembled published descriptions of the species in every particular. The seven identical strains were responsible for a variety of clinical types of ringworm, vesicular lesions of the glabrous skin, chronic scaly lesions of the feet, pustular boggy lesions of the beard. Furthermore, both typical and atypical cultures of Trichophyton gypseum have been isolated from each of the types of ringworm, so that no correlation could be found between the type of lesion produced by the fungus on the patient and any peculiarities in the appearance of the culture on Sabouraud's medium. The most obvious variations in the cultures of Trichophyton gypseum were in the color of the mycelium and in the pigmentation of the culture medium on which it grows.

Changes Produced in Brain by Exposure to Radium—

The changes in the brain that Colwell and Gladstone observed in their investigation of rat brains after exposure to radium were those of a nonsuppurative reactionary inflammation. 1 Immediate effects of irradiation were vascular engorgement and changes in the nerve cells, more especially the larger cells of the cortex of the hemispheres and cerebellum, and in the basal ganglions, pons and medulla oblongata. Frequently two adjacent cells of similar type in the same microscopic field exhibit marked contrast in the degree of damage that has been inflicted. 2 With lapse of time no attempt at repair was observed. On the contrary, degenerative changes have taken place in the damaged cells and are progressive. Adjacent cells continue to show the same contrasts, especially with regard to staining reactions. The staining reactions of the altered cells consist chiefly of the coloring of the cell body and nucleus, with the hematoxylin-eosin method, a deep purple. The stain is diffuse in distribution, coloring the broken down granular material of the cell body and chromatin material of the nucleus, and the matrix of the cytoplasm and nucleoplasm. 3 These changes are similar to those occurring in the area of hemor-

rhages or mechanical injuries, such as may occur in removal of the brain immediately after death. 4 The vascular dilatation that follows immediately after irradiation is accompanied by the escape of red blood corpuscles. 5 Twenty-four hours after irradiation the initial stages of inflammation of the membranes are accentuated and there is some proliferation of the vascular endothelium and a perivascular accumulation of small round cells. There are also signs of localized stases. 6 Evidences of inflammatory reaction, which are seen in the earlier stages, progressively increase with the lapse of time and are attended by disintegration and total destruction of nerve cells and occasional hemorrhages into the nerve tissue and ventricles of the brain, in some situations there is contraction of arterioles with interference of the vascular supply, and patches of necrosis in the affected areas.

Partial Gastrectomy—Lake declares that in the last ten years there have been two peaks of medical interest in gastrectomy: the reintroduction of intensive alkalization and recently treatment by histidine. The lesions for which the operation has been performed in his 320 cases under review were gastric, duodenal, pyloric and jejunal ulcers and carcinoma. Some of the gastric ulcer cases had progressed to hour glass contraction (eleven cases), some of the pyloric and duodenal ulcers had caused obstruction with dilatation of the stomach (twelve cases), and some of the jejunal ulcers had previous gastric operations (perforation ten cases, gastro-enterostomy eight cases, local excision two cases). In a considerable proportion of instances the ulcers have been multiple. A majority of the cases (198) have been followed for more than two years, and only fifteen of these are unsatisfactory. The after history of some cases has been studied for periods up to fifteen years after operation. The gross mortality from all causes was 9.5 per cent in ulcer cases, 14.8 per cent in anastomotic ulcers and 14 per cent in carcinoma. If an ulcer is situated in the pyloric region, the mortality of the operation is but 5.3 per cent. The commonest causes of postoperative death are lung complications and peritonitis. The incidence of jejunal ulceration after partial gastrectomy is less than 2 per cent. No cases of postoperative pernicious anemia are recorded, but a microcytic anemia of mild degree is occasionally seen. The general permanent results in the ulcer cases are probably better than those obtained by any other method of treatment. The average duration of life in the carcinoma cases after operation was two and one-fourth years, but some patients with extensive growths lived for as long as seven and nine years.

Inquiry into Etiology of Measles—Colles examined films of the secretions or blood from fourteen cases of measles and in nearly all cases definite and distinctive red stained virus like bodies have been found, not unlike but slightly larger than the Buxton bodies of vaccinia. As far as he can see, the only structures that might be mistaken for these bodies are the escaped granules of cells. In the blood of measles the leuko-

cytes and especially the polymorphonuclears are diminished in number. When once the eye has become accustomed to the distinctive appearance of these bodies, their dissimilarity from cell granules is quite obvious. The virus-like bodies of measles are to be found in fluids like that of lacrimal secretion, in which cells are scanty or absent, especially in this case in preparations made from the breath or an infected handkerchief. It is impossible at this stage to state definitely that the elementary bodies described are the actual causal virus of measles but they certainly more closely represent a filtrable organism than anything yet described.

Effect of Diet on Sterility, Growth and Survival—
Watson finds that zinc cages are unsuitable for housing mice, at least for the type of experiment dealt with. There appears to be some toxic element in the metal or solder used in their construction that adversely affects the condition, growth, fertility and survival of the mice. Glass cages give far better results. "Synthetic" diets containing wheat gluten or caseinogen or a mixture of these two proteins with the addition of bran, dextrin, lard, cod liver oil, yeast and salt mixture, reduced the fertility of the mice almost to zero. They supported the growth of young mice, but growth and survival rates were both poor. A "natural" diet consisting only of whole oats to eat, and milk and water to drink, gave results that, except with regard to fertility, were as unfavorable as those given by the "synthetic" diets. With regard to the growth of young mice they were even more unfavorable. The best results, as judged by the fertility of breeding does, infrequency of litter eating, and the growth and survival of young mice, were obtained with three diets each of which contained about 25 per cent of dried separated milk. On these diets the mice thrived well in all respects.

Diet and Resistance to Bactericidal Infection—
Watson also observed that young mice bred and reared on a diet containing oatmeal dried separated milk, dextrin or flour and water biscuit, coconut oil, cod liver oil, yeast and bran and milk and water to drink, are more resistant to oral infection with *Bacterium typhi-murium*, and to the intraperitoneal injection of a toxic substance isolated from that organism than young mice bred and reared on a diet in which the amount of oatmeal is increased, and the dried separated milk dextrin or

flour and water biscuit and coconut oil are omitted. It is probable that the factor responsible for this increase in resistance is the dried separated milk.

Virus of Foot and Mouth Disease—According to Gallo way and Schlesinger, it is possible to concentrate the virus of foot and mouth disease on filter candles coated with acetic acid collodion. The degree of concentration of the virus effected was to the limit of expectancy, i.e., the increase in titer after concentration corresponded to the reduction of the volume of the liquid. By a combination of the two methods of purification of the virus, viz., washing once in the closed agitated cylinder of the Sharples super centrifuge and repeatedly on a graded collodion membrane of 25 millimicrons, very potent purified concentrates of virus can be obtained rapidly especially if the final concentration is made on filter candles, coated with acetic acid collodion. In this way a concentrate of virus with a titer of 10^{-8} and a negative sulfosalicylic acid test for protein has been prepared in one day from virulent vesicle lymph (diluted 1:2) having a titer of 10^{-6} . The possibilities of the different methods of purification and concentration of the virus are discussed and a scheme is suggested for their application.

Extracts of Adrenal Cortex in Treatment of Addison's Disease—Wilkinson discusses the use of two adrenal cortex extracts on the market in the treatment of nine patients with typical uncomplicated Addison's disease. Four of the patients died despite intensive treatment—three from Addison's disease and one, in remission, from cardiac muscular failure. Two of these showed tuberculosis and two complete atrophy of the adrenals. Five patients have responded to treatment and are alive and in good health, the longest period of survival to date being three years and one month and the shortest nineteen months. One was a chronic case of moderate severity—not now being treated—and four were acute severely ill patients who responded to cortical extracts and are now on daily maintenance doses of sodium chloride. With this treatment symptoms of asthenia, muscular weakness and digestive disorders were relieved, appetite returned, weight increased the mental outlook improved and the pigmentation slowly faded. There was a slight improvement in the subnormal temperature after cortical extracts but the occurrence of pyrexia is a bad prognostic sign. The blood pressure may take two or three months to show any significant improvement and then apparently only if cortical extracts are given with or followed by sodium chloride therapy. Changes in the chemistry of the blood and urine show rapid responses to adequate treatment.

Unusual Forms of Spontaneous Pneumothorax—Castex and Mazzei observed a number of cases of spontaneous pneumothorax with an unusual symptomatology. They point out that usually the appearance of spontaneous pneumothorax is either insidious or manifested by evident symptoms, the most frequent of which are pain, dry cough and dyspnea. The pain although variable as to type and intensity, generally has a thoracic localization. But occasionally it is localized elsewhere and may lead to erroneous diagnoses. The authors describe several cases which illustrate that pneumothorax and hemopneumothorax may begin in an extremely atypical and unusual manner and may simulate diverse disorders of other organs. The atypical forms may be classified as follows: (1) the form that is accompanied by fainting and convulsion, (2) the anginal form, (3) the brachialgic form, (4) the form with acute abdominal pain and (5) the form with chronic abdominal or lumbar pains. After reviewing a case from the literature, in which pneumothorax was accompanied by fainting, the authors say that in the anginal form of spontaneous pneumothorax the clinical picture may be exactly like that of angina pectoris. Discussing the brachialgic form, they mention two cases of pneumothorax in which the pains radiated into the arm. Further they describe a case of spontaneous pneumothorax which was masked by a pericardiac reaction. The forms of spontaneous pneumothorax that are accompanied by abdominal pains are especially noteworthy, because they may be mistaken for gastroduodenal perforation, cholecystitis or appendicitis. Their development has been explained by Pottenger as the result of viscerosensitive reflexes with a pleural point of origin.

 *Posttraumatic Juxtadural Hematomas E Krebs and P Puech—p 512
 Abscess of the Brain P Puech and P Winter—p 520

Posttraumatic Juxtadural Hematomas—Krebs and Puech discuss the diagnosis and the treatment of posttraumatic juxtadural hematomas on the basis of eight cases in which surgical treatment was employed. First they take up the extradural hematomas, pointing out that this type of hematoma is usually a complication of cranial fractures. In typical cases the hematoma is caused by a laceration of the middle meningeal artery or one of its branches. After describing the typical symptoms they discuss the examination of the fundus oculi and of the head and point out that in case of doubt ventriculography may be helpful. They report the histories of three cases in which extradural hematoma was present. Further they give their attention to subdural hematomas, pointing out that this type occurs chiefly in severe traumatism with or without cranial fracture or in mild traumas without fracture. In the latter cases the diagnosis is most difficult. The first symptoms appear sometimes in the week, the months or even the year following the trauma. The symptoms of subdural hematomas, if the previous trauma is unknown may readily be mistaken for those of cerebral tumor. The patients complain of symptoms that indicate intracranial hypertension, often without signs of localization. In rare cases there are neurologic symptoms, attacks of Bravais-jacksonian epilepsy, hemiparesis, ocular disturbances and so on. The roentgenologic examination of the cranium rarely reveals the signs of a fracture. It is often said that the subdural hematoma is not visible in the roentgenogram. However, some observers say that the subdural hematoma gives a clear roentgenologic picture. Chavan and David observed a noticeable disjunction of the cranial sutures with warping in two or five cases of subdural hematoma. The

authors observed the same changes in some of their cases, but they noticed them also in late traumatic serous meningitis with out hematoma. The examination of the fundus oculi may or may not reveal a stasis of the optic papilla. The authors observed stasis in four out of five cases, but, on the whole, the papillary stasis is less frequent in subdural hematoma than in cerebral tumors. As a rule the diagnosis is not certain, unless it is corroborated by trepanopuncture or by ventriculography. After discussing the evolution and the clinical forms of subdural hematomas, the authors give brief histories of five cases. Then they take up the diagnosis of the late complications and finally the treatment. Regarding the latter they say that the juxtadural hematomas are amenable to surgical treatment. The technique of the operation differs, depending on whether the hematoma is extradural or subdural. The authors describe and illustrate the operation for both types of hematomas.

 *Can Epinephrine Be Considered as Cause of Hypertension? E Dicker—p 1117

Epinephrine as Cause of Hypertension?—In this paper Dicker considers whether the theory of the adrenal origin of hypertension can be confirmed. He reviews the studies of various investigators, giving especial attention to the reaction of Viale. He shows that this reaction is not specific and that its outcome depends partly on the diet of the examined patient. Moreover the method of Viale is not capable of determining a physiologic augmentation in the epinephrine content of the serum and does not give the amount of substances produced at the time of the coagulation of the serum. From the sum of facts presented by the author it stands out that, if involvement of epinephrine in the mechanism of essential hypertension or of the hypertension of nephritis cannot be formally rejected it appears impossible to produce experimental proof for the hypothesis that attributes to the adrenals a primary role in the pathogenesis of these two types of hypertension.

 *Criticism of Methods of Determination of Uric Acid in Blood and Organs H Pinosch—p 694

Criticism of Determination of Uric Acid—On the basis of experiments, Pinosch is of the opinion that the newer modifications of the colorimetric methods for the determination of the uric acid produce unreliable results in that frequently only a small portion of the uric acid is detected and then again several times as much as is actually present. He thinks that the following factors are responsible for the erroneous results: 1 A greater or smaller portion of the uric acid is absorbed by the sediment during the process of deproteinization. 2 In the deproteinized fluid, the uric acid cannot be quantitatively precipitated, whereas this is readily possible in pure uric acid solutions. 3 In case of the direct determination in the deproteinized extract, there is not the slightest guaranty that really uric acid and not one of the numerous other reducing substances is determined. 4 The colorimetric determination of the uric acid produces fluctuating values not only on account of excessive sensitivity but also on account of the instability of the reagents. Moreover, since extremely small quantities of uric acid have to be determined, the error of computation is extremely large. 5 The titrimetric determination of uric acid according to Flatow has about the same defects as has the colorimetric method (error of deproteinization nonspecificity and instability of reagents). The method of Edson and Krebs is entirely different. It avoids the deproteinization and determines the uric acid by manometric measurement of the urea that develop in the oxidative decomposition of the uric acid. To be sure the method is considerably more complicated than the methods employed heretofore but it seems to be the only one that produces reliable results.

*Artificial Pneumoperitoneum After Puerperium in Pulmonary Tuberculosis U De Michelis —p 183
Relations Between Exudative Pleuritis and Pulmonary Tuberculosis G Berio —p 188

Seasonal Cycle of Tuberculin Allergy—Rigoni and Zanfrognini followed the behavior of Mantoux-Romer's intracutaneous tuberculin test all through the different seasons of the year for five consecutive years in all adult patients who entered the medical clinic of the Bologna University for treatment of different diseases. The total number of patients in whom the test was performed during that time was 1,600. The authors found that allergy to tuberculosis greatly intensifies in the spring, decreases in the summer, rises again in the autumn (although not as much as it does in spring) and again falls in the winter. The seasonal variations of allergy are constant for every year and have no relation to the organic conditions of immunity to tuberculosis. They are an epiphenomenon of the changes of the vasomotor centers due to seasonal hyperfunction of the vagal sympathetic. The biologic phenomenon is of sympathetic origin and independent from any direct action of external factors.

Artificial Pneumoperitoneum After Puerperium in Pulmonary Tuberculosis—According to De Michelis, there are several factors that aggravate the evolution of pulmonary tuberculosis after the puerperium. There are hemorrhages, loss of organic, inorganic and hormone substances through lochia and lactation and the mechanical factor of the lowering of the diaphragm. In the case reported by the author, the aggravation of the disease after the puerperium was manifest. An artificial pneumoperitoneum was established. Intraperitoneal insufflations of from 300 to 500 cc of oxygen were administered at intervals of six days for about three months. The symptoms of the disease rapidly abated and the general condition of the patient improved. The x-ray examination of the thorax showed elevation of the diaphragm. The treatment is well tolerated by the patients. The author advises resorting to it in cases of the nature of the one he reports so as to establish precise indications, the quantity of oxygen that should be administered and the possible contraindications.

Benign Lymphocytic Acute Meningitis Case G Carella —p 525
Blood in Pulmonary Mycosis J Chasis —p 534

Blood Proteins After Thoracoplasty—Lenzi says that patients having pulmonary tuberculosis also suffer from a definite disequilibrium of the metabolism of blood proteins. There is a predominant amount of globulins over that of albumins in the blood of the patients. The latter are adapted to the disequilibrium in the course of the disease. The quantitative changes of the blood proteins are harmful to the body, as they cause physicochemical disorders of the blood and body humors in their relation to blood proteins especially after thoracoplasty, when they are greatly intensified. According to the author, proteins from cells which were disintegrated by operative trauma enter the blood, alter the stability of blood proteins and break the balance of the water and colloid metabolisms of the blood in their relations to blood proteins. The latter, especially albumin, play an important part in regulating the exchanges of water between blood and tissues. The author advises the determination of proteins in the blood of patients suffering from pulmonary tuberculosis before and after thoracoplasty. The study is advisable for ascertaining the physiopathologic processes related to the operation especially in patients with

a greatly diminished amount of albumin in the blood before the operation. The author's study is based on determinations of the proteins in the blood of eight patients suffering from pulmonary tuberculosis who underwent partial thoracoplasty. The postoperative period in all cases was without complications. His article is a preliminary report.

Effects of Roentgen Irradiation of Thymus—Bentivoglio and Fumi's experiments were carried on to clarify their postmortem observations. An infant who suffered from thymic hypertrophy made a clinical recovery after roentgen irradiation was administered to the thymus. Five months later he died from intercurrent pneumonia. At necropsy it was found that the cortex of the thymus was atrophic and the insular tissue of the pancreas was hyperplastic and hypertrophic. The other endocrine glands were normal. The authors also treated the thymus of puppies by roentgen irradiation. Some of the animals were given only 100 roentgens, whereas others received various irradiations in different amounts. The animals showed general nutritional and somatic disorders and also bone changes of the rachitic type, all of which varied with the race and individual resistance of the dogs to the treatment. The animals were killed at the end of the second month of the experiment. It was found that involution of the thymus from roentgen irradiation causes hyperplasia and hypertrophy of the insular tissues of the pancreas which are proportional to the intensity of thymic atrophy. The necessary condition for the development of insular tissues is the selective evolution of intense atrophy of the lymphoid tissues of the cortex of the thymus with relative survival of the pancreatic medulla and Hassall's corpuscles. The phenomenon shows the existence of relations between the thymus and the insular part of the pancreas, by an indirect mechanism connected with the functions of the structures in regulating the sugar metabolism. It shows also the evolution of the thymic and insular processes that probably took place in the course of the clinical case reported by the authors.

Volhard's Test of Water Elimination in Jaundice—Malamud followed the behavior of the elimination of water in jaundice by means of Volhard's test of induced diuresis. The test is performed on patients resting in bed. It consists in administering to the patient 1 liter of light, tepid, slightly sweetened, lemon flavored tea and determining the quantity of urine passed. Normally the urine eliminated for the first four hours following the ingestion of 1 liter of tea is equal to and sometimes more than the quantity of tea ingested by the subject. The author performed the test in twenty patients suffering from jaundice. In all the cases the renal functions were normal. The test was performed several times in the course of the disease. There was slow passage of the urine during the test in eighteen patients. In the largest number of cases the retardation of the elimination of urine was more intense during the acute period of jaundice and became normal as jaundice disappeared. In some cases the urinary disorder was intensified as the jaundice was aggravated. In a few cases however the time of elimination of urine was shorter in relation to previous tests.

during the course of progressive jaundice. According to the author the elimination of urine in Voilhard's test in jaundice does not follow characteristic curves. The test cannot be considered of clinical or operative prognostic value. The author concludes that jaundice is an important extrarenal factor in disturbing the elimination of water, which is retarded in the course of the disease.

Influence of Short Wave Treatment on Stomach.—Neidhardt and Schlinke studied by means of x-ray examination the behavior of the stomach after treatment with short waves, 6 meters in length. The experiments were made on fourteen patients, of whom ten were free from gastric disorders, two had an old duodenal ulcer and two had subacidity. After five minutes of exposure to the short waves there was noticeable in nearly all experiments a reduction in the tonus and the peristalsis of the stomach, whereas the secretion of gastric juice increased. When the short waves acted on the stomach for thirty minutes, the remnant of contrast medium in the stomach was in seven out of eight examined persons from two to four times as large as was the case in the same person without irradiation. Thus it may be concluded that exposure to short waves reduces the motor action of the stomach. In discussing the therapeutic use of short waves, the authors point out that it is contraindicated in bleeding ulcers. However, short waves may be tried in all spastic conditions of the stomach, whether they are due to ulcers or to other local changes, also in all conditions of hypermotility resulting from duodenal ulcer, acute gastritis, tabetic crises and so on.

Treatment of Anemia by Injection of Bone Marrow.—Since it was difficult to secure donors for blood transfusions (in southern China), Schretzenmayer decided to resort to the injection of bone marrow in the treatment of severe forms of anemia which resulted from malaria and from helminthiasis. He reasoned that the effect of blood transfusion was probably partly due to the stimulating action on the bone marrow. Assuming that substances which stimulate the bone marrow would be present also in the bone marrow itself, he decided to administer by intramuscular injection freshly withdrawn human bone marrow. At first he used the marrow that had been withdrawn from the patient's own sternum. Instead of withdrawing an amount just sufficient for the examination of the marrow, he withdrew slightly more and reinjected the surplus into the patient. Later, he also employed marrow from healthy persons and from patients with strongly regenerating marrow (patients convalescing from anemia). In order to determine whether this measure did influence the bone marrow, the author studied the reaction of the reticulocytes and found a great increase. Moreover, many of the patients suddenly felt much better in the days following the bone marrow injection. This subjective improvement was similar to that which is often observed after the first injection of liver in patients with pernicious anemia. The status of the blood usually required a longer time to reach the normal level. In the severe, chronic cases, several weeks usually elapsed before the blood status was normal.

Progressive Muscular Dystrophy and Vitamin C.—Hirata and Suzuki were interested in the action of vitamin C in progressive muscular dystrophy and so they studied vitamin C economy of ten patients who had the disease in a more or less severe form. Tabular reports of the results of these studies indicate that these patients had a C hypovitaminosis, and it was decided to resort to treatment with vitamin C, of which the patients were given daily from 200 to 500 mg by intravenous or intramuscular injection. In the course of this treatment the examination of the cerebrospinal fluid revealed an increase in the vitamin C content. Moreover, subjective as well as objective improvements could be noticed. The authors gained the impression that the continued oral administration of large doses of vitamin C surpasses in efficacy all other treatments of progressive muscular dystrophy. It exerts an especially favorable effect on the muscular adynamia. Although there is of course no regeneration of the already impaired muscle fibers, the muscular metabolism, particularly as regards the glycogen, the creatine-phosphoric acid and the adenylylphosphoric acid, is favorably influenced by the vitamin C and the dynamic power of the muscles is again utilized.

Chemotherapy of Pneumococcal Infections.—Kemkes reviews the literature on the use of quinine in pneumococcal pneumonia and in view of the different evaluations of the mode of action of quinine, he decided to make systematic studies with quinine preparations. It was his aim to determine whether and to what extent these preparations exerted a bactericidal influence on pneumococci. The *in vivo* experiments were made on white mice. In summarizing his observations the author says that the *in vitro* experiments with a quinine derivative which contains quinine hydrochloride and phenylmethylpyrazolon and with a quinine glutamate solution proved that these substances exert a bactericidal action on pneumococci of types I, II, III and IV. In testing these two substances and a quinine lactate solution in white mice that had been infected with pneumococci, he found that these substances exert a considerable therapeutic action. To be sure, a single therapeutic dose was not sufficient, but it had to be repeated several times in the course of a few days.

Röntgen Rays and Histamine.—Forfota and Karady report investigations on the action exerted by histamine on the general biologic action of röntgen rays. They began these studies on the assumption that the general effect after röntgen irradiation is actually a shocklike effect. Karady and another collaborator had previously demonstrated that histamine and the related H substances have an important part in the organism. It was found that the shocklike conditions are closely connected with histamine-like actions and that there are indications that histamine treatment might be effective in the prophylaxis of shock symptoms. In this report the authors describe observations on dogs which they subjected to röntgen

irradiation without and with prophylactic histamine treatment. It was found that after a prophylactic treatment with histamine the general reactions of a roentgen irradiation were much less severe than when the histamine prophylaxis was omitted. If the general reactions after roentgen irradiation are actually the result of histamine action, there are two possible explanations for the prophylactic histamine treatment. 1 It could be assumed that the organism in response to the stimulus of repeated histamine administration forms antihistamine-like acting bodies, which in case of a new shock stimulus (roentgen rays) compensate for the suddenly released histamine, this would explain the occasionally observed hypercompensation. 2 It is possible that a prolonged histamine medication might cause an increased formation of the so called histaminase, the ferment that decomposes histamine. The greater supply of this substance would effect a rapid decomposition of the histamine that is formed by the shock stimulus (roentgen irradiation). Both theories remain to be proved.

Postoperative Irradiation of Carcinoma—Wintz points out that the problem of postoperative irradiation is much more difficult than it appears. He first evaluates irradiation after inadequate operations, then the irradiation of recurrences and then the prophylactic irradiation. Discussing the practical application of the postoperative irradiation he says that the preliminary irradiation is always better than the postoperative irradiation and that this has been proved particularly with regard to carcinoma of the breast. The postoperative irradiation may have to be postponed on account of thrombosis or other surgical complications with the consequent danger of dissemination, particularly in cases in which the operation was incomplete. The author thinks that postoperative irradiation is always justified in inadequate operations. In the event that an apparently localized carcinoma has been removed into the healthy tissue, two points of view are possible. 1 The complete removal of all carcinoma cells is extremely rare and can never be definitely determined. For this reason the postoperative irradiation of carcinoma is justified in all cases. However, if irradiation is resorted to the entire carcinoma dose must be applied. The so called prophylactic irradiation which is given with small doses and for a long period, is worthless. The second point of view is first to take an expectant attitude and refrain from irradiation. If the carcinomatous tissue has already been completely removed, the after irradiation is not necessary, if a dissemination existed before the operation or took place during it, the local treatment accomplishes nothing. The question remains whether an expectant attitude is justified if carcinoma cells remain in the surgical region. These carcinoma cells usually develop into carcinoma nodules. In these accumulations they are probably more radiosensitive than are the single cells. Accordingly, the author assumes an expectant attitude in all apparently complete operations. He resorts to irradiation as soon as a local recurrence makes it necessary. He justifies this attitude by directing attention to the fact that roentgen therapy is by no means an indifferent method that can be repeated as often as desired.

Roentgen Therapy of Enlargement of Prostate—On the basis of experiences with roentgen irradiation in twenty-four cases of hypertrophy of the prostate, Schneider describes the technic of this treatment, the indications for its use and its favorable results. Discussing the technic he points out that the irradiation with small doses will result in failure. He also stresses the absolute necessity of determining the exact distance between the skin and the prostate so as to be able to compute the correct doses. As an epithelial proliferation the hypertrophy of the prostate must be attacked with an intense concentrated cross fire method. The focus depth dose for the glandular tissue of the prostate should be about 90 per cent of the unit skin dose. Depending on whether the rays are applied to a number of small or to a few large fields this focus dose will require a skin dose of from 360 to 500 roentgens. The author prefers to apply the rays to five fields each measuring 10 by 15 cm. One field is located at the perineum and two each are parasymphysial and parasacral fields. If this is not possible he applies the rays in the front and the back to three smaller fields, approximately 6 by 8 or 8 by 10 cm. If the distance

between the skin and the center of the prostate is unusually long, he irradiates fields around the pelvis, each measuring 10 by 15 cm. In order to determine the distance between each field and the prostate, he first verifies by rectal palpation the distance between the prostate and the perineum. This one is usually shorter than that from the abdominal and from the sacral fields. The latter are determined by means of a combination pelvic compass by introducing the straight branch rectally. On account of the sensitivity of the mucous membranes of the bladder and of the rectum, the back scattering of the rays must be taken into account. To determine thus the distance between the sacrum and the pubic symphysis must be found. In this connection the author stresses the value of Baudelocque's diameter. He further says that the irradiations of the different fields should be given as close together as possible. After the first main dose has been applied, and it is found to be inadequate he gives in addition the so called saturation dose. He irradiates from a greater distance a large field either in the region of the symphysis or in this and the sacral region and perhaps also in the perineal region. Regarding the efficacy of this treatment, he says that he obtained good results in all of the twenty-four cases and that there was not a single fatality. Moreover, he stresses that it can be used even in the severe forms of the disorder.

Treatment of Gas Gangrene—Borchard reports a case in which, in a bicycle accident, a man, aged 23, sustained a small excoriation on the external surface of the little finger. The swelling spread to the upper arm and the crackling typical for gas gangrene could be heard. The rapid progress of the infection and the poor general condition of the patient indicated a highly virulent infection. Since amputation in the healthy tissue was no longer possible, the author made an incision around the area, about a hand's breadth away from the margin of the crepitant swelling. The incision surrounded the pectoralis muscle, nearly the entire scapula and reached downward to the fifth rib. Everywhere, except in the region of the neck, the incision went through the fascia. Hydrogen peroxide compresses were applied to this entire incision. Wherever accumulations of gas could be detected, wide incisions were made and finally the wound on the little finger was excised. All incisions were treated by means of hydrogen peroxide compresses. The general treatment consisted of the administration of large doses of gas gangrene serum, cardiac stimulants and oxygen. The patient recovered completely. The movement of the arm was not impaired. The author thinks that before resorting to amputation in case of gas gangrene the described method of isolating the focus of infection could be tried.

- Cardiac Echinococcus Case A. Wyzim—p 1135

Weil's Disease in Animals—Studies on 166 rats that were caught at different times in the sewers of Vienna revealed to Wirth that about 35 per cent of the rats are carriers of the type of *Leptospira* which is entirely like that causing Weil's disease. Field and house mice were likewise examined for the presence of *Leptospira* and it was found that 13 per cent of the field mice and 16 per cent of the house mice harbored *Leptospira*. The rats and mice that carry *Leptospira* eliminate in the urine

living and dead organisms. Whether this leptospiruria of the rats is the result of an attack of Weil's disease, or whether the animals just harbor *Leptospira* and remain healthy cannot be definitely stated. The examined rats that were carriers of *Leptospira* seemed healthy. In dogs leptospiroses occur under different symptomatology, Weil's disease being one form, which develops not only in old dogs but especially in young ones, frequently, an entire litter has it. The nonicteric forms of leptospiroses of dogs are known under various terms (dog typhoid, hemorrhagic gastro-enteritis and so on). Whether leptospiroses of dogs represent a danger to man cannot be definitely decided. There is no definite proof of transmission from dog to man, but the literature relates two cases in which such a transmission seemed possible. At any rate the danger seems slight. If icterohemorrhagic leptospirosis is induced in dogs, rats or mice, the animals rarely die from the infection. Guinea-pigs remain practically healthy or develop only a temporary indisposition, following infection with *Leptospira*, although the blood and abdominal punctate may contain *Leptospira*.

Case of Cardiac Echinococcus.—Wjdrin reviews the literature on cardiac echinococcus and calls attention to the fact that according to the majority of authors the clinical diagnosis of cardiac echinococcus is extremely difficult and often impossible. Many cases remain unrecognized. The author reports the clinical history and the necropsy of a case of cardiac echinococcus which likewise was not diagnosed during the lifetime of the patient. The anatomic examination disclosed echinococcosis of the liver and echinococcosis of the ventricular septum of the heart, thrombosis of the left coronary artery and sclerosis of a part of this artery. Death was caused by the thrombosis of the coronary vessels.

*Intravenous Carbon Therapy. A. Van Meeteren.—p. 3548
Culture of Tubercle Bacilli from Plug of Cotton Field Over Larynx During Cough. C. G. J. Dornick.—p. 3553

Phosphatide Lipoidosis.—Lignac and Teunissen list the different types of lipoids and then show that the lipoidoses are best classified according to the types of lipoids that are deposited in excessive amounts. They differentiate phosphatide lipoidosis (Niemann-Pick disease), cerebroside lipoidosis (Gaucher's disease) and cholesterol lipoidosis (Hand-Schüller-Christian disease). They report the clinical history of a male infant, aged 6 months. Anatomic, histologic and chemical studies proved that the child had died as the result of phosphatide lipoidosis. The authors also describe the results of the chemical analysis of the spleen of a patient with Gaucher's disease. Although this spleen had been in solution of formaldehyde for a number of years, the examination for lipoids still produced satisfactory results. Tabular reports list the results of the chemical analysis of the spleens and livers in several cases in the literature and in the authors' own cases.

Intravenous Carbon Therapy.—Van Meeteren reviews the literature on intravenous carbon therapy, pointing out that the carbon is usually administered in the form of a 2 per cent suspension of animal or wood charcoal in physiologic solution of sodium chloride. The individual dose usually varies between 4 and 6 cc. The number of injections likewise varies, the largest reported number being ten. Following these introductory remarks, the author reports the clinical history of a woman, aged 28, who developed a pneumococcal septicaemia after childbirth. After several therapeutic methods had failed including chemotherapy and serotherapy, the author resorted to the intravenous injection of a 2 per cent suspension of carbon. After that the attacks of chills ceased and did not recur. Subsequently the patient was given several additional injections of the carbon suspension. When the temperature increased again it was feared that the carbon therapy had likewise failed, but examination disclosed a pneumonia in the right lower lobe. After the last injection of carbon, the temperature decreased again and the patient recovered.

Epicardiac Coelothelioma.—Andolf and his associates say that the mediastinal tumor which was clinically and roentgenologically established at the onset in a man, aged 27, decreased in size on roentgen treatment, the cerebrospinal pressure became normal and the papillary stasis diminished. Before long a tumor of the parietal bone was established, but it yielded to roentgen treatment. Some months later the mediastinal shadow had grown larger and metastases were found in the fourth lumbar vertebra, the left iliac bone and the head of the femur. A gradual decline was followed by death. Necropsy showed the heart so transformed by large masses of tumors as to be hardly recognizable. The trunks of the pulmonary artery and the ascending aorta were surrounded by a neoplastic mass 1 cc in thickness. The posterior surface of the heart was covered with more isolated tumor nodules. The pleural cavities each contained about a liter of greenish yellow fluid and showed the same characteristics as the heart. Behind the manubrium of the sternum was a mass of grayish white tumors almost as hard as cartilage. In the liver were white tumors from the size of a pea to that of a kidney bean. The manner of growth of the tumors differed according to their localization. They tended to develop in the preformed intermediary spaces of the maternal tissue, without noticeably destroying it, although destruction was fairly well marked in some places. Distinguishable were (1) a diffuse sarcoma-like structure, (2) a trabecular structure with greater resistance to infiltration and (3) a type of alveolar kind in the metastases to the liver, lymph nodes and lungs. In the bone metastases the tumors in general resembled endothelial cells. In the vertebral column were an osteoplastic and an osteoclastic type. Twelve cases of endothelial tumors of the pericardium are cited. The authors conclude that the primary tumor in their case originated in the heart and they consider the serous endothelial cells the mother tissue of the tumor. They also say that epileptic attacks occurred during attacks of coughing at the time of the marked cerebral stasis, choked disk and augmented cerebrospinal pressure before the roentgen treatment of the mediastinal tumor and disappeared when the mediastinal tumor decreased in size under roentgen treatment and that the attacks of coughing ceased, which seems to them proof that marked cerebral stasis, acutely increased, can induce attacks of epilepsy.

Arterial Symptoms in Deep Thrombosis in Lower Extremities.—Lindgren says that a weakened femoral pulse is a frequent and early, if not constant, phenomenon in thrombosis of the deep veins and describes eleven cases of thrombosis in the femoral-iliac vein in which examination by the oscillographic method revealed more or less marked reduction of oscillation on the affected side. He also presents three cases of clinically established deep venous thrombosis in which no decrease in oscillation could be detected. He states that examination of ten cases of thrombophlebitis in the saphenous vein showed no diminution in oscillation and that no change in oscillation appears in thrombosis limited to the peripheral veins. The best prospect of establishing deep thrombosis by oscillogrometry is at the start of the thrombosis. If in a case, usually postoperative, beginning development of deep thrombosis is feared oscillogrometry is a valuable aid in diagnosis. Prognostically no conclusion can be drawn from the result of the examination, cases of long continued marked reduction of the oscillogram are reported in which no graver disturbances in circulation occurred than in cases with less pronounced reduction.

URINARY ANTISEPSIS

HISTORICAL REVIEW AND PRESENT EVALUATION

CHAIRMAN'S ADDRESS

HENRY W. E. WALTHER, M.D.

NEW ORLEANS

No ideal urinary antiseptic for internal use has yet been found. No single bactericide, when taken by mouth, will destroy all bacteria in the urinary tract. The physical and chemical problems involved here are so complex that it is doubtful whether there will ever be so universal a panacea. Recent investigations of a more scientific nature, however, should convince many skeptics of the need for these agents in urologic therapy. These studies reemphasize the dangers of an indiscriminate use of a single drug for all types of infections in the urinary tract, clinical research directed toward determining the selectivity of certain chemicals, for special bacterial groups, opens a field of untold possibilities.

Most of the reports appearing in the literature dealing with internal urinary antiseptics make no differentiation between (a) uncomplicated conditions and (b) complicated ones. Certainly one would expect that in the two instances drugs would affect bacteria differently. By all the rules of physical and therapeutic reasoning, the uncomplicated conditions would obviously respond more favorably to treatment. It is not easy, to be sure, for the general practitioner, lacking the refined instrumental equipment for differentiating the one group from the other, to pass judgment on a series of observations. It should, however, be comparatively easy to predict that, in the complicated instances, he will not relieve the patient by internal medication alone.

OIL OF SANTAL

Historically, oil of santal has been held in high regard from remote times as a specific for gonorrheal urethritis. Especially was this true among the Chinese, who are said to have spread its use gradually to other parts of the Old World. In 1750 the Dutch physician Rumphius of Amsterdam reported that he had seen virulent gonorrheal discharges in both sexes clear up under its administration. Ducoudray¹ in 1900 asserted that the somewhat undependable results from its use are due to the inconstancy of its composition, since it not only has been produced from widely different varieties of santal but has also been subjected to extensive adul-

terations with cheaper and worthless oils, on account of its high price. Midy² drew attention to its superiority over the time-honored oil of cubeb and oil of copaiba, with their repulsive eructations, gastro-intestinal disturbances, vomiting and frequently diarrhea, pointing out that its taste is most agreeable and that it causes no disturbances in the digestive system, while bringing to the suffering mucosa of the urethra a relief so prompt and complete that the discharge often disappears by the end of the third day.

Jordan³ in 1913 found that after administration of oil of santal the urine is germicidal to staphylococci but that the colon bacilli continue to grow luxuriantly under the same medication. Perutz and Kofler⁴ in 1923 stated that from a clinical point of view four effects have been attributed to oil of santal: an inhibitory effect on the secretion, a relief of spasm, a sedative effect and a diuretic action. They proved experimentally that it exerts an action on the autonomic nervous system of the urogenital tract, bringing to rest the pendular movement in the smooth musculature, reduces secretion and promotes diuresis. Tait⁵ recommended capsules combining oil of santal with methylene blue as a useful sedative. Gilbert Thomas⁶ states that he has often found oil of santal beneficial to patients with strangury and a severe posterior urethritis.

Oil of santal is excreted in the urine partly unchanged and partly as a compound of glycuronic acid. It is thought to have a specific action on the staphylococcus, which may apply to cocci in general. Stockman⁷ thinks we must conclude that the action of these essential oils is a selective one for the gonococcus, an action not shared by any of the ordinarily used urinary antiseptics. Winternitz,⁸ however, had already proved as far back as 1901 that santalol promptly inhibits the formation of exudate in an artificially produced pleurisy and promotes its rapid absorption, thus showing its beneficial effect on mucous membrane in general.

The Council on Pharmacy and Chemistry of the American Medical Association in its 1936 edition of *Useful Drugs* recognizes oil of santal but recommends the restriction of its use in gonorrhea to the subacute and chronic stages, in which its irritant action may stimulate healing. Although less popular than formerly, oil of santal and the other related volatile oils still have a place in urinary antiseptics.

METHENAMINE

Hinman¹⁵ pointed out that the factors influencing the excretion of methenamine are of two kinds those concerned with its excretion and those affecting its conversion. He showed that the larger the dose, the higher will be the percentage concentration on excretion, that large doses are safe and small doses useless. He also discovered that the character of the changes in an acid stomach continually affect the result the amount of methenamine broken up in the stomach means much less for subsequent conversion in the urine. The duration of exposure is also of moment, medium doses are of no use for the kidneys, since there is no time for formaldehyde to form before the drug is excreted. The dilution of the drug on its excretion is also a factor influencing the amount that is subsequently converted, since the higher the concentration, the more readily will the drug be broken down. Thus a polyuria would largely offset the advantage of large doses. Two years later Hinman,¹⁶ in evaluating the method, called it the most efficient urinary antiseptic in the greatest number of cases but drew attention to its very definite limitations. The alkalinity of urine due to the presence of bacteria which decompose the urea can as a rule not be changed by feeding acid-producing drugs. The value of methenamine for kidney antiseptics is largely destroyed by the necessity for concentration and for time to permit accumulation of formaldehyde in antiseptic amount. The same is true for cystitis unless retention is present. Hinman thinks the greatest usefulness of methenamine lies in its value as an agent for prophylaxis in the bladder in cases in which the foregoing conditions are not present. At the present time, twenty-two years later, he writes⁶ that he still makes use of methenamine and finds it quite effective.

Levy and Strauss¹⁷ showed that to kill the colon bacillus a concentration of 1:5,000 or more is necessary, and that with a dose of 7 grains (0.45 Gm.) of methenamine three times a day formaldehyde is never present in greater concentration, and the only bacteria that will be killed at that are the typhoid. An increase to an acidity sufficiently high to kill the colon bacilli would be liable, in combination with the formaldehyde, to produce injury to kidney tissue. Carroll¹⁸ pointed out that, although the method is the oldest and most reliable antiseptic, it is irritating to the glomeruli and mucous membranes if given too long and that it should accordingly never be given in acute gonorrhea or tuberculosis. Thomas and Wang¹⁹ found that 15 grains (1 Gm.) three times a day frequently causes indigestion and that excretion of bactericidal urine is a matter of great uncertainty, they were frequently disappointed to find a very low concentration of formaldehyde in a specimen of highly acid urine. Edwin Davis²⁰ in 1932 stated that methenamine is incomparably more efficient than either pyridium or hexylresorcinol in causing the normal person to secrete urine that is antiseptic against both the colon bacillus and the staphylococcus. In 1937

he had not changed his opinion. In answer to a recent questionnaire he states⁶ "With respect to methenamine, I am forced to the conclusion that this is a valuable remedy, the merits of which we have tended to overlook in our search for something newer and better." He writes that it has been demonstrated that the administration of methenamine, together with ammonium nitrate or chloride, imparts an antiseptic value to the urine with amazing consistency—an observation that he has been able to verify with subsequent checks. Gilbert Thomas⁶ also writes that at the present time he uses methenamine widely, but always in association with some drug that will thoroughly acidify it. He says that this combination has been exceedingly useful in the treatment of infections produced by bacilli.

Helmholz²¹ warned in 1932 that treatment with methenamine without constant control of the hydrogen ion concentration is likely to be unsuccessful. He found as the result of experiments that at a p_H of 6 urine with a 0.5 per cent concentration of methenamine rarely sterilizes itself at the end of twenty-four hours. At a p_H of 5 urine can be sterile after four hours at 37°C. This agrees with my own observations that the p_H should be below 5.6 if a sufficient amount of formaldehyde is to be generated in the urine. The old idea that methenamine and an acidifier should be given separately has proved fallacious, the custom of giving them together is now universal, without the gastric irritation that was supposed to result.

METHYLENE BLUE

Methylene blue is undoubtedly the best known of the group of the diphenylamine dyes, in which are found methylene blue, gentian violet, acriflavine and mercurochrome. It was first used as a urinary antiseptic by Einhorn²² in 1891, who found it efficient either by mouth or by rectum. Furthermore, the good results seemed to be permanent. He observed that urine from patients receiving 0.2 Gm. two or three times a day remained sterile in test tubes for three weeks, without further precautions, while control test tubes inoculated with ordinary 1 day old urine produced large colonies. Methylene blue became very popular during the last decade of the nineteenth century, being turned to good account in gonococcal infections. It also found a peculiar application in tuberculous conditions of the urinary tract. Hinman¹⁶ pointed out in 1915 that methylene blue is not an individual chemical substance and that it often undergoes decomposition in its passage from the blood to the urine, appearing in the form of leuko derivatives or chromogens, which are mostly non-bacteriostatic. This decomposition may also occur as the result of bacterial activity. Thus *Escherichia coli* was found to decolorize a 1:1,000 dilution, showing imperfect antiseptics, but the growth of the staphylococcus was still inhibited in a dilution of 1:100,000 or even 1:150,000. Absence of deep blue color denotes either incomplete antiseptics or deficient excretion by the kidneys as the result of renal disease, under the latter conditions the use of methylene blue may cause serious renal injury. According to Hinman,¹⁶ administration of methenamine with methylene blue will convert the leuko derivatives provided the urine is properly acidified. He considers it of some value in staphylococcal infections of the bladder and kidneys but worthless in urethritis. In a recent communication he states

on urination, he found its best results in the acute, fulminating posterior gonorrheal infections, in which it had a surprisingly prompt effect on the presence of pus and cocci. Rudnick²⁸ worked out a new azo compound, 104, which he called ambazin and which he regards as a step forward in that it has no undesirable staining qualities, is well tolerated by the gastro-intestinal tract and has a high bactericidal and bacteriostatic action, with a very low incidence of secondary complications. Only fourteen of 100 cases failed to respond favorably to this treatment.

From Germany come reports of gratifying results from pyridium in a form known as neotropin (niazo) as well as from the original pyridium product. Minder, Skrop and Babics³⁷ consider that these dye preparations surpass all other forms of antiseptic medication, since they act not only on the surface but within the depths of the tissues, thus greatly reducing inflammation and proving their claim to recognition. Kulitzky³⁸ reports from the Franz Josef University in Szeged (Hungary) that it acts admirably on the gonococcus, staphylococcus and streptococcus and less efficiently on the colon bacillus. He found it effective in forty cases of cystitis in women and considers its ability to allay irritation in the mucous membranes one of its best qualities.

Gillespie³⁹ of the Mayo Clinic sounds an unfavorable note. He found no bactericidal properties in any of the concentrations of pyridium that he used. There was no tendency to kill or even inhibit *Escherichia coli* in urine having a concentration of pyridium even of 1,600 to 1,800. It does not seem to him that the recommended dosage of 0.2 Gm of pyridium or 0.1 Gm of serenium, even with restricted water intake, would attain a concentration sufficient to inhibit even *Staphylococcus aureus*.

About 33 per cent of answers received to our questionnaire stated that pyridium and the rest of the azo dyes seemed to be of no material benefit, 46 per cent stated that they were definitely of value, 21 per cent had never tried them. All in all, however, it would appear that these substances constitute valuable stepping stones in the path of progressive urologic therapy.

HEXYLRESORCINOL

The chief sponsor for hexylresorcinol-Sharp & Dohme, a product of synthetic chemistry, was Veader Leonard,⁴⁰ who gave a minute description of its properties in 1924. He stated that it meets all the experimental qualities enumerated by Davis²⁴ as essential to the ideal urinary antiseptic in the following manner: It is chemically stable, nontoxic in therapeutic doses, nonirritating to the urinary tract, bactericidal in high dilution in urine of any reaction and is excreted by the kidneys unchanged in sufficient percentage to impart active bactericidal properties to the urine. In addition, it is susceptible of being administered by mouth, secreted in the urine at a rate which admits of continuous local action in the urinary tract, and finally the urine secreted possesses a bactericidal action against organisms exposed to it, and not a mere growth-inhibiting property. Leonard's⁴⁰ results up to the date of his writing seemed to justify the claim that in

chronic infections of the urinary tract in adults, due to *Staphylococcus albus* and *aureus* and in some strains of *Bacillus pyocyaneus*, oral administration of hexylresorcinol, without any other treatment, has resulted in prompt and complete disinfection of the urinary tract, accompanied by clearing up of the urine and disappearance of symptoms. After several months of treatment there were no recurrences. In colon bacillus infections more persistent treatment is usually necessary and, as a rule, local treatment will be found necessary, as well as intensive courses of the drug. Under this combined treatment, these too have been completely overcome. There was, according to Leonard, increasing evidence that, in cases in which this complete disinfection of the urinary tract did not occur, pyelonephritis was present.

My own experience²⁵ with this method was confined to use of the bulk olive oil solution and given to children, each drachm containing 0.1 Gm of the drug. Later I used the capsules, giving at first two after each meal and later four. In no case was the treatment continued longer than seven days if no beneficial results were seen within that time. We have, in fact, made it a rule in all our cases to discontinue any form of treatment that gave no evidence within seven days of producing useful results. Our results were not sufficiently encouraging to seem to warrant a continuance of this method at our clinic.

THE KETOGENIC DIET

Five and a half years ago Clark,⁴³ and also Helmholtz,²¹ working independently, tried for the first time the effect of acidification of the urine by feeding a special type of high fat, low carbohydrate diet designed to produce a state of ketosis. For its first application Clark chose a patient who had been under other forms of treatment for fourteen months for cystitis and pyelitis due to a colon bacillus infection. After twelve days of this ketogenic diet there was permanent disappearance of the bacilli. This encouraged Clark to make a wider application of the method. In the next 200 tryouts about two thirds were successful. He and Helmholtz both observed that results were better in children and suggested that this is perhaps because the adult liver has a greater glycogen storage.

The ketogenic diet in its original form was very elaborate and was so exacting in the precision of its minutest details that it was quite unsuited for practical use at home. It had, therefore, the disadvantage of requiring hospitalization of patients otherwise not in need of hospital care. A simplification was then tried which could be managed under normal home conditions. But the diet in its new simplified form, which called for 40 per cent cream and eggs, produced disgust that resulted in gastro-intestinal upsets. Patients were refusing absolutely to continue to take so unpalatable and repulsive a diet. Then Nesbit and McDonnell⁴⁴ suggested that a low calory or starvation diet would serve equally well to produce ketosis, by forcing patients to consume their own endogenous fat. It is well known that the body will call on this supply whenever energy of diet falls below the expenditure of energy. Production of ketosis then depends on inadequacy of available dextrose. These workers observed a rapid and profound degree of ketosis following their low calory ketogenic diet and reported good results from its bactericidal properties.

The idea of controlling bacilluria by a diet was enthusiastically taken up by urologists. Cook and Braasch⁴⁵ made a report two years ago on their use of the method in 600 adult cases of urinary infection. They found the diet most effective in cases of simple initial recurrent pyelonephritis and cystitis without any demonstrable complication. In a group of sixty-five such uncomplicated cases, the diet eradicated the microorganisms successfully in fifty-six, of course in association with other appropriate treatment. In forty-four of these the infection was due to *Escherichia coli*, in six to *Aerobacter aerogenes*. They found that in a certain percentage of cases in which the diet was used it was desirable to employ in addition some such acidifying drug as ammonium nitrate or ammonium chloride.

Crance⁴⁶ pointed out the same capacity of the ketogenic diet to overcome *Escherichia coli* infections. In his experience, however, it fails entirely with *Aerobacter*. Like others, he deplored the lack of cooperation on the part of patients but observed that it is quite feasible to apply the simplified form of the diet in short courses, with very satisfactory results, several short courses being better than one long one.

Poor renal function has been found to be a contraindication for use of the ketogenic diet, in view of the fact that the bacteriostatic agent has to pass through the kidneys.

Clark and Keltz⁴⁷ utter a warning that the mechanical and chemical irritation of the catheter and lavage may offset the relief afforded by the diet. They have found two types of cases in which they were at a loss to account for the unsatisfactory results, one being a group in which ketonuria will not develop in spite of the treatment, and the other one in which the hydrogen ion concentration remains high notwithstanding attempts at acidification.

In order to get the best results from the ketogenic diet, the hydrogen ion concentration must be kept at 5.3 or less. Shohl and Janney⁴⁸ showed long ago that *Escherichia coli* is not inhibited until a p_H of from 4.6 to 5 is reached and that the optimum p_H for its growth is from 6 to 7.

On account of the marked gastro-intestinal disturbances caused by the ketogenic diet, it became increasingly difficult to persuade patients to take it. In view of the larger percentage of elderly patients with urosepsis—the great percentage of our hospital patients being over the age of 50—and with established gastro-intestinal disorders, the problem was far from being solved by the ketogenic diet, which seemed at best a clumsy, roundabout way of producing a high degree of acidity that might be achieved in some other way. Attempts to find this better way, therefore, were continued.

MANDELIC ACID

Just two years ago Rosenheim⁵¹ announced his discovery that mandelic acid would do in a direct way what had been done in an indirect and complicated way with beta-hydroxybutyric acid and the ketogenic diet. After trying and rejecting several other similar agents, he chose mandelic acid because it is a hydroxy acid, it is nontoxic, and it is excreted unchanged in the urinary

tract, which it renders bacteriostatic. He recommends that it be given in the form of a salt, such as sodium or ammonium mandelate. At the present time he writes that he is using practically only the latter, in the form of a syrup containing 3 Gm of the acid to the dose of half an ounce, and he finds that except in puerperal cases it is rarely necessary to use additional ammonium chloride to increase the acidity.

This treatment has a tremendous advantage over the ketogenic diet in that the patient may eat whatever he likes. This new product is unpleasant to the taste and often causes the gastro-intestinal upsets so common to many of the urinary antiseptics now in use. Rosenheim showed that given orally, mandelic acid escapes metabolism or conjugation in the animal organism and is excreted by the kidneys in the urine in a concentration sufficient for bactericidal action, provided the hydrogen ion concentration is lowered at the same time.

This new form of treatment has achieved a very wide vogue, because of its incontestable bactericidal potency. Helmholz⁶ has just written that the most obstinate of all the cocci, *Streptococcus faecalis*, has yielded and that it, as well as *Staphylococcus aureus*, has been killed off by mandelic acid in concentrations that can be achieved in man as well as in the test tube, provided the kidneys are normal or approximately so. Clark⁶ writes that mandelic acid has practically replaced his use of the ketogenic diet in nearly all cases of bacillary infections of the urinary tract. He utters the warning, however, that the general practitioner should be cautious in his use of this product, since there is no "bedside test" for renal insufficiency. Unless a physician is equipped in his office to do a urinalysis, including microscopic examination of the centrifugated sediment, Clark feels that he should not take the responsibility of prescribing mandelic acid. "During the time that he is prescribing this drug, he should do a urinalysis preferably every second day and not less frequently than every third day. In the initial test of the urine, before prescribing the drug, if there are casts present or if there is no blood in the urine but the test for albumin is positive, the physician should feel sufficiently warned to proceed cautiously. If an elderly patient is drinking a normal amount of fluids during the day with no particular emphasis being placed on the amount of the intake late in the day, and at the same time comparatively little urine is excreted during the day while urinary output at night is larger than the output during the day, the physician should be likewise cautious in his use of mandelic acid. Also an increased blood pressure should warn against mandelic acid."

Young⁶ writes that, while the ketogenic diet has been very beneficial in a few cases of bacillary infections, he thinks that mandelic acid and its compounds are better, he would always combine this with an acid-ash diet and acid sodium phosphate to bring the urine down to a p_H of 5, or lower, if possible. Lowsley⁶ states that he has used mandelic acid in several cases with good results but that the expense of the drug is a great disadvantage. And Frank Hinman⁶ says that, of all the antiseptics, mandelic acid has proved to be the most effective.

In placing mandelic acid in the hands of the medical profession, Rosenheim postulated that its use was effective only in cases unassociated with urinary obstruction. Dolan,⁵² however, had occasion to note apparent cure in three cases presenting marked obstruction, which he thinks is explained by the fact that the drug is held

longer in situ, thus giving its bacteriostatic powers a longer time in which to function. The same is true in cases of bladder diverticula, in which he has seen good results. He warns that hematuria has been known to follow the use of mandelic acid in some cases.

Edwin Davis,⁶ who is not enthusiastic about mandelic acid, suggests that it is likely to follow the same sequence as all other new discoveries in medicine all such are followed "first by enthusiasm and then by commercial exploitation, after which come recognition of defects and danger, poor results, fear, decreased use, followed by overcorrection, until, finally, the drug reaches stability at its proper level of usefulness. This period of trial or evaluation may take months or years."

Our work with mandelic acid in our service at the Southern Baptist Hospital, extending from last summer up to the present time, has been only partially encouraging. Rosenheim⁶ reports that Schnohr^{52a} of Copenhagen is using calcium mandelate because it is almost tasteless and still equally acidifying, my own investigations with this new formula have not, as yet, advanced sufficiently to warrant a report. I do not feel that I am ready to acknowledge all the rosetate claims made for the mandelates, but I propose to continue my investigations in the strong hope that further studies and experience will accentuate its value. Although not a panacea for all infections of the urinary tract, it will find its own niche in the hall of urologic science and will take its place alongside the urinary antiseptics that are reviewed in this paper.

SULFANILAMIDE (PRONTYLIN)

Work on azo compounds in 1932 by Meitzsch and Klarer led to their synthesizing a hydrochloride of 4-sulfamido-2'-4'-diaminoazobenzene, a red crystalline powder soluble in cold water to 0.25 per cent. Domagk⁵³ demonstrated in 1935 that this azo dye, when given intravenously, exerted a selective action on streptococcal infections in mice. These results were confirmed by Colebrook and Kenny⁵⁴ both experimentally and clinically. Trefouel, Nitti and Bovet⁵⁵ proved that the diazo linkage in prontosil⁵⁶ was not essential for its therapeutic effectiveness and that the parent sulfanilamide (prontylin), a colorless compound, was equally effective. Colebrook and Kenny gave sulfanilamide orally with satisfactory results in thirty-eight severe cases of puerperal infection with only three deaths.

In Europe, Imhauser⁵⁷ first reported on the efficacy of prontosil album tablets (prontylin) in urinary infections. He observed favorable results in treating *B. coli* infections in the bladder and kidneys but does not record the number of cases that he observed.

In America, Helmholtz⁵⁸ recently made observations with sulfanilamide which demonstrate that urine of patients taking the drug develops definite bactericidal power for such organisms as are commonly found in infections of the urinary tract. Those urines contain-

ing *Escherichia coli* and *Aerobacter aerogenes* yielded the most striking results, however, with *Streptococcus aureus* and *Streptococcus faecalis*, five strains of organisms out of eleven were killed in from twenty-four to seventy-two hours after incubation. *Proteus vulgaris* and *Pseudomonas aeruginosa*, in eight strains studied, gave five positive cultures, demonstrating that the action of sulfanilamide was less effective here.

Dees and Colston⁵⁹ are the first to record their experiences with sulfanilamide in the treatment of gonococcal infections. In nineteen cases observed the smears and urines became negative for gonococci in two days in five cases, in three days in five cases, in five days in two cases, and in four, six and twenty three days respectively in single cases. In one case smears became negative on the ninth day, positive on the fourteenth day and again negative on the seventeenth day. In three cases gonococci were still present after eleven days. All patients received, in four divided doses a day, 4.8 Gm of sulfanilamide daily for two days, 3.6 Gm daily for three days, and then 2.4 Gm daily for from four to eight days. They warn against a continuance of the drug immediately on complaint by the patient of headache, fever, lassitude, cyanosis, general malaise or extreme weakness. Personally I would warn against so large an initial dose of this new drug as routine, disagreeable and at times serious reactions may follow such a plan, I consider it far safer to begin by giving 1.2 Gm daily for the first two days and if this is well tolerated, increase the dose to 2.4 Gm daily for two days. Beginning with the fourth day, provided sulfanilamide is still being taken without untoward effects, the drug then can be gradually increased daily until 4.8 Gm is reached.

Two hospital patients with severe urosepsis observed by us recently, one with *Staphylococcus aureus* alone and one with *Escherichia coli* and *Staphylococcus aureus* (one with positive blood culture and one without), responded promptly to a combined therapy of prontosil intramuscularly and sulfanilamide orally. In the one case the infection followed a prostatectomy while the other resulted from a cystotomy. Not only was the persistent fever controlled promptly—within three days in each instance—but the general condition of both patients improved proportionately. Each convalescence was uneventful thereafter. From my limited experience with sulfanilamide—which includes eight cases of gonorrhea—I am convinced that, provided adequate care is exercised, this drug will occupy an important niche in our armamentarium for combating the various strains of coccic invasion.

Finally, I believe that every one of these agents reviewed has a place in treating urogenital ailments. In office and hospital practice I employ them all. When one does not show itself adapted to a particular case, I seek to find another one better suited to its needs. I play no favorites. Every case is an individual problem, every patient may have his idiosyncrasy, his own capacity for reaction to one method of treatment and not to another. None of the present known urinary antiseptics can be called specifics. Every new agent announced should be given its day in court, it should have a fair trial, after which it will, as Davis has pertinently said, reach stability at its proper level of usefulness. Every clinician is an investigator, the final verdict is given not in the laboratory but in the knowledge gained from experience at the bedside.

ABSTRACT OF DISCUSSION

DR ANSON L CLARK, Oklahoma City With the facilities for the distribution of knowledge through medical literature it is surprising how long it takes to evaluate the true effect of a drug or therapeutic regimen. Reports of medical discoveries often are heralded too enthusiastically by newspapers and magazines. Some of these false impressions are due to information emanating from investigators before thorough tests of the action of any type of therapy have been carefully studied, and some of these erroneous ideas are circulated by pharmaceutical houses in overselling a product they are distributing. As the result of a recent article in a national news magazine in which a large medical center was alleged to have announced a cure for gonorrhea in four days at a cost of 40 cents per patient, we are fast approaching the peak of the curve so aptly described by Edwin Davis for evaluating all new discoveries in medicine. Sulfanilamide is the drug of the moment in urinary antiseptics, but before the true effect of this product can be clearly defined, much more data will have to be gathered and many more carefully controlled clinical cases will have to be studied. In experimenting with sulfanilamide in mice the fatal effect of the pneumococcus can be delayed for a considerable period by the drug and, as Rosenthal reports, "The chemical apparently has the power of holding the infection in check for a while, but eventually the chemotherapeutic effect is lost and the mouse succumbs to pneumococcal infection." In the clinic with which I am affiliated we have observed that with both gonococcal and nonspecific infections involving the prostate gland remarkable results are apparently obtained immediately after the administration of sulfanilamide. However, when the drug is discontinued or when it has been administered over a sufficient period it seems to lose some of its initial effect, as evidence of the infection will again be found in the urine and prostatic secretion of the patient. I should like to warn against a too early verdict in favor of an announcement that the millennium has been reached in dislodging gonococcal infections easily and rapidly. From our experience this is a remarkable drug which will be a most valuable addition to the list of urinary antiseptics when it is carefully prescribed with a full knowledge of its possible toxic effects and a full realization that in some types of infection it may diminish but not entirely eradicate the organisms.

DR MONROE E GREENBERGER, New York Dr Walther's paper is certain to lead to useful reflection and sober realization of the truth of the warning against the dangers of an indiscriminate use of a single drug for all types of infections in the urinary tract. It is just about one month since I began observing the effects of sulfanilamide in twenty-three cases of gonorrheal urethritis. The improvement in some, though combined with the time-honored procedures, has been encouraging and almost phenomenal in one particular case that failed to respond to all other methods of treatment. I agree with Dr Walther's closing remarks, "None of the present known urinary antiseptics can be called a specific."

DR HENRY F HELMHOLZ, Rochester, Minn A certain amount of information is available that will help one in judging as to which is the most effective form of treatment in a particular case. In these careful bacteriologic studies it must be remembered that of the gram-negative bacilli in the urine the colon bacillus probably overgrows all the rest, and that one may get rid of the colon bacillus and find a *Pseudomonas* infection still remaining. Repeated cultures are necessary to find out exactly with what combination of organisms one is dealing. A certain amount of information has been obtained as to the choice of procedure. I do not know how much success has been obtained in treating adults with the organic acids, but I know that only when the kidney can excrete beta-oxybutyric acid and mandelic acid in concentrations above 0.5 per cent and with a urine which has a pH below 5.5 can one expect a bactericidal effect. Success in treatment with the organic acids is very unlikely in cases in which there is disturbed kidney function. Recently Buchtel and Cook have been able to show that with sulfanilamide they were able to clear up infection in the urinary tract of patients with a blood urea over 100. I should like to show a few slides to illustrate

the effect of sulfanilamide and mandelic acid on various organisms. In the first slide it will be noticed that sulfanilamide in a concentration of 51 mg per hundred cubic centimeters in the free form kills off eight different strains of *Proteus ammoniae* in a twenty-four hour period. With an acid urine of higher concentration these organisms were not completely killed off, but on alkalinization of the urine they were. So it can be said that if the patient has a *Proteus* infection one would not try mandelic acid or the ketogenic diet but would use sulfanilamide. The second slide shows the complete absence of bactericidal effect on five strains of *Streptococcus faecalis*. In the original publication we did seem to have one or two streptococci that were killed off by this drug. But we have checked our streptococcus cultures and we did not find a single urine that, although bactericidal for all the gram-negative bacilli and for *Staphylococcus aureus*, was bactericidal for *Streptococcus faecalis*. The next slide shows that mandelic acid at the same pH and in the same concentrations that kill off the gram-negative bacilli also kills off *Streptococcus faecalis*. In *Streptococcus faecalis* infection it would therefore be advisable to use mandelic acid treatment rather than sulfanilamide treatment. The last slide shows the effect of the reaction to sulfanilamide therapy. We were rather surprised to find a urine with a pH of 6.0, with 57 mg per hundred cubic centimeters of free sulfanilamide and 68 mg of the conjugated form that had very little bactericidal effect as compared with the same urine alkalinized to a pH of 7.5, which in turn had a very decided bactericidal effect on all the organisms. I think the time will come when, as the chairman has suggested, we shall know definitely, after careful bacteriologic examination of the urine, which one of these urinary antiseptics to use.

ACUTE HEMOLYTIC ANEMIA DURING
TREATMENT WITH SULFANILAMIDE

S E KOHN, M.D.

MILWAUKEE

That sulfanilamide is not entirely without toxic manifestations was recognized by Long and Bliss,¹ who stated that in their experiences patients given this dye often complained of dizziness, anorexia, nausea and vomiting. They also describe another toxic manifestation in the form of a cyanosis, which is sometimes associated with methemoglobinemia. This varied in intensity from a mild bluing of the lips to a rather intense slaty discoloration of the lips and nail beds. Rises in fever were also described. When this occurred, the drug was stopped for two or three days, during which time the temperature would fall to normal if the rise had been due to the drug.

Since sulfanilamide or its derivatives contain the benzene ring, it is possible that it may cause damage to the hematopoietic system. Long² stated that he has seen five cases of anemia following the use of this drug. Harvey and Janeway³ report three cases of acute hemolytic anemia following the use of sulfanilamide.

This paper reports another case of anemia with acute hemolysis and hemoglobinuria.

REPORT OF CASE

B H, a white girl, aged 1 year, was seen March 15, 1937, with a cold and a fever. She was again seen March 19 with croup and a fever. She was again seen March 21 with an acute

bilateral otitis media. A bilateral paracentesis revealed a slight discharge of watery pus.

The infant was sent to the Milwaukee Children's Hospital March 22 for observation.

On examination at the hospital the child was acutely ill with a temperature of 102 F. Both canals were filled with a thin pus. There was a thick yellow nasal discharge and a coated tongue. The pharynx and the tonsils were acutely injected, and a bilateral cervical adenitis was present. The heart and lungs were grossly normal. The abdomen was soft with no distention. The extremities were essentially normal.

The blood count on entrance, March 22, showed leukocytes 20,400, neutrophils 67 per cent (segmented 56 per cent, nonsegmented 11 per cent), monocytes 5 per cent, small lymphocytes 22 per cent, large lymphocytes 4 per cent, plasma cells 2 per cent, erythrocytes 4,700,000, hemoglobin 12.5 Gm. Examination of the urine revealed acid reaction, albumin 1 plus, and negative reaction for sugar, acetone and diacetic acid. The microscopic examination revealed 5 white blood cells per high power field and some amorphous urates. Cultures of the ears and throat yielded hemolytic streptococci. The Kline test was negative. March 23, 175 cc of citrated blood from the father (typed and cross typed) was given intravenously. There was no untoward reaction. March 23, sulfanilamide, 5 grains (0.3 Gm) three times a day, was begun. This was continued for twelve doses to March 28, on which day a faint jaundice and a pinkish brown discoloration of the urine were noted. The sulfanilamide was stopped immediately. The fever, which had fluctuated between 99 and 101 F, dropped March 23 to 98 F only to rise again to 101 F on March 29. On this day the jaundice became very profound. The child became listless, appeared toxic and had labored respirations. There were several emeses of fluids and food. The urine became increasingly reddish brown. Examination of the urine at 6 a. m. showed an alkaline reaction, and a negative reaction for sugar, acetone and diacetic acid. The hemoglobin was strongly positive. The microscopic examination showed an occasional red blood cell and white blood cell and granular casts. At noon of the same day large quantities of albumin were found and the urine was acid in reaction. The reactions for sugar, acetone and diacetic acid were negative. The hemoglobin was very strongly positive. Urobilin was also present. An occasional red blood cell, 10 white blood cells per high power field and many granular casts were found on microscopic examination. The blood count at this time revealed leukocytes 20,100, neutrophils 40 per cent (segmented 35 per cent, nonsegmented 5 per cent), monocytes 1 per cent, small lymphocytes 52 per cent, large lymphocytes 7 per cent, erythrocytes 3,250,000, hemoglobin 8.5 Gm. Two normoblasts were found in 100 white cells counted. Anisocytosis, poikilocytosis and polychromatophilia were present in the red cells.

There was some question as to whether the transfusion of March 23 might have had any etiologic bearing on this acute hemolysis. Therefore grouping of the father's and baby's blood was carried out again and found to be correct. Cross matching showed no agglutination or hemolysis between the patient's serum and the donor's cells and vice versa. Incubation for eighteen hours showed no hemolysis.

March 30, two days after the sulfanilamide was stopped, the infant appeared slightly improved. The jaundice had faded somewhat. The mucous membranes were still very pale but she was less irritable and appeared brighter and less drowsy. Examination of the urine at 6 a. m. revealed an acid reaction, a brown coloration and negative reactions for albumin, sugar, acetone, diacetic acid and hemoglobin. The microscopic examination was also negative. At 10 o'clock the hemoglobinuria was still negative but the kidney irritation was also still manifest. Examination of the urine at this time was as follows: yellow, neutral reaction, and negative reactions for sugar, acetone, diacetic acid, hemoglobin and bile. The urobilin and albumin had a 1 plus reaction. The microscopic examination showed an occasional red blood cell, 10 white blood cells and many granular casts per high power field.

The blood picture at noon revealed a profound anemia. The erythrocyte count was 2,000,000, hemoglobin 6.0 Gm, 8 normo-

blasts and 2 megaloblasts per hundred white blood cells counted. Marked anisocytosis, slight poikilocytosis and marked polychromatophilia were present. The platelet count was 226,000. The coagulation time and bleeding time were two minutes and one-half minute respectively. The white blood cell count was 47,400 with 27 per cent neutrophils, (nonsegmented 6 per cent segmented 17 per cent, metamyelocytes 3 per cent, myelocytes 1 per cent), 37 per cent small lymphocytes, 32 per cent large lymphocytes and 4 per cent monocytes. Twenty cc of whole blood was given intramuscularly, followed in six hours with 160 cc of citrated blood given intravenously.

The blood count at 4:30 p. m. showed an apparent cessation of hemolysis, the erythrocytes being 2,500,000 and the hemoglobin 6.0 Gm.

From this point until the time of discharge the blood picture improved rapidly, showing on March 31 a leukocyte count of 30,800, neutrophils 40 per cent, (nonsegmented 9 per cent, segmented 25 per cent, metamyelocytes 4 per cent, myelocytes 2 per cent, monocytes 15 per cent, small lymphocytes 41 per cent, plasma cells 1 per cent, erythrocytes, 3,350,000, hemoglobin 11 Gm, and 12 normoblasts in 100 white blood cells counted. A slight anisocytosis, poikilocytosis, achromia and a marked polychromatophilia were present in the red cells. Urinalysis revealed an acid reaction, a yellow color, a trace of albumin and negative reactions for sugar, acetone and diacetic acid. Eight white blood cells per high power field and mucus were reported in the microscopic examination. A report on the blood picture April 2 was 3,900,000 erythrocytes and hemoglobin 12.5 Gm. The appearance of the red cells showed a slight anisocytosis and polychromatophilia. The leukocytes were 16,600, neutrophils 30 per cent (nonsegmented 2 per cent, segmented 26 per cent), metamyelocytes 1 per cent, myelocytes 1 per cent, small lymphocytes 68 per cent, large lymphocytes 2 per cent.

The following day the erythrocyte count increased to 5,100,000 and the hemoglobin increased to 14 Gm. A slight achromia was present. The leukocyte count was 15,700 with 22 per cent neutrophils, 4 per cent monocytes, 64 per cent small lymphocytes and 10 per cent large lymphocytes.

The child was discharged from the hospital April 4 in good condition. She had an uneventful course at home for five days.

In an effort to ascertain whether the child had really reacted unfavorably to the drug, sulfanilamide was again begun April 16. One 5 gram tablet was given three times a day for four doses. The child became very restless and irritable and the fever rose to 101 F. The drug was stopped immediately. The symptom complex subsided within twelve hours after cessation of the drug. The urine showed no evidences of hemoglobin at this time.

It would appear that certain individuals have some predisposition to react to this dye. Obviously with the great number of patients who have received the drug in the past year and with the few reports of toxic reactions, most persons are not unfavorably affected. If sulfanilamide is to be used, one must constantly keep in mind, however, that it is not entirely without some danger.

425 East Wisconsin Avenue

Between the Two Extremes—But, since education is a lifelong process, we are all conscious of persistently shoring up to atone for educational deficiencies which could not possibly have been anticipated. Between these two extremes, a happy medium must be found. And there is no better goal, I think, than to aim from the beginning to make of every student a capable practitioner. In this process, as well as in any other, the exceptional men will come to the top, those gifted with a scientific imagination will feel the appeal of a life devoted to investigation, the majority, meanwhile, will find themselves prepared for a professional career no less rich in opportunities both for service and for research.—Cushing, Harvey, *Consecratio Medici and Other Papers*, Boston, Little, Brown & Co., 1928.

TOXIC OPTIC NEURITIS RESULTING
FROM SULFANILAMIDEPAUL C BUCY, M.D.
CHICAGO

A toxic optic neuritis or a toxic neuritis of any other nerve has not previously been reported as occurring as a result of the administration of sulfanilamide or of any of the related drugs in man. Likewise manifestations of involvement of the central nervous system have been limited to the observation of mental confusion by Paton and Eaton,¹ and to the unamplified statement by Whitby² that he is familiar with one human case in which symptoms of involvement of the nervous system, such as occur in mice developed. In mice, according to Long and Bliss,³ symptoms of vestibular dysfunction and spastic paralysis develop as a result of the administration of sulfanilamide. The majority of toxic manifestations that have resulted in human cases from the use of these drugs are concerned with the blood. They are cyanosis,⁴ sulfhemoglobinemia (especially when some sulfate has been administered simultaneously⁵), methemoglobinemia,⁶ severe hemolytic anemia^{4b} and anemia with the appearance of nucleated red blood cells, polychromasia and moderate anisocytosis.⁷ Dees and Colston⁸ recorded the development of leukopenia in patients being treated with these drugs but they did not feel that this development could be directly attributed to the drug. Borst,⁹ however, recorded the case of a woman with pyelocystitis and "thrombopenic purpura" who was treated with "prontosil flavum." Agranulocytosis developed and she died. He believed that agranulocytosis was the result of a toxic action of the drug. Southworth,⁹ Dees and Colston,⁸ and Harvey and Janeway⁴ have recorded the development of acidosis. Southworth stated that in fifty cases in which sulfanilamide was given clinical acidosis developed in two and fifteen others without clinical manifestations showed "a consistent though variable drop in the CO₂ combining power of their blood plasma." Harvey and Janeway⁴ also recorded a depression of hepatic function as determined by bromsulfalein excretion tests. Fever resulting from the administration of these drugs has also been recorded.¹⁰ Various symptoms such as urinary irritation,¹¹ lassitude and dizziness,⁶ nausea, headache and abdominal discomfort¹ have also been noted. In

the main, with the exception of Borst's⁹ case as noted, the toxic manifestations have been mild and have subsided when administration of the drug has been discontinued. However, some of the developments have been serious and severe,^{4b} if not fatal. It is obvious that sulfanilamide, though apparently a therapeutic agent of great value, has also toxic qualities of no little import which must be reckoned with. The present case in which a toxic optic neuritis apparently developed as a result of the administration of sulfanilamide is reported in order to point out another possible toxic action of the drug—the fact that some individuals seem to tolerate the drug poorly and that with the development of any of the more severe toxic manifestations the drug should be withdrawn at once. In view of the frequency with which the hematopoietic system is involved, it would appear advisable to make blood counts frequently, if not daily, on all patients receiving this drug.

REPORT OF CASE

J. R., a girl, aged 16 years, was first admitted to one of the general surgical services at the University of Chicago Clinics, May 27, 1936. In 1925 at the age of 6 years a bilateral mastoiditis developed. This illness was complicated by

Visual fields June 25. The peripheral fields for a 3 mm white target at 1 meter are generally constricted. The peripheral fields for a 3 mm blue target are indicated by the solid line and for a 3 mm red target by a broken line. The crosshatched area in the center of each field indicates the relative scotoma for the 3 mm white target and the absolute scotoma for the 3 mm colored targets. (Visual fields studied by Dr. McClelland Shellman.)

pain and tenderness in the left hip and both knees. The knees recovered spontaneously. The hip was immobilized in a cast for nine months. Six months after the cast was removed the left hip was again involved and a second cast was applied for three months and the hip became ankylosed. Subsequently she was well until June 1935, when she suffered from German measles, which was associated with a severe cervical lymphadenitis. Two weeks after recovery from this a swelling in the left groin developed, which was incised and drained a thick yellow pus. This abscess extended into the perineum and subsequently ruptured into the rectum. The sinuses continued to discharge purulent material thereafter. Physical and roentgenologic examinations led to a diagnosis of chronic osteomyelitis of the head and neck of the left femur and of the ilium, with an intrapelvic abscess. This was treated by incision and drainage of the pelvic abscess June 3, colostomy October 23, and incision and drainage of the pelvic abscess December 31. April 27, 1937, she was again admitted to the hospital because of fever and pain in the region of the left buttock. April 28, two sinuses, one in the buttock and one over the coccyx, were incised, curetted and packed. Cultures of the purulent discharge from the sinus revealed hemolytic *Staphylococcus aureus*, *Bacillus proteus*, *Staphylococcus albus*, *Streptococcus viridans* and *Alcaligenes fecalis*. May 17, *Streptococcus viridans* was recovered from a culture of the blood. June 7, the blood culture was negative. Throughout May the temperature showed a septic febrile course, rising to 100.6 F.

From the Division of Neurology and Neurosurgery, University of Chicago.

The sulfanilamide used in the case herein reported was a product of the Winthrop Chemical Company.

or 101 F daily and occasionally to 102 F. Repeated blood transfusions were given without more than transitory effect. The patient's leukocyte count varied from 11,100 to 16,200, with 69 per cent polymorphonuclear leukocytes at the time of admission. Hemoglobin varied from 40 to 67 per cent (Sahli), the erythrocytes from 3,560,000 to 4,450,000.

Because of the failure of the patient to improve it was decided to administer sulfanilamide. June 14 she was given four tablets (12 Gm) at 8 a. m., 12 noon and 6 p. m. and five tablets (15 Gm) at 9 p. m., a total of 51 Gm or 0.1 Gm per kilogram of body weight. The following day the patient was given 12 Gm at 8 a. m. and at 12 noon. That afternoon about 2 p. m. she had a large liquid bowel movement and complained of headache. At 6 o'clock marked cyanosis was noted. All medication, including the sulfanilamide, was stopped. She had received acetylsalicylic acid, phenobarbital and ferrous sulfate (Feosol) daily for a long time. June 16 she felt much better and the cyanosis soon disappeared. June 18 she was again given sulfanilamide. She received 48 Gm (in doses of 12 Gm) that day. The following day she received 12 Gm at 8 a. m. and 0.6 Gm at noon. That afternoon she was again cyanotic and complained of a headache and a choking sensation. The medication was again stopped and the symptoms soon subsided. June 20 the blood count revealed 13,300 white blood cells, 4,970,000 red blood cells and 65 per cent hemoglobin. June 24 she was given one tablet (0.3 Gm) of sulfanilamide at 8 p. m. On awakening the following morning she complained that she could not see clearly. Cyanosis was not noted. All medication was discontinued. The impairment of vision continued throughout the day. She volunteered that it was most marked directly in front and that she could see more clearly to either side of the point of fixation. At 6 p. m. she was seen by the ophthalmologist who found the vision reduced to 6/200 in the right eye and to 4/200 in the left. There was an absolute central scotoma in each eye for 3 mm. red and blue targets and a relative central scotoma for a 3 mm. white target as shown in the accompanying illustration. Ophthalmoscopic examination revealed a marked tortuosity of the retinal vessels (which had previously been observed and was considered congenital) and some blurring of the margins of the optic disks. I first saw the patient June 25. During the next two days, June 26 and 27, the vision improved but was still blurred. Late on the afternoon of the 27th the visual acuity was 15 in the right eye and 1.2 in the left, and the central scotomas had disappeared. Ophthalmoscopic examination revealed that both disks were redder than normal and moderately elevated. Because of the marked congenital tortuosity of the retinal vessels, elevation of the optic disks was difficult to measure. During the month of July the optic disks have gradually resumed what is believed to be a normal appearance for them. There is still some blurring, particularly of the nasal margins, but the disks were probably flat by the first of August. By June 28 vision seemed normal to the patient and has remained so. There were no other complaints relative to the eyes or the nervous system, nor have there been any manifestations indicative of any other neurologic involvement.

The condition of the osteomyelitis and associated abscesses has continued much as before. July 21, a perineal abscess was incised and drained.

COMMENT

There can be little doubt that this patient had an intolerance or idiosyncrasy for sulfanilamide, as evidenced by the repeated occurrence of toxic symptoms after the brief administration of the drug. It is very likely that the administration of ferrous sulfate (Feosol) simultaneously with the giving of sulfanilamide contributed to the patient's intolerance for the latter drug, especially in view of Colebrook and Kenny's and Paton and Eaton's observations that sulfanilamide and related drugs give rise to toxic symptoms when given simultaneously with magnesium sulfate or other sulfates or even when wounds are dressed with sulfate solutions. There would also seem to be little doubt that the disturbance of vision due to a toxic optic neuritis resulted also from this drug. In view of Harvey and Jane-

way's⁴ failure to obtain positive reactions with skin tests on patients having toxic symptoms, we did not attempt similar tests in this case. The obvious test of again administering the drug did not seem justified. That the drug is toxic to the nervous system has been shown by its action in the mouse⁵ and in at least one instance in man.²

SUMMARY

A girl with osteomyelitis of the ilium was given sulfanilamide on three separate occasions. On each occasion toxic manifestations appeared: headache, cyanosis, diarrhea and a choking sensation on the first two occasions, a severe loss of vision due to a toxic optic neuritis after administration of a single tablet (0.3 Gm) of the drug on the last occasion. In each instance the symptoms rapidly subsided after withdrawal of the drug.

This case again emphasizes the importance of not administering sulfanilamide and any sulfate simultaneously. In all cases the blood picture should be followed by frequent examinations, and the drug should be withdrawn on the appearance of any toxic manifestations.

SKIN ERUPTIONS IN PATIENTS RECEIVING SULFANILAMIDE

REPORT OF FOUR CASES

JOHN G. MENVILLE, M.D.

AND

JOHN J. ARCHINARD, M.D.

NEW ORLEANS

When new drugs rapidly gain widespread popularity, their beneficial action is quickly recognized but their by-effects often reveal themselves more slowly and are often overlooked. Few drugs have come to the front with more eclat than have the sulfanilamide derivatives, marketed under the names of prontosil and prontosil.

This report is presented not to detract from the value of these drugs but merely to mention the occurrence in a small series of cases of annoying but apparently not serious symptoms following their administration—namely, maculopapular eruptions with intense itching over areas of skin exposed to the sun in patients to whom large doses of sulfanilamide were administered. In one case chilliness, high fever and prostration were noted.

While this series of four cases is obviously too small to permit any definite conclusions regarding the ill effects of sulfanilamide, it may serve as a means of calling the attention of the users of this drug to the possible cutaneous manifestations which they may produce.

No explanation is offered for the phenomena observed. We have been unable to find any mention of them in the literature to date.

REPORT OF CASES

CASE 1.—A white man aged 26, weighing 145 pounds (66 Kg) and suffering from a chronic gonorrheal urethral discharge was given 53 Gm of sulfanilamide a day in four divided doses for ten days. On the ninth day the patient, clad in bathing trunks, was exposed to the hot sun on a bathing beach for approximately four and a half hours. On the afternoon of the tenth day he was again exposed to the sun for one hour. That evening a rash developed on his back, his hands and a portion of his face and neck. The rash was a maculopapular eruption which produced an intense itching associated with chills and fever. Prior to the fever, the patient experienced a slight cyanosis, hyperpnea and nausea. On the eleventh

day the drug was discontinued. At this time the patient had received 53.3 Gm of sulfanilamide. The rash, which first appeared on the hands, face and neck, now became generalized over these areas, including the legs and body, with the exception of that portion covered by the bathing trunks. In addition to the maculopapular eruption, very minute vesicles appeared.

The height of the fever was 104.8 F. The blood count was as follows: red blood cells, 5,100,000; white blood cells, 15,600; neutrophils, 89 per cent; small mononuclears, 8 per cent; and large mononuclears, 3 per cent. Physical examination was negative. The urine showed no abnormalities. On purely symptomatic treatment the fever gradually decreased and disappeared in four days. The rash and itching sensations lasted about one week.

There was nothing unusual in the patient's diet to explain the eruption. Many years before, he had an attack of urticaria. It may be of interest to mention that before he took the sulfanilamide he had been exposed to the sun on many occasions and the skin had become a deep tan. For this reason exposure to the sun would not explain the symptoms that he manifested after he took the drug.

CASE 2—A white man, aged 36, weighing 180 pounds (81 Kg), was suffering from a chronic gonorrheal urethritis and prostatitis. He was given 34.7 Gm of sulfanilamide over a period of eleven days. The first two days he received 5.3 Gm a day, then 2.7 Gm a day for the following nine days. The urethral discharge ceased on the seventh day after medication was started. On the eleventh day a maculopapular eruption associated with intense itching and swelling developed on the back of the hands, and to a slight extent on the forearms and also on the neck and face. The rash converged and formed minute vesicles, which did not erupt. The drug was then discontinued and the rash and swelling disappeared within three days. In this case the only parts of the body exposed to the sun were the hands, neck and face. A mild cyanosis and hyperpnea were also noted in this case.

CASE 3—A white man, aged 30, weighing 155 pounds (70 Kg) suffered from a chronic gonorrheal urethritis and was given 35.3 Gm of sulfanilamide over a period of eight days. For four consecutive days he received 5.3 Gm of sulfanilamide each day, divided into four doses. The next two days he was given 4 Gm a day in four divided doses, and the following day he received 3.3 Gm divided into two doses. On the eighth day the patient received 2.7 Gm divided into three doses. On this day a maculopapular rash associated with severe itching developed on the right side of the neck, right ear and dorsum of the hands. There was no swelling associated with the rash, as was observed in one of the cases already mentioned. However, some cyanosis and hyperpnea were noted. At this time the drug was discontinued, and the rash disappeared within two days. In this case only the face, neck and dorsum of the hands were exposed to the sun.

CASE 4—A white woman, aged 26, weighing 110 pounds (50 Kg), suffering from a colon bacillus infection of the urinary tract, was given 32 Gm of sulfanilamide over a period of ten and a half days. The daily dose was 3 Gm divided into three doses. On the eighth day no bacilli were found in the urine. Two subsequent examinations of the urine were negative. On the tenth day the patient was exposed to the sun while riding in an automobile. The same evening, a maculopapular rash developed on the hands, the forearms and the neck. The rash, as in the other cases, was associated with itching and contained some minute vesicles, which did not erupt. The rash on the right side of the neck and right forearm was more marked than on the left side. It is of interest to mention in this connection that the right side of the patient was more exposed to the sun. The rash disappeared two days after the drug was discontinued.

SUMMARY

Relatively large doses of sulfanilamide were given to four patients, in whom a maculopapular eruption developed associated with severe itching and the formation of minute unerupted vesicles. In one case the rash was associated with severe chills, fever and a leuko-

cytosis. In all the cases the rash and its associated symptoms disappeared within several days after the drug was discontinued.

It is interesting to note that in all four cases the rash appeared only on the parts of the body exposed to the sun.

No saline cathartic and no other form of medication other than sulfanilamide were given the patients while under treatment.

We have had other patients to whom we have given smaller doses of sulfanilamide whose hands, face and neck have been exposed to the sun without the development of an eruption of the skin. It would seem to indicate, therefore, that cutaneous eruptions are more likely to occur in patients receiving large doses of sulfanilamide when they are exposed to constant rays of the sun.

THE DEVELOPMENT OF A CUTANEOUS ERUPTION (TOXICODERMATOSIS)

DURING THE ADMINISTRATION OF SULFANIL-
AMIDE, REPORT OF TWO CASES

M. H. GOODMAN, M.D.

Instructor in Dermatology, Johns Hopkins Medical School
AND

CHARLES S. LEVY, M.D.

Associate in Urology, Sinai Hospital
BALTIMORE

In addition to its specific therapeutic potency in beta hemolytic streptococcus infections, sulfanilamide has been found to exercise a striking beneficial influence on the course of meningococcal, pneumococcal and also gonococcal infections. An agent of such wide scope of usefulness merits watching for its side effects, especially in view of its possibly indiscriminate use in a disease such as gonorrhea.

Long and Bliss¹ in their studies point out that sulfhemoglobinemia may develop in patients under sulfanilamide therapy and quite frequently an unexplained cyanosis which is sometimes associated with methemoglobinemia. A few hours after an initial ingestion of a large dose there may be dizziness, nausea, anorexia and a feeling resembling alcoholic intoxication. The patient may develop fever or exhibit a depression of liver function as determined by the bromsulfalein excretion test or a mild acidosis.²

Since sulfanilamide is essentially a substituted aniline it might also produce an anemia as an expression of the well known hemolytic properties of the benzene structure. Confirmatory of this is the reference by Long and Bliss to two cases in which an acute anemia developed and the recent report of Harvey and Janeway,³ who studied three patients in whom there developed an acute hemolytic anemia attributable to the sulfanilamide. Long and Bliss expressed uncertainty as to whether such effects spoke for toxicity of the drug or for idiosyncrasy in the recipient.

Harvey and Janeway's first patient received sulfanilamide orally, an initial dose of 4.8 Gm (74 grains) and

1 Long, P. H. and Bliss, Eleanor A. The Use of Para Amino Benzene Sulfonamide (Sulfanilamide) or Its Derivatives in the Treatment of Infections Due to Beta Hemolytic Streptococci, Pneumococci and Meningococci. *South M J* 30: 479-487 (May) 1937.

2 Southworth, Hamilton. Acidosis Associated with the Administration of Para Amino-Benzene Sulfonamide (Prontylin). *Proc Soc Exper Biol & Med* 36: 58 (Feb) 1937.

3 Harvey, A. M. and Janeway, C. A. The Development of Acute Hemolytic Anemia During the Administration of Sulfanilamide (Para Aminobenzenesulfonamide). *J. A. M. A.* 109: 12 (July 3) 1937.

for the next two days 0.9 Gm (14 grains) every four hours, and after this 0.6 Gm (9 grains) every four hours. On the fifth day of medication the first evidence of acute anemia became apparent. Since such doses had been given to many patients without effect on the blood picture and since two of their patients after complete cure failed to show a reappearance of the anemic blood picture after an additional small dose of the drug, the authors concluded that the anemia was not due to toxicity from overdosage or to the type of drug idiosyncrasy that occurs in some cases after aminopyrine. Rather, they saw a resemblance of these hemolytic anemias to the hemolytic crises produced by phenylhydrazine and therefore considered it possible that their patients represented a type of individual which produces from the sulfanilamide a small amount of a toxic product having an action like phenylhydrazine or produces such a substance much more rapidly than the average patient.

The method devised by Marshall and his associates⁴ for determining the sulfanilamide content of the body fluids enabled them to show that absorption from such a single oral dose of the chemical was complete within four hours. Applying this information to their clinical experience, Long and Bliss considered it advisable in severe infections in which it is desirable to reach a high blood level of the chemical rapidly to administer a large initial dose with the aim of attaining a blood level of 10 mg per hundred cubic centimeters within four hours. This concentration they found will usually be achieved in adult patients weighing 100 pounds (45 Kg) or more by administering an initial dose of from ten to sixteen 5 grain (0.3 Gm) tablets. Thereafter, to maintain this level they advised three 5 grain tablets every four hours.

In cases recorded here a cutaneous eruption developed in the course of treatment with sulfanilamide. The dosage administered was in accordance with a scheme which had been used in a number of other cases which exhibited no side effects. This scheme although adopted for convenience and ease of administration of the drug, parallels fairly well the range of dosage recommended by the authors cited.

REPORT OF CASES

CASE 1—J. O., a healthy white man, aged 20, of slender physique, weighing about 125 pounds (57 Kg), was first seen by one of us (C. S. L.) June 12, 1937, complaining of a urethral discharge, which showed numerous intracellular gram-negative diplococci. The urine in glass 1 was very cloudy and in glass 2, clear. The diagnosis was acute gonorrheal anterior urethritis, uncomplicated. The history revealed that the patient had been in good general health. Aside from the fact that his mother suffers with hay fever, there had never been any manifestation of allergic disease in the patient or in any other member of his family. He had not recently suffered with any disease that required medication, and close questioning revealed that he had taken no drugs for any reason for at least the past year.

Treatment with sulfanilamide was immediately instituted as follows. The patient took four 5 grain tablets every four hours, totaling 80 grains (5 Gm), on each of the first two days, on the third and fourth day, three 5 grain tablets every four hours totaling 60 grains (4 Gm) a day, and thereafter two 5 grain tablets every four hours, totaling 40 grains (2.6 Gm) a day. As has been stated, this scheme of treatment had been applied in a number of cases of acute gonorrheal anterior urethritis. The patient began this treatment June 13, and on June 22 he complained of an eruption on the skin which had appeared during the preceding night. On questioning it was discovered

that, owing to a misunderstanding, he had not reduced his daily dose to 40 grains after the fourth day of treatment but had continued with the total of 60 grains a day since the third day of treatment. He had taken no other medication during this period of sulfanilamide treatment. Examination showed that there was still present a marked urethral discharge.

The eruption was distributed over the face, occipital portion of the scalp, neck, shoulders and arms downward to the mid portion of the backs of the fingers. The characteristic features of the eruption could be best observed on the lower part of the arms and forearms, where the primary lesions consisted mostly of discrete, roundish and oval macular and papular elements varying in size from a pea to that of a quarter (24 mm), but on the average that of a dime (18 mm). Most of the lesions were a bright red but they varied in shade from a pinkish to a dusky red. These lesions were smooth and sharply circumscribed, and the papular elements presented a flattened, slightly dome shaped surface, being a trifle more elevated in the center than at the periphery, which sloped in a gentle curve into the surrounding skin. In other areas, aside from the regions just described, a few lesions were irregularly rounded and oval and occasionally not so circumscribed. The papular elements were slightly infiltrated and edematous, but the color of all the lesions could be blanched out completely on pressure except in the case of a number of the individual elements on the forearms, which presented an ineffaceable, centrally placed hemorrhagic spot, in the larger ones sometimes reaching the diameter of a pea.

The lesions were more numerous on the extensor aspects of the arms than on the flexor surfaces and extended over the back of the hands to the midportion of the fingers, whereas the palms of the hands were entirely free from lesions. About the shoulders and over the neck extending into the occipital portion of the scalp, although there were many discrete lesions of the type previously described, there was a tendency to coalescence with the formation of diffuse and patchy areas of redness and slight infiltration, which served to accentuate the picture so characteristic of a toxic erythematous type of eruption. On the face the outlines of individual lesions were only here and there faintly discernible because their borders had fused into one another to form a diffuse and patchy erythematous process. Because of variation in the size and color of the lesions, which ranged from a pinkish red to a dusky red, and in the amount of infiltration in different areas, the face presented a peculiar, irregular, superficially bloated, splotchy and glazed appearance. The eruption stopped at the hairline in front and on the sides but was continuous below with the lesions on the neck. It was interesting that there was no cyanosis of the lips, and in the mouth there was neither any change of color nor any lesions. The eruption was strictly limited to the areas described—a feature rather unusual for a toxicodermatosis, especially of the type due to a drug. Itching occurred only spasmodically and was not annoying, as was evidenced by the fact that there were no excoriations from scratching. The patient had a temperature of 100.5 F., and there was a trace of albumin in the urine, which was otherwise negative. As nearly as could be determined, the eruption began on the back of the arms and then appeared on the face. The process ran a fairly rapid course, fading out almost completely within four days from the time of its onset. During the greater portion of this period the patient felt sick and weak and was obliged to rest in bed. About ten days after the eruption had cleared up, skin tests were performed. The soluble, chemically pure powdered sulfanilamide (para-aminobenzenesulfonamide) was available. A freshly prepared 1 per cent aqueous solution was applied as a patch test, and 0.15 cc was injected intracutaneously into the left forearm. In a scratch on the arm a small amount of the pure powder was applied moistened with a 1 per cent solution. No reaction was noted in the scratch after half an hour. The intradermal and patch tests were also entirely negative after twenty-four hours.

About three weeks after the disappearance of the eruption, the patient was given a 5 grain tablet of sulfanilamide, followed four hours later by a second tablet. Shortly after the ingestion of the second dose, he noticed the appearance of a diffuse erythematous blush of the face and arms with burning and itching. He refused to take any further medication and this reaction cleared up after about twelve hours.

⁴ Marshall E. K. Jr., Emerson Kendall Jr. and Cutting W. C. Para-Aminobenzenesulfonamide Absorption and Excretion. Method of Determination in Urine and Blood. J. A. M. A. 105:953 (March 20) 1937.

CASE 2—E J, a white man, aged 28, in robust health, first consulted one of us (C S L.) June 16, 1937, with the complaint of a purulent discharge from the urethra. Examination of the pus revealed numerous gram-negative intracellular diplococci, the urine voided in glass 1 was very cloudy and in glass 2, clear. The diagnosis was acute gonorrheal anterior urethritis, uncomplicated.

The family and personal history of the patient disclosed nothing relevant to the present complaint. The patient had been in good general health all his life aside from a few minor ailments of no import. Neither he nor any member of his family as far as could be determined suffered with any disease of an allergic nature. Close questioning revealed that he had not taken medication for any reason whatever during the past year.

Treatment with sulfanilamide was outlined for the patient in accordance with the same scheme used in case 1, namely, 80 grains a day for the first two days, 60 grains a day for the second two days, and thereafter 40 grains a day until the patient would again be seen, about ten days after the first visit. The patient began this treatment June 17, and on June 25 returned with the complaint of an eruption which had appeared on his arms and face during the preceding twenty-four hours. He had very definitely taken no other medication aside from the sulfanilamide. He complained of feeling weak and "out of sorts," and also of marked itching of the face and arms. The urethral discharge had cleared up.

He presented an eruption which was distributed in a manner identical to that of the eruption in case 1. The eruption was of an exactly similar type, consisting of roundish, reddish macules and papules distributed over the face, neck, shoulders, occipital area of the scalp and arms, where the lesions were more numerous on the extensor aspects than on the flexors. The palms of the hands were uninvolved, there was no cyanosis of the lips and no lesions in the mouth. The face was diffusely red, and the surface presented an uneven blotchy appearance produced by numerous, varying sized irregular coalescent macules and papules resulting in a picture of a glazed, delicately ridged and patchy process so suggestive of the full blown florid exanthematic facies. In other areas the eruption simulated that in case 1 in all respects except for the fact that there were no hemorrhagic spots in any of the lesions. The patient had a slight fever and a trace of albumin in the urine. He felt "grippy" and was obliged to go to bed. Within four or five days the eruption subsided, there remained only some superficial scaling, which disappeared a short time afterward. About two weeks after the eruption had cleared up skin tests were performed on the patient with the sulfanilamide. A patch test with 1 per cent solution of the drug was applied and 0.15 cc was injected intracutaneously in the left forearm. To a scratch on this arm a small amount of the pure powder, moistened with a 1 per cent solution was applied, as in case 1. The intradermal test after half an hour showed no change, whereas in the site of the scratch there was an elevated flat-topped indurated wheal-like papule measuring 7 mm in diameter but unaccompanied by any surrounding erythematous flare. Twenty-four hours later there were no reactions in any of the test areas.

CASE 3—C W, a young white man in good general health suffering with an acute gonorrheal anterior urethritis, uncomplicated, and treated with sulfanilamide for at least one month by the standard scheme followed in the other two patients, served as a control for the skin tests. He manifested no reaction, cutaneous or otherwise, as a result of the treatment. The three skin tests were performed on this patient in the same manner as in the other two. All the tests were entirely negative.

COMMENT

The eruption provoked by sulfanilamide was identical in all respects in the two patients except for the hemorrhagic spots in a number of the lesions on the forearms in case 1. This purpuric factor points to an injury to the wall of the blood vessels, this injury was probably greater in case 1 because this patient, as was brought out, had taken (by error) after the fourth day of treatment 20 grains more daily than the second

patient. The two reacted about the same time after commencement of the treatment, that is, within eight days. A number of other patients suffering from urethritis, treated with sulfanilamide in similar dosage and for longer periods, as for example our control patient, suffered no reaction whatever. One might argue that the eruption with mild febrile reaction in the two patients is simply a pharmacotoxic effect of the chemical itself or a substance which these individuals produce from it and which attacks the walls of the superficial cutaneous blood vessels. Such a theory was entertained by Harvey and Janeway³ to account for the anemia in their cases. However, in view of the apparent rarity of the cutaneous reactions that our patients manifested, the suggestively positive scratch reaction in case 2 and the erythematous flare of the face and arms in case 1 when the patient ingested an additional small dose (10 grains) of the drug, it is quite possible that these were cases of induced hypersensitivity to sulfanilamide and that the eruption was allergic.

SUMMARY AND CONCLUSIONS

1 Two cases of toxic erythema (toxicodermatosis) of peculiarly limited distribution developed in the course of treatment with standard maximum doses of sulfanilamide.

2 In one case there were hemorrhagic lesions, indicating probably that sulfanilamide has vasculotoxic properties.

3 In view of the apparent rarity of cutaneous reactions from sulfanilamide, the elicitation of a suggestively positive scratch test in case 2 and an erythematous flare following ingestion of an additional small dose in case 1, it is possible that the eruptions represent an allergic cutaneous reaction to the drug.

4 Unless one is dealing with acute, serious infections, the dose of sulfanilamide should be kept within moderate bounds.

DERMATITIS FROM SULFANILAMIDE

LOUIS J. FRANK, M.D.
SIoux CITY, IOWA

The toxic effects of sulfanilamide are yet largely to be evaluated. In the American literature the only references to dermatologic manifestations that I have noted were mention that a morbilliform eruption and urticaria have been observed and sensitiveness of the skin of the lower extremities. Inquiry among practitioners who are using much sulfanilamide revealed that many eruptions are occurring and are at least being attributed to sulfanilamide. I believe that the following cases are worthy of a report.

REPORT OF CASES

CASE 1—J C, a white man, aged 38, referred to me July 22, 1937, because of a severe skin eruption, stated that about three weeks before, while taking sun baths, he noted a bluish color and sensitiveness of the skin of the legs, which did not itch. This condition disappeared after six days. A week before I saw him, after he was working in the garden in his undershirt, the back of the neck began to break out with hive-like lesions, which itched severely and spread rapidly to the face, ears, arms, legs and trunk. It was more severe on the parts exposed to the sun, although he stated that he was not severely sunburned.

When he was questioned directly as to ingestion of drugs, he stated that some time before he had been feeling tired and weak. A physician in another city had given him some tablets

(sulfanilamide) to take. He had had the prescription refilled at the drug store several times and from June 30, 1937, to the present time he had taken four tablets a day. He was feeling well up to the time that his skin broke out. He said there was no shortness of breath.

The general physical examination was essentially negative except for the skin. The sclerae showed no evidence of jaundice, but the lips were strikingly cyanotic. The temperature was 99.2 F. The face was diffusely erythematous and showed marked edematous swelling. The skin on the back of the neck was less edematous but was thickened, presenting a suggestion of lichenification. The arms from the shoulders down were swollen to half again their normal size. The lower halves of both forearms were covered with small confluent vesicles, which over the palms and fingers were discrete and deep seated. The trunk and lower extremities showed a patchy morbilliform eruption without much edema. Certain features, namely, the vesicles and the localization, suggested a contact dermatitis. However I could determine no contact factors and he had not been using any inappropriate local medication.

Examination of the blood revealed a hemoglobin of 93 per cent, 5,150,000 red blood cells and 10,800 white blood cells with 59 per cent polymorphonuclear leukocytes and 41 per cent lymphocytes. Examination of the urine was negative for sugar, albumin, casts and blood.

The intake of sulfanilamide was stopped, sodium thiosulfate was given intravenously and calamine lotion was applied locally for the itching. Within four days the edema had entirely disappeared. The skin of the face, neck and arms was subacutely inflamed and exfoliating. Two more days produced further improvement. I then gave the patient some 5 gram (0.3 Gm.) tablets of sulfanilamide with instructions to take one every six hours and return the next day. Two hours after he took the second tablet the back of the neck began to itch violently and break out with hive-like lesions, which rapidly spread to the face and arms. The acute itching subsided in twelve hours after he took the second tablet, and the dermatitis is rapidly improving at the time of this writing.

CASE 2—A white man, aged 48, seen through the courtesy of Dr. Walter F. Harriman, had been given sulfanilamide, twenty-two 5 gram (0.3 Gm.) tablets in two days and four tablets a day for the following seven days, for a prostatic infection, the symptoms of which disappeared completely in the first few days. Before discontinuing the tablets, the patient took an automobile trip, during which the left side of his face and the left arm were much exposed to the sun. These areas soon began to swell and itch. After twenty-four hours the redness and edema extended from the left side to involve the entire face; the eyes were swollen shut. The left arm continued to swell up to the shoulder. He said that there were no blisters. Two days after the onset, the right arm began to swell and break out, after this the eruption extended over the legs, chest and back.

On examination, one week after he discontinued the drug, the pitting edema had disappeared. There was a multiform erythema with urticarial tendencies scattered over the trunk and extremities.

COMMENT

The factor of sunlight in these cases was a rather striking clinical observation. In both cases the dermatitis appeared only after exposure to sunlight. After full development, the dermatitis was not confined to the exposed parts, but the more severe involvement and intense edema was localized in these areas. It is known that a mild erythema resulting from the sun or other sources can hasten the appearance and, for a time, localize many dermatologic conditions, including such infections as syphilis and smallpox. As an alternative, I offer the suggestion that heliosensitivity created by the drug or some of its chemical reactions with hemoglobin may play a part in this type of toxic reaction. This would help account for the infrequency of this type of toxic manifestation in the numerous cases reported in

the American literature in which sulfanilamide therapy is being employed, because the patients have been predominantly hospitalized. Whether or not this is just a chance observation will be borne out when more cases are reported and studied.

CHRONIC CHOLECYSTITIS VERSUS IRRITABLE COLON

S. ALLEN WILKINSON, M.D.

BOSTON

A problem always confronting the internist and the surgeon is the diagnosis of cholecystitis without stones. The symptoms of noncalculous cholecystitis are by no means clearcut and definite. The classic description portrays a patient, usually female and obese, suffering from epigastric distress, gas, belching, nausea and pain in the upper part of the abdomen. Constipation is a prominent complaint and, if the symptoms enumerated are present, it is rarely absent. Acute pain or colic is a rare complaint and in the vast majority of cases indicates the presence of stones or an acute infection in the gallbladder. Cholecystography is admittedly a great help and in most cases should be the deciding factor, but there is marked variation in the interpretation of cholecystograms. Much significance has been placed on the finding of delayed emptying and poor visualization of the gallbladder. Visualization depends on many variables besides the function of the gallbladder mucosa: the absorption of the dye from the intestinal tract, the function of the liver itself in removing the dye from the blood stream, the entrance of the dye into the gallbladder, the presence of gas or fecal material in the colon and the x-ray technic. It is no wonder, then, that patients who have pronounced digestive complaints and constipation frequently show poor visualization or no visualization of the gallbladder.

The prevalence of chronic cholecystitis has been assumed largely from autopsy reports. Mentzer¹ has reported evidence of chronic cholecystitis in 66 per cent of necropsies. In 8 per cent of his cases the diagnosis was made clinically. This implies that 58 per cent of the people who died at the Mayo Clinic had some degree of gallbladder disease which was causing so little trouble that no such diagnosis was suspected. The question might well be raised as to whether a mild degree of lymphocytic or leukocytic infiltration into the wall of the gallbladder is an actual indication of disease or whether it is merely an expression of the general process of wear and tear incident to living and to the disease which actually causes the death of the patient. Stanton² tried to correlate the pathologic observations after cholecystectomy with the clinical observations and was unable to arrive at any satisfactory basis. He felt that there was a wide discrepancy between the symptoms and the degree of disease as shown by pathologic sections. It seems therefore that one is not logical in accepting a pathologic report of chronic cholecystitis as a satisfactory justification for

From the Gastro-Enterological Department of the Lahey Clinic. Read before the Section on Gastro-Enterology and Proctology at the Eighty-Eighth Annual Session of the American Medical Association, Atlantic City, N. J., June 10, 1937.
¹ Mentzer, S. H. A. Clinical and Pathologic Study of Cholecystitis and Cholelithiasis. *Surg. Gynec. & Obst.* 12: 782-793 (June) 1926.
² Stanton, E. M. The Stoneless Gallbladder. *Am. J. Surg.* 18: 244-250 (Nov.) 1932.

the operation. If this is true in the surgical cases, it is just as true in the nonsurgical cases in which the condition is diagnosed and treated as cholecystitis.

The symptoms of irritable or unstable colon are just as varied as those of cholecystitis. The most common symptoms are epigastric distress, gas, belching, distention, shifting abdominal pain which may be equally in the upper and in the lower part of the abdomen, and constipation or alternating constipation and diarrhea. If there is associated hyperchlorhydria, and often if there is an acidity, the patient complains of sour stomach, gnawing pain in the upper part of the abdomen, nausea and attacks of vomiting. Migraine-like attacks are a common symptom and are almost invariably described by the sufferer as bilious spells with headache, nausea and vomiting of bile.

The fundamental difference between the diagnosis of chronic cholecystitis and that of irritable colon would be of little moment but for the fact that one condition is organic and likely to be treated surgically while the other is a functional disorder amenable to dietary management. It is important to the patient and to the doctor to determine into which group the diagnosis falls. Since there is such a similarity in the two types of complaints, it does not seem proper immediately to classify chronic dyspepsia as gallbladder disease because of a dull ache in the right upper part of the abdomen and a poorly seen gallbladder. Lahey and Jordan³ have shown that 44 per cent of the patients with chronic dyspepsia whose gallbladder cannot be visualized will later show normal filling after an adequate period of bowel management. This 44 per cent can hardly be classified as having gallbladder disease, even though there was originally no visualization of the gallbladder. The patients who show delayed emptying or poor visualization will be even more likely to fall into the functional group.

Greene, Twiss and Carter⁴ described three types of distended gallbladder, which they called atonic, hypertonic and vagotonic gallbladder, in which there are delayed filling or delayed emptying and sometimes crystals in the bile sediment and which they associated with such varied conditions as hypo-acidity, ulcer, duodenitis, pregnancy, neurosis, spastic colon and appendicitis. They stated that failure to correct the stasis is responsible for many of the cases of recurrence of symptoms following cholecystectomy. It is difficult to see how there could be stasis after cholecystectomy, and it is permissible to assume that treatment of the underlying condition would obviate the necessity for a cholecystectomy.

Brown and Dolkart⁵ described the treatment in sixty-five cases of gallbladder disease with ketocholanic acids combined with a bland, high fat diet and antispasmodics. They noted subjective improvement in all but four cases. A bland, high fat diet, with antispasmodics, is a very effective form of treatment for functional disease of the gastro-intestinal tract particularly of the colon, and one wonders how much of the improvement noted was due to correcting faulty dietary habits and restoring normal function of the colon.

Many writers recommend the use of biliary drainage as a therapeutic measure in the treatment of cholecystic disease. I acknowledge with admiration the many

valuable contributions of numerous workers to the diagnosis of disease of the biliary tract by the use of biliary drainage, but I have found dietary care alone adequate to control the nonsurgical cases, while operation is recommended for the more severe cases.

Twiss and Greene,⁶ in describing the dietary and medical treatment of diseases of the gallbladder, pointed out that much of the epigastric fulness and distress, the flatulence and nausea of which the patients complain is due to disturbance of the activity of the stomach, duodenum and bowel. They emphasized the importance of treatment by adequate dietary methods, stressing the necessity of a normal daily movement, of large amounts of hot water and of avoiding fried food, roughage, nuts, spices, raw fruits and salads. Thus they very accurately described the type of dietary regimen which I have found effective in controlling functional digestive disturbances regardless of whether or not the gallbladder is involved. It is just this regimen which so effectively prevents the return of symptoms after operation for chronic cholecystitis.

Many surgeons have called attention to the disappointing results after cholecystectomy when stones were not found at operation. Cattell and Kiefer⁷ showed that in 51 per cent of the cases of noncalculous cholecystitis at the Lahey Clinic the postoperative results had to be classified as poor.

TABLE 1—1032 Consecutive Cholecystectomies

Year	With Stones	Without Stones
1929	117	18
1930	117	16
1931	99	15
1932	106	5
1933	104	7
1934	130	11
1935	118	14
1936	137	13
Totals	933	99

Deaver and Bortz⁸ cited 903 operations for gallbladder disease, of which 50 per cent revealed stones and 48.5 per cent disease of the noncalculous variety. Scott⁹ reported 550 gallbladder operations in which the incidence of stones was 47 per cent. Giles¹⁰ reported 6,953 cholecystograms, with 5.4 per cent showing stones and 2,822, or 41 per cent, showing noncalculous cholecystitis. A review of the cases of gallbladder disease treated in the last eight years by myself and my associates at the Lahey Clinic, as summarized in table 1, is illuminating in this connection.

There were 1,032 patients operated on for gallbladder disease. Of this group, 933, or 90.2 per cent, had stones, and 99, or 9.8 per cent, had no stones. A study of the symptoms and of the end results in the noncalculous group yields some interesting figures. Typical gallbladder colic, with pain radiating to the right scapular region, was present in 19 per cent and jaundice in 12 per cent. These two symptoms are most characteristic of the more severe grades of disease of the gallbladder or biliary ducts, and of the group exhibiting them five were found to have acute, gangrenous cholecystitis, and five had cancer of the gallbladder.

10 Giles R G Texas State J Med 30 431-434 (Nov) 1934

A total of 55 per cent of the patients complained of persistent pain in the epigastrium or right upper part of the abdomen without colic or jaundice. Twenty of thirty-one patients who had normal filling of the gallbladder (sometimes after one or more repetitions of the Graham test) had this complaint, and it is in this group that the largest percentage (55) showed a normal gallbladder at operation. In the same group the post-operative end results were poorest, 55 per cent being unimproved.

The symptoms of irritable colon were present in 63 per cent, whereas 31 per cent were found at operation to have some other organic, recognizable cause for the complaint. In many of these cases the correct diagnosis was made or was suspected preoperatively and the operation was chiefly a confirmatory one. In others the true condition was unknown until the abdomen was open. In some of the cases in which the preoperative diagnosis was irritable colon, operation was done only at the urgent insistence of the patient and with adequate warning by the surgeon and internist that no organic disease would be found. In one such case, to our chagrin, we found general carcinomatosis of the abdomen, but the other patients proved to be quite normal.

Cattell and Kiefer⁷ reported in an earlier paper that 90 per cent of the patients with stones showed a good postoperative result. The results in 31 per cent of this group of noncalculous cases must be classified as poor or unimproved, but this percentage includes the cases of organic disease other than chronic cholecystitis. It is of more interest that only 15 per cent of the patients were sufficiently well after operation not to want or require any dietary regimen, while 42 per cent considered the result good provided they followed proper bowel regulations.

TABLE 2—Cholecystectomies in Cases Without Stones, from 1929 to 1936, Inclusive

	Normal Filling	Poor Filling	No Filling	No Cholecystography	Totals

1 Normal gallbladder	2	2	0	0	4
2 Infected gallbladder					

If statistics generally report from 30 to 50 per cent of all gallbladder operations as indicating noncalculous cholecystitis, and if necropsy reports show that up to 66 per cent of the population over 40 have noncalculous cholecystitis, what has become of this large group in our cases? Simply this: Careful preoperative study has convinced us that there is no recognizable diagnostic criterion by which these cases can be labeled gallbladder

disease. The symptoms do not justify it, the laboratory data do not confirm it and proper consideration of the roentgenologic evidence indicates a functional rather than an organic process. We recognize that these abnormalities of function are not all strictly attributable to the colon, but so many of the symptoms are referred

to the colon that we use the diagnosis of irritable colon as a convenient peg on which to hang most of the functional gastro-intestinal disturbances.

SUMMARY

The diagnosis of chronic, noncalculous cholecystitis is indefinite, difficult to make and difficult to justify in the light of poor operative end results.

Of more than 1,000 consecutive gallbladder operations at the Lahey Clinic, 90 per cent were for gallbladder disease with stones and 10 per cent for such disease without stones.

In the noncalculous group, 30 per cent of the patients had some other organic process to account for the symptoms, 42 per cent had normal gallbladders, 42 per cent required dietary care to be comfortable after operation and 31 per cent were unimproved.

In nonsurgical cases we feel that proper study and dietary care will rule out the gallbladder as a cause of symptoms, and instead of chronic cholecystitis, we prefer the simpler term of functional digestive disease or irritable colon.

605 Commonwealth Avenue

ABSTRACT OF DISCUSSION

DR. CARL H. GREENE, New York: Improved diagnostic methods permit the physician to make the diagnosis of cholecystitis early, before the development of advanced pathologic changes. The results of operation in these early cases without stone or acute infection are often disappointing. Dr. Wilkinson has described the clinical manifestation of the dyspepsia that characterizes these patients. Moynihan referred to this symptom group originally as the "inaugural symptoms of gallstones," but it is now accepted that they are indicative neither of the presence of stones nor of infection. Dr. Wilkinson points out that many of these symptoms are functional in origin. My associates and I agree that they are functional in origin, but we believe that the mechanism of their production in many

cases can be explained on the hypothesis of biliary stasis Dr Wilkinson objects to the use of this term Biliary stasis not only serves to explain the mechanism by which many gastro intestinal symptoms are produced but also is applicable to a far wider field than indicated because it explains these functional disorders and also accounts for many of the cases in which postoperative symptoms occur, showing failure of relief by operation I agree that stasis in the gallbladder is hard to conceive after cholecystectomy, but biliary stasis includes not only the gallbladder but also the biliary tract as a whole Once the gallbladder is removed the common duct is more likely to endure the effects of stasis, and in consequence many of the patients complained of an exacerbation and intensification of symptoms after operation because of such stasis in the common duct In many cases the biliary stasis is primarily functional and both it and the irritable colon, which Dr Wilkinson emphasizes, may be manifestations of different phases of the same functional disorder A true colitis may reflexly cause sufficient spasm of the sphincter of Oddi to produce biliary stasis Appendicitis and many other lesions may produce similar reflex disturbances In such cases treatment or removal of the primary lesion, whether in the colon or elsewhere, will break the reflex arc and relieve both the biliary stasis and the patient's symptoms Functional disturbances of the biliary tract are common, for they occur either alone or in association with true organic disease They may be recognized and the causal factors determined by study not only of the biliary tract but also of the patient as an individual Once recognized, they are amenable to appropriate treatment If this is done, the question of nomenclature is perhaps of secondary importance

DR CLARENCE F G BROWN, Chicago I am in agreement with Dr Wilkinson's presentation The widespread use of surgical treatment is largely due to hasty roentgen interpretations and inability to diagnose irritable bowel Lack of progress in medical management makes his dissertation most timely A critical study of the medical and surgical aspects of gallbladder disease does much to clarify some of the controversial points between surgeons and internists as to the choice of treatment for the patient Attempts to differentiate between gallbladder disease and bowel distress are not essential to the decision as to whether the patient should be managed medically or surgically On the basis of our studies, I feel that in instances in which the symptom picture is confusing, i e, patients who have only slight distress resembling gallbladder disease, with no or very rare acute attacks, surgical intervention is contraindicated The patient should first receive the benefit of a management planned to help the colon and stomach outlet as well as the gallbladder The three nearly always are in trouble together Dr Wilkinson as well as Stanton, Howard, T E Brown and others, have shown that such patients do poorly when subjected to operations on the biliary tract Regardless of the presence of stones, a large number of patients can be satisfactorily managed by adequate medical treatment The difficulty appears to lie in the fact that the general conception of the medical management of gallbladder disease, using low fat, low cholesterol diets and magnesium sulfate, is not physiologically sound In 850 consecutive cases seen in the gastro-intestinal clinic of the St Luke's Hospital Outpatient Department, with complaints of upper abdominal distress, the final diagnoses were 28 per cent gallbladder disease, 22 per cent functional nervousness, 19 per cent gastroduodenal ulceration 6 per cent distress from systemic causes, 4 per cent neoplasms and 20 per cent miscellaneous, including reflex intestinal disturbance, such as bowel distress or amebiasis, ulcerative colitis, and so on All these patients were put on routine bowel management before any therapy was started We make no attempt to evaluate any pathologic changes until reflex bowel disturbances can be minimized I agree with Dr Wilkinson that a certain amount of improvement in patients occurs from this alone The remaining clinical picture consequently becomes more obvious for differential diagnosis

DR RUSSELL S BOLES, Philadelphia The noncalculous gallbladder is perplexing enough without having to deal with the equally vexatious problem of the irritable colon When one has to discuss the two at the same time, it is sort of further

confounding confusion, but it seems to me that the crux of this whole matter is the question of differential diagnosis I feel that the diagnosis must be based on an intelligent and experienced interpretation of the symptoms I cannot agree with Dr Wilkinson that cholecystography "should be the deciding factor" in most cases There is no question that cholecystography, if properly interpreted by experienced observers, is accurate from a diagnostic standpoint, but it must be remembered that x-ray cholecystitis is not necessarily clinical cholecystitis I am afraid that many unsatisfactory operations on the gallbladder have been performed throughout the country as the result of a diagnosis based particularly on the cholecystographic examination The x-ray appearances must be consistent with the history and clinical signs Operation should not be considered in view of a positive roentgenologic diagnosis unless it is accompanied with very definite clinical indications that one is dealing with a case of cholecystitis, preferably with stones What are the indications for operation? Certainly not indigestion The more vague the symptoms, the more uncertain one is that the entire symptomatology is due to the gallbladder, the more certain is the failure from operation No one will question that definite, well defined biliary colic, especially if repeated, is an absolute indication for operation, this and jaundice, especially following an attack of well defined colic, jaundice proved to be due to obstruction by stones, regardless of colic, are the safest indications for operation The presence of stones, relatively without symptoms, does not necessarily indicate to me the necessity of operation In many cases I look on such stones as sleeping dogs I believe in letting them lie I have never seen a great deal of grief come from letting a sleeping dog lie, whether it be a gallstone or anything else In view of the ill defined picture of chronic cholecystitis and the equally uncertain problems presented by the irritable colon, I strongly endorse Dr Wilkinson's management of these cases Unnecessary operation will be prevented and a distressing post-operative morbidity should thereby be reduced

DR RUDOLF SCHINDLER, Chicago I should like to ask Dr Wilkinson whether he was able to carry out gastroscopy in some of his patients I realize, of course, that psychic factors play a tremendous role in gallbladder disease I contended, myself, as long as ten years ago, that often cholecystitis starts with psychogenic spasms of the muscle sphincter of Oddi, however, chronic gastritis may be primary or secondary to chronic cholangitis It may or may not heal by cholecystectomy The gastric symptoms usually are due to the condition of the stomach They may be due also to organic changes of the intestine, and, finally, they may be due to psychoneurosis alone The diagnostic position of the intestine is much worse than that of the esophagus, gallbladder, rectum and now also the stomach, but it should not be forgotten to what extent the diagnosis of gastric neurosis has had to be given up in favor of some organic disease, especially chronic gastritis, in the last few years, therefore an expression such as "irritable colon" should be used very cautiously, and it should be based only on the direct evidence of the psychogenic origin of the distress in the respective case

DR SIDNEY A PORTIS, Chicago Since the advent of cholecystography there has been much more gallbladder surgery than previously Dr Wilkinson has said that many a patient with a so-called nonvisualization of the gallbladder has at operation a relatively normal gallbladder That is probably true However, has one the right to subject patients to surgical operation just because nonvisualization exists? May this phenomenon not accrue from faulty technic? One of the most important reasons for nonvisualization, other, of course, than an unsuitable dye preparation, is that many patients are told to eat any type of food previous to the ingestion of dye It is to be remembered that the sphincter of Oddi may remain patent for at least six to eight hours after the ingestion of fats Therefore this dye may run right through and cause a nonvisualization of the gallbladder Secondly, I cannot agree with what Dr Boles has said regarding the question of gallstones I can see no reason to treat patients with gallstones medically except when a contraindication for surgery exists If we are to believe that 95

per cent of all carcinomas of the gallbladder are associated with stones and that 5 per cent of all gallbladders with stones become carcinomatous, we may be putting an approximately 5 per cent mortality on every patient with gallstones, for once a carcinoma has developed in the gallbladder, it is more or less a hopeless picture. In the hands of a good surgeon the mortality for operative intervention for all types of gallbladder disease is usually less than 1 per cent. Therefore it is probably better to let the patient with gallstones have surgery at the outset, provided no contraindication exists. Furthermore, patients with gallstones may have a superimposed suppurative cholecystitis on a quiescent gallbladder and one is adding to that a mortality and a morbidity which should not exist. I have seen too many patients get into trouble with gallstones because their physician procrastinated too long, and I wish to emphasize again that I prefer surgery if not contraindicated in all cases of gallbladder disease with gallstones.

DR B B VINCENT LYON, Philadelphia. I am glad that Dr Wilkinson reopened this timely topic. I am glad to see that the Lahey Clinic has presented its figures. Of the ninety-nine noncalculous cases on cholecystography there were fifty-four in the group that showed nonvisualization or poor visualization. At the operating table 42 per cent of that group were found to be normal gallbladders. This brings back the question as to diagnosis. Diagnosis depends first on history, second on physical examination, third on cholecystography. Biliary drainage and laboratory maneuvers each have their place. I dare say that, of these 42 per cent normal gallbladders that were nonvisualized or poorly visualized, a considerable majority had cystic duct catarrhal obstruction, which is readily diagnosable by duodenal tube drainage. Let us agree that the calculous patient should be operated on and that the chronic gallbladder bound down in adhesions or with other definite pathologic considerations should be removed. Beyond that there is a large borderline group which today can be considered medical gallbladders and can be adequately treated. In the treatment of those cases there are three things—I approve of the Lahey Clinic attitude with regard to dietetics, but dietetics alone is not adequate if one is going to reduce that 31 per cent of postoperative morbidities. In addition to that there must be drugs: antispasmodics, sedatives and cholagogues, there must also be drainage to keep control of the adverse results of biliary microscopy, thus frequently checking on the progress of the case: repeated cholecystography, eventually coming back to a normal gallbladder. Now then hooked up with the chronic irritable colon why shouldn't one expect to have postoperative morbidity when one disturbs the physiologic function of Oddi's sphincter, permitting bile to be constantly discharged into the duodenum, nature's laxative bile. One has to expect this as many of us who have been cholecystectomized have found out. In the nonsurgical group one has to use a fat-full diet and exercise the gallbladder to contract. It may hurt in the early days, possibly for ten days but as a result the gallbladder exercises and begins to drain. Thus the only hope of saving that gallbladder is to establish free drainage by diet drugs and the duodenal tube.

DR MANFRED KRAEMER, Newark, N. J. I hesitate to speak of my small number of cases in the light of the many cases presented by Dr Wilkinson. However, in studies made at the gastro intestinal clinic at the Presbyterian Hospital and in private practice in Newark it has been concluded that there is something radically wrong with the medical treatment of cholecystitis because this treatment causes an irritable colon. I have made careful laxative studies on all my patients and am surprised to find that in the treatment of cholecystitis 90 per cent of the patients are receiving laxatives of one kind or another. If irritable colons in patients with cholecystitis are to be prevented the medical method of treatment must be changed. I think the first axiom in the treatment of gallbladder disease is to withdraw all laxatives: bran liquid petrolatum and other bowel irritants.

DR ANTHONY BASSLER, New York. The gallbladder question seems to be swinging from surgery into medicine the reverse of what happened with ulcer not long ago. Many

diverse points have been expressed here. They answer the question that not enough is known, and I rather hesitatingly rise to give the most diverse idea so far advanced. I believe, predicated on a study of a hundred cases of chronic cholecystitis without stones, and carefully checked, that while relief of symptoms is easy by a number of methods and patients are perfectly satisfied, I agree with the statements of Green, Carter and Twiss. With careful checking and metabolic studies, one would be surprised to see what a small percentage of those patients are really well. On the other hand, on the basis of a hundred cases of chronic gallbladder disease handled as an intestinal condition which has a catabolic effect on the hepatobiliary apparatus and generally throughout the body, it has been possible to raise the percentage of sustained benefits, as checked by blood chemistry and in other ways, from about 8 to 61 per cent. I now feel (and it would take an hour to tell the story) that it is worth while to begin to think that gallbladder disturbance is not an entity of itself alone, that it is essentially due to a toxic condition in the upper levels of the small intestine from an anaerobic infection in the region of the ileocecal valve, and a parasitizing of the bacteria in upper levels of the small intestine. Handling it entirely as an intestinal question, apart from the gallbladder, one can accomplish far better and sustained results from medical treatment. I can say definitely that this intestinal condition may present a hepatobiliary syndrome and what is called gallbladder disturbance, it may, however, also present an almost totally neurologic syndrome or an enteric syndrome, and in those who have presented these nonbiliary syndromes the condition of the gallbladder has been checked and it is most interesting to find that the incidence of gallbladder disease was 35 per cent. Gallbladder disturbance is intestinal in origin with catabolic results, which catabolic results further act unfavorably on the hepatobiliary system and should be treated as such.

DR SAMUEL FRIEDMAN, New York. The question of the diagnosis of the borderline cases of chronic cholecystitis and chronic colitis is one of the most puzzling of all the chronic ailments that come to the attention of the internist. They require most careful deliberation in arriving at a diagnosis and in determining whether the case is to be treated conservatively or surgically. I should like to stress one point in this connection. Often the internist is confronted with a patient, after middle age, particularly the stout female, who has a coronary sclerosis as well as a chronic cholecystitis. It must be particularly kept in mind that such a patient will often refer her pains of angina pectoris from a coronary spasm or not very rarely from a mild or even severe coronary thrombosis to her epigastrium or gallbladder area, so that even the best clinicians may be misled and overlook the true condition of angina and advise operation. A gallbladder attack may precipitate an attack of angina in which case one becomes even more puzzled. Here, the most delicate weighing of symptoms and clinical signs is most essential. I have seen such cases of angina mistaken for cholelithiasis and operation urged often enough so as not to forget them. Therefore, in dealing with a stout patient, particularly a woman past 50, unless the diagnosis of purely a cholecystitis or calculus is definite, one must think of the possibility of dealing with angina pectoris or coronary thrombosis alone or in conjunction with a gallbladder condition, one having been precipitated by the other.

DR SAMUEL ALLEN WILKINSON, Boston. Since it is impossible to answer adequately all the questions raised, I shall only stress one or two things, in order to clarify them. Unless we are fully convinced that we are dealing with a definitely diseased gallbladder my associates and I make every effort to keep that gallbladder away from the surgeon and treat the case medically. In cases in which gallbladder disease is sufficiently severe to warrant surgical intervention, medical treatment after the operation is of paramount importance. If this postoperative medical treatment is neglected many of these patients will do poorly. Cases in which adequate postoperative dietary treatment is given with due regard to antispasmodics and to regulation of bowel activity, will be the cases that give the best results, whether or not gallstones were found at operation.

PERICARDITIS

ARTHUR M. SHIPLEY, M.D.
BALTIMORE

It seems best to limit this discussion to the various types of pericarditis, especially as there is little agreement in belief and practice and it is apparent that many cases of this condition, in its different phases, are still overlooked.

It is striking that operations for pericarditis are reported from only a relatively small number of clinics. Cooperation between the different services is urgently needed. Much has been accomplished in other clinical fields, such as disturbances of the thyroid gland, diabetes, tuberculosis, peripheral vascular disease, tumor of the lung and many other disease conditions in which the internist and the surgeon are equally interested. The patients with cardiac disease that may come within the scope of surgery should be studied by the internist, roentgenologist and surgeon working in unison. In the clinics from which progress is reported this cooperation is evident.

In coronary thrombosis, pericarditis with effusion is sometimes present. It may be confined to the area of infarction, and the amount of effusion is usually small. Occasionally, however, the quantity of fluid present is considerable and may cause uncertainty as to diagnosis, especially if thrombosis and infarction with effusion occur during the course of some infectious process, such as pneumonia, furunculosis, osteomyelitis or peripheral infections seen during the course of uncontrolled diabetes.

A 39 year old white man was admitted Aug. 31, 1936, to the Baltimore City Hospitals, in the service of Dr. Thomas R. Boggs. He had entered another hospital in June because of intense anterior pain in the chest, bloody sputum, dyspnea and orthopnea. The onset was sudden, and after three weeks he was discharged. In the interval before admission to the Baltimore City Hospitals his symptoms gradually returned, with anasarca, enlargement of the liver and ascites. On admission there were engorgement of veins in the neck and dusky cyanosis. Respirations were hurried, and there was generalized subcutaneous anasarca. No pulsations were visible in the precordium, the heart sounds were distant, there was no murmur, there was a constant protodiastolic gallop rhythm, and the pulse was small in volume and definitely paradoxical. The liver was felt 3 fingerbreadths below the costal margin and a fluid wave was demonstrated.

The vital capacity was 2,100 cc. A roentgenogram of the chest showed that the heart was enlarged to the right and the left and the aorta normal. The lungs were clear. Pulsations of the heart were not clearly defined. The venous pressure in the right arm was 290 mm. of water. The impression was of either myocardial infarction or limitation of myocardial activity due to pericardial effusion or constricting myocarditis. The patient became more edematous in spite of intensive cardiac therapy. The blood pressure dropped from 140 systolic and 120 diastolic on admission to 110 and 90. The venous pressure remained around 300 mm. of water.

This patient was seen in consultation by the surgical service and exploration of the pericardium decided on which was done with tribromethanol anesthesia aided by local infiltration with procaine hydrochloride. The pericardium contained 300 cc. of serosanguineous fluid. The postoperative course was steadily downhill, and death occurred in profound cardiac failure.

At autopsy, complete occlusion of the anterior descending coronary and extreme narrowing and almost complete occlusion

of the right coronary were observed. There was a large infarct in the left ventricle involving the entire anterior wall and a portion of the interventricular septum.

Suppurative pericarditis has been well covered in the literature in recent years. Bigger¹ has reported eight cases and I² have reported thirteen, which indicates that the disease is not rare. The latter statement is supported by autopsy records, which show a considerable number of overlooked cases. There are two chief avenues of approach for drainage, the anterior and the posterolateral. In early cases some one of a number of anterior operations may be done: transsternal, right or left parasternal, chondrophoid or a combination of transsternal and left parasternal. These anterior approaches should be as low as possible. In late cases with a large effusion, anterior drainage may not be effective, and Truesdale,³ Heuer,⁴ Loucks,⁵ Moore⁶ and Cottam⁷ have reported a posterolateral approach, as far as the pericardium is concerned, by resection of the seventh rib near the midaxillary line. In all the cases reported the pericardium was adherent to the pleura and pericardiectomy was possible without producing pyopneumothorax. Ballance,⁸ in his Bradshaw lecture, discussed this problem.

Tamponade of the heart is associated with pericarditis with effusion, whether purulent or serous, and with constricting pericarditis, and because other conditions produce tamponade, all possible causes of compression are of interest. Tumor of the heart and pericardium, while rare, may cause serious compression of the heart, either because of the presence of the tumor itself or because of the effusion.

After compression of the chest, with injury to the heart, there may be early or late hemorrhage into the pericardial sac, especially if there is laceration of the heart muscle or later rupture of a surgical aneurysm of the cardiac wall.

Tamponade is frequently overlooked in spite of the increased reference to it in the literature. It may be acute or chronic and is a symptom of a wide variety of cardiac conditions and shows its presence in a number of ways. It is most dramatic and acute in hemo-pericardium, especially if there is a penetrating wound into one of the cavities of the heart, and, because the left ventricle has the highest pressure, a wound of this chamber produces rapid tamponade. In suppurative pericarditis the symptoms of tamponade may be secondary in importance to those of infection and in slowly

forming serous effusion large quantities of fluid may be present in the pericardium with no outstanding symptoms of compression of the heart

The time during which the effusion is accumulating determines the amount of fluid present before symptoms of tamponade show themselves. In rapid bleeding the heart is seriously embarrassed when from 200 to 250 cc of blood is present, while in slowly forming serous effusion from 1 to 2 liters of fluid or more has been reported.

The amount of pus present has not been the most important consideration in a number of my cases. The rapidity of the accumulation and the kind of infection, plus associated infectious processes, have been more important than the actual amount of pus found in the pericardium at operation.

Dinsmore reported a case of tamponade due to bleeding into the superior part of the mediastinum after removal of a large substernal adenoma of the thyroid and a mediastinal hematoma following trauma. Post-operative exudate following intrathoracic operations may seriously compress the heart. Pneumopericardium may cause compression. Mediastinal tumor and aneurysm are extrapericardial causes of tamponade. In one instance I did a wide resection of the anterior wall of the chest in a patient with a large aneurysm of the innominate artery, with dramatic relief of the symptoms caused by cardiac crowding.

In the rare instances of rapidly developing mediastinal emphysema it is sometimes difficult to say whether tamponade of the heart or asphyxia causes death. Constricting pericarditis as a cause of tamponade will be discussed under that heading.

The symptoms of tamponade vary somewhat, depending on whether the condition is acute or chronic. In cases of acute tamponade the diagnosis must be made quickly, while with chronic tamponade every diagnostic aid may be used. The outstanding symptoms of tamponade are high venous and low arterial pressure with a paradoxical pulse and heart sounds that are suppressed. If the tamponade is acute and developing rapidly, there will be also anoxemia of the central nervous system, going on to unconsciousness, if chronic, there will be congestion and enlargement of the liver with ascites and anasarca.

There will be the physical signs of an enlarged cardiac-pericardial shadow, with the base of the triangle caudate, and x-ray examination will show this enlargement and alteration in shadow, as well as a relative absence of pulsations along the margins of the shadow. Griswold,⁹ in reporting a case of constricting pericarditis with operation and recovery, referred to the use of the roentgenkymograph as described by Johnson¹⁰ and reported that it gave "gratifying and irrefutable evidence of the reduced amplitude of cardiac pulsation and the throttling effect of the disease on the heart." The angle made by the shadow of the heart and the right diaphragm is often absent. If the fluid is free, most of it is found dorsal and lateral to the heart, and the apex is usually close up against the anterior layer of pericardium.

The heart sounds are muffled and appear distant, not because the heart is pushed away from the listening ear but because compression is interfering with their quality. In acute tamponade the sounds may almost

disappear as compression interferes more and more with diastole and systole, while in chronic tamponade the heart is aptly spoken of as being "small and quiet."

The heart is both free and attached. The two layers of the pericardium give it a range of motion, within definite limits, that allows a remarkable freedom from consciousness of its movements, especially when one considers the force with which the heart works and its nearness to the surface of the body. On the other hand, the heart is closely attached to a number of structures. It is fixed to the diaphragm at the quadrate opening, where the two layers of the pericardium are fused to the diaphragm in order to allow the inferior vena cava an unimpeded access to the right auricle. It is attached to both lungs by means of the pulmonary artery and veins. It must be remembered that the lungs, and diaphragm are movable structures. Fortunately for the heart, they move in unison. The heart is firmly fixed to another structure, with which it is continuous—the aorta—and the aorta moves very little. The two layers of the pericardium are continuous on the walls of the great vessels at about 7 cm cephalad to the base of the heart, and therefore the outer layer of the pericardium has little part in fixing the heart in health. However, adhesions between the two layers of the pericardium inject a real anatomic and functional problem into the picture, and around this fact a great deal of controversy has developed, while constriction of the heart by the merged epicardium and pericardium causes *concretio cordis*.

Perhaps physicians and surgeons have been paying too much attention to the anatomic departures from the normal and assuming that such departures must of necessity interfere with the function of the heart. This is especially true in two instances, in cardiac displacement and in chronic adhesions between the layers of the pericardium without constriction and without mediastinopericarditis. In both of these conditions there may be little disturbance of cardiac function.

Anatomically, chronic adhesive pericarditis may be divided into four types.

There may be adhesions between the two layers of the pericardium, without constriction and without fixation of the outer layer. Usually such adhesions are not productive of cardiac disability and may be of value to the heart in establishing a new vascular bed in cases of coronary occlusion. This type of adhesion may follow drainage of the pericardial sac for pyopericardium, and there is ample clinical evidence that the heart may have its function very little disturbed.

Another type of pericardial adhesion without serious cardiac disturbance is seen in pulmonary tuberculosis with adhesive pleuritis, the adhesions fastening the pleura or diaphragm to the outer layer of the pericardium. Such adhesions explain many of the displacements of the heart seen in fibroid phthisis. The heart may be smaller than normal, because of long periods of rest in bed.

Chronic constrictive pericarditis has become established as a separate and distinct entity and is slowly becoming recognized as a disease calling for surgical treatment. There is considerable confusion as to etiology, especially as to its possible relationship to rheumatic fever and tuberculosis. Because the condition is a chronic one, cultures have given little information. Even examinations of tissue have not been very helpful. There are a number of reports of tubercles being present in acute and subacute cases, but in the chronic

⁹ Griswold R. A. Chronic Cardiac Compression Due to Constricting Pericarditis. *J. M. A.* 106 1034-1037 (March 28) 1936.
¹⁰ Johnson S. E. The Roentgenkymograph as a New Aid in the Diagnosis of Adhesive Pericarditis. *Surg. Gynec. & Obst.* 61 169 (Aug.) 1935.

cases, although fibrosis is constant and calcareous deposition in the pericardium often present, tubercles are rarely seen

Cushing and Feil¹¹ reported that "microscopic examination of the resected pericardium in all instances showed the parietal and visceral layers to be fused and indistinguishable, with densely fibrous and hyalinized tissue, which was poorly vascularized. Occasional small collections of lymphocytes were observed. Some of the cases showed focal areas of calcification. There were no changes that could be construed as characteristic of rheumatic or tuberculous infection."

It is striking that in many cases of constricting pericarditis there are no previous history of rheumatic fever, little evidence of tuberculous pleuritis at the time of operation and no history of previous attacks of chronic pyogenic infection elsewhere in the body. In one case in Churchill's¹² series tuberculosis of the abdominal cavity resulted from the injection of pieces of pericardium, removed at operation, into the pericardial cavity of a monkey.

Blalock¹³ said that tuberculosis has an important role in the etiology of constricting pericarditis. In eleven of twenty-one cases of this condition tuberculosis was proved to be present, and it was strongly suspected in five. He performed pericardiectomy on six patients with tuberculous constricting pericarditis, with three recoveries and three deaths.

The incidence of tuberculous pericarditis is interesting. In different reports from autopsy records it varies from 0.7 to 1.1 per cent. In Bellet's exhibit at this annual session one is struck by the high percentage of enlarged cardiac-pericardial shadows in the roentgenograms.

Perhaps tuberculous pericarditis will come to be classified in three groups: first, acute, in which effusion predominates; second, subacute, in which adhesions and thickening are outstanding; and, third, chronic, in which fibrosis and constriction are present.

There is little evidence that previous drainage of the pericardial sac causes constrictive pericarditis. However, Darrach¹⁴ reported one such case, and a number of late deaths have been reported in the literature, with adhesive pericarditis given as the cause. Whether the cause of death is mediastinopericarditis, with cardiac hypertrophy and dilatation, or constrictive pericarditis is, in most instances, not clearly stated. I have follow-up records of six of seven patients who recovered after pericardiectomy for pyopericardium, and in all six there is no evidence of cardiac disability.

Beck and his associates¹⁵ have done a great deal of experimental work, and their experience has convinced them that adhesions between the layers of the pericardium are not disabling unless constriction is present. Churchill¹² has written two excellent papers on this subject. In the first he reported thirty-seven cases collected from the literature and in the second ten cases in which he operated, with seven cures, two improvements and one death.

Heuer¹⁶ stated that he has operated on six patients by the left parasternal approach. In five cases the operation was completed and the improvement in the condition of the patient dramatic. In one case the operation was not completed. There was no death.

Beck¹⁷ has emphasized a triad of symptoms present in constrictive pericarditis: (1) high venous pressure and low arterial pressure, (2) enlarged liver with ascites and (3) a small, quiet heart.

Churchill¹² advised strongly against operating on patients with acute tuberculous pericarditis, even when the symptoms of compression are present. He stated that repeated aspiration may offer some hope of survival until the chronic stage is reached, when pericardiectomy may be done. Graham,¹⁸ Bigger,¹ Blalock¹³ and Piersol and his associates¹⁹ have reported on this condition, while Schmeiden²⁰ and others in Europe have contributed valuable papers. Trout,²¹ in reporting a case, gave an excellent review of the literature, and Bigger¹ has reported two cases. Beck and Cushing²² and Cushing and Feil¹¹ reported eleven cases in which Beck operated for this condition.

The variation in the method of approach has been wide. Schmeiden²⁰ practiced an intercostal incision in order to reach the left side of the heart, while others have done some variation of the Duval-Barast²³ procedure (median sternotomy). A third approach has been used by recent operators: a long curved incision through the soft parts extending from the second to the sixth rib and running roughly parallel with the left margin of the sternum. After the flap of soft tissue is turned out, the ribs, cartilages, periosteum and left margin of the sternum are removed. This procedure exposes a large area of the anterior layer of the pericardium and gives sufficient exposure for performing a wide decortication of the heart.

There is considerable difference of opinion as to the effect of atmospheric pressure on the exposed heart and great vessels. Most operators disregard this factor, but all take care to have at hand the means of differential pressure anesthesia in order to control collapse of the lung, if the pleura is opened, which usually happens. Churchill reported opening four serous cavities in the same patient, the pericardium, both pleurae and the peritoneum.

By removing the anterior wall of the chest over the heart the advantages aimed at in cardiomyolysis are obtained, and for this reason wide resection of the left side of the sternum and the left cartilages and ribs is gradually replacing the bony flap operations, the Spangaro approach, the long intercostal incision and median sternotomy. The wound should be closed snugly, layer by layer and made air tight and every precaution taken against infection. Drainage should be avoided if possible.

Some operators believe that mishaps are apt to be caused by increased atmospheric pressure with decreased cardiac output, while others think the weakened cardiac walls are overdilated by the increased

amount of venous blood reaching the heart when constriction is removed Churchill operates with the patient in a sitting posture and may leave a pleural cavity open if the patient is breathing well. On the other hand, too rapid a fall of venous pressure because of hemorrhage, shock or anesthesia is to be avoided.

Another type of adhesive pericarditis is mediastinopericarditis and is associated with the name of Brauer.²⁴ There is a tendency to disregard this condition or to confuse it with constricting pericarditis. The two conditions may exist in the same patient, and when they do constriction is more important, but there is a considerable number of well authenticated cases of adhesive pericarditis without constriction, in which the heart is seriously handicapped and sooner or later suffers damage. In such cases the two layers of the pericardium are adherent but without constriction, and the outer layer of the pericardium is likewise adherent to the diaphragm and the wall of the chest. This condition does not often follow pericardiotomy for pyopericardium, although one would expect it to because, in the operation for drainage of pus from the pericardium, little attempt is usually made to marsupialize the pericardium and pus is bound to bathe the entire free portion of the pericardium. In mediastinopericarditis, heart, pericardium, wall of the chest and diaphragm are all bound together, and during systole the heart contracts against a pull that is unyielding as far as the wall of the chest is concerned, and both the heart and the diaphragm are hampered in their movements. Graham²⁵ quoted Wenckebach²⁶ as follows:

The crura of the diaphragm will try to pull the diaphragm downward, the diaphragm is fixed to the heart, the heart is fastened to the chest wall in front and to the surrounding mediastinal parts behind. The heart is, therefore, unable to follow the diaphragm and the diaphragm is hampered in its descent. As a result it is noted that (1) the descent of the diaphragm is insignificant, (2) during inspiration the crura pull at the heart and via the heart at the chest wall, at the roots of the lung and the posterior mediastinum, (3) the heart and large vessels being fixed to their surroundings inspiration produces a worse condition than expiration, and (4) respiration becomes very defective in all its factors.

The symptoms will vary, depending on the extent and denseness of the adhesions and on the time factor. If the function of the heart is disturbed, myocardial changes gradually take place and the heart may become enlarged and finally undergo degeneration.

The adhesive nature of the malady may be evident in retraction of intercostal spaces during systole. In 1928 Smith and Liggett²⁷ reported 107 operations for this condition, collected from the literature. The operative treatment is the cardiomyolysis of Brauer, which consists of removing enough of the bony wall of the chest over the heart to liberate the heart and lessen the tug on the diaphragm, the mediastinal tissues and the lungs. The operation in itself is not difficult. The patient may be a bad risk and the choice of anesthetic difficult. Postoperative complications are dangerous, and great care should be taken in the diagnosis, preparation of the patient and after-care. The condition should not be confused with constricting pericarditis. The operation is undertaken to free the adherent pericardium from the overlying cartilaginous and bony wall of the chest. It

may be necessary to remove a portion of the sternum, but the sternum should not be cut across. It is an extra pericardial operation throughout. In most instances the operation is confined to resection of the cartilage and anterior ends of the left fourth, fifth and sixth ribs, together with a portion of the sternum.

In a number of recent reports emphasis is laid on myocardial changes with hypertrophy in patients with this condition who had a history of rheumatic fever. Many of these patients at autopsy showed chronic endocarditis, valvular disease or disease of the cardiac wall. It is therefore possible that the enlargement and impairment of the heart are caused by rheumatic fever, valvular disease or hypertension, rather than by mediastinopericarditis. It is most important to keep the whole range of possibilities in mind and not to undertake operation unless the indications are clear, especially as the causative agents and pathologic changes are not, as yet, definitely outlined.

CONCLUSIONS

- 1 Pericarditis in all its phases is more common than is generally supposed.
- 2 In many instances the disease is a combined medical and surgical problem.
- 3 Tamponade of the heart is its most important symptom, but tamponade is caused by many extrapericardial conditions.
- 4 Constrictive pericarditis merits more thought and action than are now given to it.
- 5 The etiology of the condition needs more study.
- 6 The operative results of pericardiectomy for constricting pericarditis warrant a much wider use of this therapeutic agent.
- 7 The operative approach in pericardiectomy is being standardized and simplified.
- 8 In removing the constricting and often adherent pericardium, many surgeons no longer attempt to uncover the atria.
- 9 The relationship between mediastinopericarditis and impairment of cardiac function needs to be more clearly defined.

ABSTRACT OF DISCUSSION

DR CLAUDE S. BECK, Cleveland. Dr Shipley's paper contains a great deal of information that is important in the way of diagnosis. It will bring patients to receive proper surgical treatment. He described the compression syndromes of the heart. Many different anatomic lesions produce chronic compression of the heart, and one should bear in mind the clinical picture that is always found. The clinical picture of chronic compression of the heart consists of a high venous pressure taken at the elbow, ascites and, again, a small, quiet heart. This triad of signs is diagnostic of the chronically compressed heart. I do not believe that either of these triads can be wrong. I think that these clinical pictures produced by compression of the heart ought to be recognized, and after they are recognized the next step is to make an anatomic diagnosis of the lesion producing the compression, whether the lesion is pus or blood, scar tissue or neoplasm. It is only by approaching the subject in this way that proper, logical treatment to the patient's condition can be given. I am against the use of terms like "constrictive pericarditis" or "adhesive pericarditis," or "Pick's disease," or "Concato's disease." All these terms are misleading and should not be used. I should also like to emphasize that adhesions play no part in the production of compression of the heart. I have had the experience of operating on twenty-seven patients with compression of the heart. Twenty of these had chronic compression of the heart due to pericardial scar. One had a low grade chronic compression of the heart due to a localized collection of tuberculous pus lying over the right auricle. Six of them had acute compression of the heart due to the rapid formation of pus in the pericardial cavity.

DR ISAAC ALEXANDER BIGGER, Richmond, Va Cardiac compression characterizes those conditions involving the heart and the pericardium which are most amenable to surgical treatment. Acute compression of the heart is shown most dramatically in cases of hemorrhage into the pericardial cavity as a result of cardiac injury. The signs and symptoms develop rapidly and are quite characteristic, especially the signs. Compression of the heart sometimes develops rapidly in acute suppurative pericarditis, occasionally producing marked signs and symptoms within twenty-four hours, but the increase in pressure is rarely sufficient to produce a clinical picture simulating shock, as in intrapericardial hemorrhage. However, at times there is a considerable fall in the systolic blood pressure and a rise in the venous pressure. Chronic cardiac compression is usually caused by the constricting type of adhesive pericarditis, which, developing insidiously, gives a clinical picture in which the blood pressure changes are less prominent and liver enlargement and ascites more prominent. I wish especially to emphasize the importance of cardiac compression in acute suppurative pericarditis. The diagnosis is not made in a large percentage because the characteristic signs are not recognized. The symptoms are not especially characteristic and are frequently overshadowed by the symptoms of the antecedent disease, so it is essential that physicians and surgeons who are treating patients with sepsis, especially those with severe infections within the thorax, make frequent examinations of the cardiac area in an attempt to discover the signs of pericarditis. It is probable that a pericardial friction rub occurs at some time in all cases of suppurative pericarditis and that it is not found in a large percentage of them because the heart is not listened to at the proper time. Following the friction rub, which may disappear rapidly, there will almost certainly occur the signs of gradual compression of the heart with enlargement of the area of cardiac dullness and distant heart sounds. When these changes are noted, radiographic and fluoroscopic examinations should be made, I think the latter are much more important than the former.

THE NEW YORK CITY PLAN FOR COMBATING SYPHILIS

CHARLES WALTER CLARKE, M.D.

Director Bureau of Social Hygiene Department of Health
NEW YORK

In its last analysis, any plan for combating syphilis which falls short of practical application in towns and cities is sure to be a failure. Paper plans, state-wide and nation-wide plans are futile unless they come eventually to grips with the medical and social problems of individuals in homes and shops, hospitals, clinics and doctors' offices. The solution of the problem of syphilis really begins only when the doctor, nurse or instructor makes helpful contact with Tom, Dick and Harry, and Mary, Mollie and Maggie who are infected or who stand in danger of becoming infected. That is why, since cities are by definition areas of concentrated population, the fight against syphilis in cities is most important. It is in cities that people can be reached most easily and economically by popular instruction, by diagnostic and case finding measures, and by treatments. One should beware of generalities which fail to get spirochetes under microscopes, which put no arsphenamine into veins, which restore no lapsed infectious sufferers to treatment and which fail to guide individuals in the prevention of syphilis and gonorrhea. While New York City is not, perhaps, a typical American community, the principles and procedures which have been developed there are believed to be sound and practical and, with appropriate modifications, can be applied in any city.

Read before the Section on Preventive and Industrial Medicine and Public Health at the Eighty-Eighth Annual Session of the American Medical Association Atlantic City N. J. June 11 1937

Nearly a thousand newly diagnosed cases of syphilis are reported each week to the New York City Department of Health. This means over 50,000 a year, but this is believed to be only a small part of the vast number in our population. If the prevalence rate of syphilis in New York City is as high as that of the United States as a whole, we must assume that there are in New York City about 378,000 cases—in other words about 5 per cent of the entire population. When the dangers of syphilis to the individual and the community are considered in relation to its widespread distribution, we have some conception of its urgency as a public health problem.

At present our best hope of eventual conquest of syphilis and of relief from the burden of its care appears to lie in the fact that syphilis can be rendered noninfectious by treatment. This is the foundation on which has been built the success that has thus far been attained—success that is brilliant, though limited to but a few small countries. In Denmark, a country having about half the population of New York City, syphilis has been reduced from about 700 per hundred thousand in 1885 to 35 in 1935. Syphilis is now about as uncommon in Copenhagen as typhoid is in New York City. In Sweden the highest prevalence rate recorded was in 1919, when an explosive epidemic carried the rate to about 600 per hundred thousand. In 1934 it had fallen to 43. Great Britain has apparently reduced the number of cases of syphilis by one half since 1920, the highest point. In each of these countries the essential factor in achieving success appears to have been the treatment of infectious cases to render them noninfectious.

There are in New York City almost 14,000 licensed practitioners of medicine. I maintain that these physicians constitute the shock troops in our battle against syphilis, more valuable than all the many clinics and hospitals, voluntary and official, in the city. Private practitioners collectively see or have the opportunity to see more persons with syphilis than all the institutions combined, for many of these persons, unaware of syphilitic infection, are visiting general practitioners and specialists for every malady to which the flesh is heir. More general use of modern diagnostic procedures and a "lower threshold of suspicion" of syphilis would lead to the discovery of many thousand more cases of syphilis and the treatment of these cases, to the enormous benefit of the public health and the profit of the profession.

THE IMMEDIATE OBJECTIVE

Therefore the immediate objective of the New York City Department of Health is to aid private physicians in discovering, treating and controlling syphilis among patients who go or could go to private practitioners. The practical aids which the Department of Health offers may be briefly described, as follows:

1 *Diagnostic Services*—The Department of Health laboratory performs serologic tests for syphilis without charge (345,000 specimens were tested during 1936). At every one of the seventeen diagnostic centers, blood specimens are taken for private physicians on request. Expert darkfield examinations and diagnostic consultations are offered in these centers, the reports being sent directly to the physicians. These diagnostic aids are available for all types of syphilis and gonorrhea, and physicians are invited to use this service freely without fear of losing their patients.

2 *Treatment Services*—To enable private physicians to care for a larger number of patients having syphilis, especially that large body of individuals who cannot pay the full regular fee, the Department of Health, using Social Security funds, provides neoarsphenamine and preparations of bismuth or mercury in amounts sufficient for one year of the treatment in accordance with modern therapeutic methods. These drugs are supplied free on request without distinction as to the patient's ability to pay the physician a full fee or any fee for his service. This enables private physicians to give medical care to many patients who can pay only a small fee—fees comparable with those charged by many so-called pay clinics. Judging from the numerous requests received by the Department of Health there are many physicians who are happy to treat certain patients free of charge if the necessary drugs are supplied. Because the funds for this purpose are limited, drugs are provided to private practitioners only for the treatment of early syphilis, syphilis in pregnancy and congenital syphilis. Later it is hoped that the same assistance may be extended for all cases of syphilis found under private medical care. Physicians willing to cooperate with the Department of Health in the diagnosis and treatment of syphilis are asked to report their cases at the time of requesting drugs, if they have not already done so, and supplies are furnished in four allotments, each sufficient for three months of continuous modern treatment. Every effort is made to supply the drugs of the physician's preference and by a system convenient for the practitioner. It should be understood that the Department of Health does not require the physician to state that his syphilitic patient is indigent or unable to pay a fee for medical service, nor does the department suggest any schedule of fees which the physician should charge if he uses drugs furnished by the department. It is anticipated however that, when a patient is able to pay the full specialist fee for medical care, few physicians will wish to administer drugs obtained at public expense.

On request, the services of especially selected and trained nurses are available to follow up lapsed cases of syphilis or gonorrhea reported by physicians, the nurse for the time being working under the direction of the physician reporting the lapsed case. This is an important feature of the plan, since by sufficiently sustained treatment syphilis may be rendered permanently noninfectious and in many cases a clinical cure may be achieved.

3 *Epidemiologic Service*—After a case of syphilis has been brought under treatment, the next most important duty is to answer the question "from whom did the patient acquire the disease and to whom may he or she have transmitted it?" This in substance is the epidemiology of syphilis. Early syphilis, syphilis in pregnancy and congenital syphilis offer the best opportunity for epidemiologic work and many physicians in their daily practice are doing excellent case-finding work with patients of these types. The Department of Health offers its services to aid the physician in finding the source of infection of the patient having early syphilis, syphilis complicating pregnancy or congenital syphilis. For this service a group of specially trained physicians are employed. The department makes their services available to physicians requesting drugs and to any other physician who wishes the cooperation of the epidemiologist in finding sources of infection and in bringing them under treatment. But in no cases will action be taken except at

the request of the physician with whom we are cooperating. Where this plan has been in operation, about 25 per cent of the sources of infection have been brought under medical care.

4 *Educational Activities*—The New York City Sanitary Code requires that every person found by a physician to have syphilis or gonorrhea shall be given a pamphlet of instruction with regard to his infection and the protection of contacts. The Department of Health furnishes this pamphlet to physicians and clinics. New editions in appropriate foreign languages have been prepared. The department also cooperates in making postgraduate instruction available to physicians, bringing to their attention the most accepted modern ideas and methods of diagnosis and treatment of syphilis and gonorrhea in all their stages and manifestations.

5 *The Reporting of Syphilis*—In reporting a case of syphilis or gonorrhea or other communicable disease to the Department of Health, a physician renders a valuable public service. It would be appropriate in New York City to compensate the physician for this report and, if funds were available, I should be glad to see this done. The least that the Department of Health can do, it seems to me, is to make reporting convenient and free even of the cost of postage. A plan to that effect is in operation in New York City. The physicians fill in the facts, slip the form into an envelop provided by the Department of Health and deposit it in the post box. Reporting by initials and address is permissible, and I wish to emphasize that all reports are strictly confidential and are kept under lock at the Department of Health. Direct reporting by a physician is of great service to the department and will be of greater service as our plans get under way, for this source of information will be taken into account in judging the progress of our fight against syphilis.

These plans are subject to modifications as the need and recommendation of physicians may indicate. These measures should enable private physicians to participate more fully in the attack on syphilis and bring them to the front as auxiliary health officers.

VOLUNTARY HOSPITAL CLINICS

The fifty clinics of voluntary hospitals in New York City should play a more important part in the fight against syphilis. Many of these clinics are willing and able to provide treatment without charge for a larger number of poverty stricken patients if drugs are supplied by the Department of Health. To clinics which charge only low fees—fees that cannot possibly compete with those of private physicians—the Department of Health now provides drugs to enable them to care for indigent syphilitic patients. In this manner, facilities are increased and brought closer to those who need them.

The sanitary code regulates the conduct of these clinics and requires the maintenance of certain standards, including adequate personnel for the follow up of cases. After clinics have exhausted their resources in endeavoring to return lapsed infectious cases to treatment or to bring sources of infection under control, the Department of Health employs its legal authority to seek out such uncooperative individuals and bring them under medical care.

THE CITY HOSPITALS

The provision of treatment for syphilis in indigents and others who cannot pay, whether this treatment is ambulatory or inpatient, is primarily the function of the

various tax supported hospitals of the city. In spite of the best efforts of the Department of Hospitals and although progress has been made in 1936, the facilities are still very far short of the needs of the city, especially in respect of bed accommodations. The greatest single need in New York City, it is believed, is more bed accommodations for infectious cases of syphilis and gonorrhea, whether they are voluntary admissions or legally removed by the order of the health department. In the New York City fight against syphilis, scarcely any more important development has occurred than the provision of funds for the payment of physicians rendering medical services in the syphilis and gonorrhea clinics of the city's hospitals. This will result, it is believed, in much more and much better service for the infected poor.

The relation of the health authority to the city hospital clinics is defined by the provision of the state law and of the sanitary code. They provide for the follow up by the Department of Health of lapsed infectious cases and sources of infection and give the department power to require examination and treatment if indicated. Certain city hospitals receive and give medical care to persons with infectious syphilis and gonorrhea removed to them by the authority of the health department. Neither the private physician nor the hospital, whether voluntary or official, has the authority to detain forcibly a person with infectious syphilis or gonorrhea. But when such a case is brought to the attention of the Department of Health, appropriate action can be and is promptly taken for the full protection of the public health, and such cases are received by a city hospital designated by the board of health. More use should be made of this authority vested in the Department of Health, but more bed accommodations are needed before the laws can be used to the fullest extent for these quarantine procedures.

THE DEPARTMENT OF HEALTH

The Department of Health has primarily the duty of promoting, directing and aiding the attack on syphilis as a communicable disease. As a matter of sound policy it may work through other agencies both official and voluntary to gain its ends. It must supply deficiencies. Thus for the present it is obliged to supply a part of the treatment facilities for the very poor and it now maintains ten treatment centers, all of which are crowded to capacity with the unemployed and other very poor infected persons. Still more treatment facilities are badly needed, though it is hoped that the larger participation of private physicians and voluntary hospitals and the increased services of the Department of Hospitals will partly meet this need. When the Department of Health can properly close its treatment clinics it will do so, believing that treatment can eventually best be carried out by private physicians and in hospitals, both public and voluntary. With from 60 to 90 per cent of our clinic patients on some form of relief, we seem far removed from that desirable solution at present.

No permanent service of the Department of Health is more important than that of instruction of the public with regard to syphilis. An encouraging start has been made especially in cooperation with the liberal press of New York City, the radio and numerous voluntary societies. Diagnostic services and consultations are believed to be permanent case-finding functions, so long as syphilis remains a major health problem. The

epidemiology of syphilis is a permanent obligation and the epidemiologic service should be rapidly developed, for, through the finding and treating of infectious cases, syphilis can be brought under control.

The Bureau of Social Hygiene in the Department of Health was created by Health Commissioner John L. Rice, Oct. 1, 1935. The progress report indicates (a) the increase in the city budgetary funds for control of syphilis and gonorrhea by the Department of Health, (b) the increase in clinic services and (c) the increase in the number of treatments given from 1933 to 1936 inclusive.

Progress Report

Year	Budget	Clinics		Treatments
		diagnostic and treatment	diagnostic	
1933	\$118 810	5	2	122,651
1934	131 000	5	2	153 507
1935	180 000	6	2	186 291
1936	254 680	*10	7	†327 918

* Includes three new WPA clinics

† Estimates on basis of six months experience

In addition to budgetary funds, the Department of Health cooperates with the WPA in a project for the diagnosis and treatment of syphilis and gonorrhea. The expenditure of WPA funds amounts to about \$17,000 a month, or \$204,000 a year. Through the Security Act funds, amounting to \$50,000 a year, drugs are being supplied to private physicians and voluntary hospital clinics for the treatment of syphilis, and personnel for epidemiologic work are employed.

The figures given in the tabulation of bureau personnel and services denote progress.

Bureau Personnel and Services

	Oct 1, 1935	Dec 31, 1936
Civil Service	66	144
WPA	20	145
Number of clinics	8	16
Number of sessions	49	96

During the year 1935, 13,711 individual patients were given treatments in our clinics. During the year 1936 the number was 19,808, an increase of 44 per cent. During the same period there was an increase of 41 per cent in the number of cases of syphilis and of 25 per cent in the number of cases of gonorrhea under treatment by all sources in New York City.

The number of reported cases of syphilis has increased 50 per cent from 42,315 in 1932 to 67,010 in 1936. Five years ago the health department was responsible for only a comparatively small percentage of the total number of cases discovered, in the period 1932-1936, department clinics have increased their case finding by 260 per cent. It is significant to note in this connection that the total number of individuals under treatment for syphilis in department clinics has increased by only 82 per cent within approximately the same period. Two simultaneous successes in department procedure have thus been scored: first, great increase in case finding; second, disposal of the majority of these cases to private physicians and nondepartment clinics.

Without expecting miracles, but anticipating that the changes will be indicated as we progress, we believe

that a start in the right direction has been made and that with the cooperation of our colleagues in private practice and in hospitals we shall, if we persevere, see a radical reduction in the prevalence of syphilis and in the disasters which it causes

50 West Fiftieth Street

ABSTRACT OF DISCUSSION

DR CHARLES C DENNIE, Kansas City, Mo. Most of us are syphilis minded and therefore we do not stress enough the control of gonorrhea, a disease that is not as severe as syphilis but is more widespread. Our main aim is to make it unnecessary to treat those diseases by preventing them in the first place. It was my privilege to be the chief medical officer at one of the great camps in France, Camp Jenicart at Bordeaux, where we examined between 200,000 and 300,000 men on their return from France to the United States. We had efficient medical officers and were equipped completely with laboratories. We found 0.46 per cent of venereal diseases, in which 0.24 per cent was syphilis. This was entirely due to the thorough prophylactic methods carried out under the direction of General John J. Pershing. Dr William L. McBride classified the 400,000 prophylactic records in Fort Reilly and found that if prophylaxis was used within six hours, less than 1 per cent of the soldiers contracted venereal disease. Prophylactic methods protect not only against syphilis but also against gonorrhea, and these procedures are simple. How are we to carry out these procedures? If you accept the camel of contraceptive measures, please accept the little needle's eye of prophylactic measures and allow yourself to become more socially minded on this subject. Even doctors do not know these prophylactic measures, but the public must know them. They do not come to the doctor's office for prophylaxis but city health officers can carry out this program. If there is a clinic for contraceptive measures, why can't there be a station for prophylactic measures in which the public can apply for the valuable deterrent to venereal diseases? That idea as it goes along becomes less of a factor of prudery and more of a factor of common sense.

DR CARL A. WILZBACH, Cincinnati. The control of syphilis is in the hands of organized medicine, from the U. S. Public Health Service down to local boards of health, with organized medicine and the public official agencies as the chief persons concerned. There is, of course, a lay possibility for public education which might be done by a third organization, such as the American Social Hygiene Association and some of its component bodies. In a discussion of the public education aspects of this problem by Drs. Parran, Vonderlehr and W. W. Bauer, whole-page newspaper publicity, magazine articles and a great campaign for industry on educational lines were considered. The public is greatly interested and the problem which I think we have is to guard against this campaign's failing and dying out. It is interesting to know that in many localities there are lay groups of people much interested in the problem. I know of three separate groups in the country now attempting to start national organizations to combat syphilis. All these agencies, unless definitely tied up with organized medicine and with the official health agencies, are going to make for a great deal of confusion. It would seem wise, therefore, to see that these groups be given guidance through the medical profession. We have had efforts to control syphilis in the past and they have died out. We don't want that to happen again, and we do want the control of it kept where it belongs, largely in the hands of the people who know how to deal with it and they are, of course, the health officer, the private physician and organized medicine.

DR HOWARD MORROW, San Francisco. There are a number of important points in programs for the eradication of syphilis, and I have labeled them: 1. Early diagnosis. 2. Follow up of contacts. 3. The reporting of all cases by initials, age and sex, particularly early infections. The cooperation of physicians is most important. 4. Continuous treatment from one and a half to three years. 5. Treatment of pregnant women who have had syphilis, even with negative blood and spinal fluid reactions. 6. Continuation of professional secrecy between physician and patient in compliance with the rules of the state board of health.

DR STANLEY H. OSBORN, Hartford, Conn. I felt that I should report to this section the results of the requirement in Connecticut that all persons applying for a marriage license must have a Wassermann test. The results of this test have shown that approximately 1 per cent of the persons who apply for marriage give a positive reaction and that most of these did not realize that they had syphilis. The state of Connecticut was interested because of the fact that institution costs were going up to a certain degree because of syphilitic children and adults, and innocent progeny were being born with this disease. As a result of that, and because Connecticut is deeply interested in the prevention of syphilis, the marriage test program went through the legislature of the state two years ago. Since that time there have been no administrative difficulties in carrying it out. We have had no brickbats thrown at us, no collective opposition, and there was no attempt to eliminate the bill at the recent session of the general assembly.

DR WALTER CLARKE, New York. As Dr. Dennie states, there is no doubt that prophylaxis ought to have a place in the program against syphilis and gonorrhea, as a matter of fact it is very important because enormous quantities of prophylactics are sold and used. In New York City about a year ago a meeting of all the medical men and women interested in syphilis and gonorrhea was called. The commissioner of health presented to them the problem of prophylaxis, but there was no agreement whatever as to what the department of health should do except that the department should encourage practitioners to advise patients about prophylaxis and be prepared to give prophylactic treatments. That is as far as we could get, but we are not without hope that we may find some method hereafter. I appreciate Dr. Wilzbach's comments. Our educational work aims to do two quite simple things: (1) to prevent syphilis and gonorrhea and (2) to bring the infected persons under medical supervision. And I agree with him that medical guidance for this whole program, whether it is official or voluntary in its backing, is absolutely vital and essential. Dr. Marrow clearly summarized the most important elements in a syphilis program.

A NEW METHOD OF DIAGNOSIS IN BACILLARY DYSENTERY

DANIEL N. SILVERMAN, M.D.

Assistant Professor of Clinical Medicine Tulane University
of Louisiana School of Medicine
NEW ORLEANS

The method described in this paper has its greatest value in the diagnosis of bacillary dysentery, since it greatly enhances the chance of recovering the specific bacillus in culture. Repeated culturing of the dejecta in certain cases of bacillary dysentery prior to the use of this method has resulted negatively so far as growth from the stool of dysentery bacilli is concerned. These cases undoubtedly fall in a group that are chronic, and the causal agents are apparently down deep in the lesions, so that very few escape to the contents of the intestine, too few to be detected by the casual examination of the stool.

According to my experience, the application of the method concerns especially the strain of dysentery bacilli known as the lactose fermenter. This strain was discovered and first described by Duval¹ in 1904.

The bacillus of Duval, which is the lactose fermenter, was isolated and was first identified by me² in 1931 as a cause of endemic and sporadic bacillary dysentery.

From the Departments of Medicine and Bacteriology Tulane University of Louisiana School of Medicine.

Read before the Section on Gastro-Enterology and Proctology at the Eighty-Eighth Annual Session of the American Medical Association Atlantic City, N. J., June 10, 1937.

¹ Duval, C. W. and Schorer, E. H. Bacteriological and Clinical Studies from Rockefeller Institute for Medical Research 1901. Duval, C. W. Another Member of the Dysentery Group. J. A. M. A. 43: 351 (Aug. 6) 1904.

² Silverman, D. N. and Harris, W. H. Unusual and Common Forms of Bacillary Dysentery Observed in the South. T. Am. Gastro-Enterol. A. May 1, 1931.

in the United States. At that time I pointed out that this type of the dysentery bacillus is more prevalent than any other member of the dysentery group. It is encountered far more frequently than the Flexner strain in sporadic cases of bacillary dysentery. Unfortunately, some writers have erroneously referred to Duval's strain as the Sonne bacillus. Sonne³ himself, publishing years after Duval's original discovery, gave the latter credit for the discovery.

Craig⁴ stated, in his review of Topley and Wilson's textbook:

It is also noted that in the discussion of bacillary dysentery no mention is made of the fact that the so called "Sonne's bacillus" was first described by Duval, nor is there mention made of the latter's papers upon this organism. As a matter of fact, the name of this particular dysentery bacillus should be "Duval's bacillus," as Sonne described it after Duval and in his paper credits Duval with its discovery. It is unfortunate that the name "Sonne's bacillus" appears to have become so fixed in the literature that credit cannot be given where it is due, and the name changed to "Duval's bacillus."

METHOD

The stool of the infant commonly shows some one of the acidophilus group as a predominant member of the flora. Apparently, shortly after the regular ingestion of food other than mother's milk, the intestinal flora changes, and in consequence members of the colon group predominate. The stool of children and of adults as well may contain one or more of the strains of the acidophilus bacillus. With special methods and mediums it is then relatively easy to culture the acidophilus from the normal dejecta. In this connection it is to be borne in mind that members of the acidophilus group are not observed ordinarily in the stool of either children or adults in sufficient numbers to alter for any length of time the reaction of the content of the large bowel. It may also be mentioned here that when one definitely alters the reaction by the administration of acidophilus culture the changed reaction persists only as long as the administration. A permanent change in the reaction following even the long administration of acidophilus culture is never obtained.

The main point of the new method of diagnosis is to change the flora from one in which the colon bacillus predominates to one in which the acidophilus is more numerous and at the same time there is a change in the reaction of the content of the large bowel. Both factors, but probably more the change in reaction, make possible the detection in stool cultures of *Bacillus dysenteriae*. Certainly in my cases it was seldom possible, even with repeated plating of the stools, to detect the dysentery bacillus, while after the ingestion of acidophilus culture dysentery bacilli appeared in culture from the stool in large numbers.

The acidophilus culture used in this work is one of milk previously inoculated with a pure culture of *Bacillus acidophilus*. The stock culture is maintained in sterilized cow's skimmed milk and kept active by transferring 15 cc to fresh sterilized milk. The acidophilus milk for administration contains the culture that represents an eighteen hour growth. The amount given to the patient was approximately one quart (liter) every twenty-four hours.

The stool of the patient who received acidophilus milk was examined for the presence of the dysentery bacillus at frequent intervals during the period that acidophilus culture was administered. The dysentery

bacillus usually appeared in the stool about the third week after the institution of the preliminary treatment. How long it persisted after administration of the acidophilus milk culture was discontinued was not determined. It is to be noted here that the patients were clinically regarded as having chronic bacillary dysentery largely on the basis of a positive, or suggestive positive, agglutination reaction and certain clinical symptoms, although repeated examinations of the stools failed to reveal the presence of the dysentery bacillus. Therefore, since administration of the acidophilus milk was followed by positive culture of dysentery bacilli from the stool, one is convinced of the great value that this method has in the positive diagnosis of chronic bacillary dysentery.

TYPE OF CASE

The type of case in which treatment with *Bacillus acidophilus* milk gave positive results for the bacillus of dysentery on culture of the stool was one of chronic, long standing diarrhea. Most of the patients had a history of acute dysentery many years before the examination of this new method. In addition to the diarrhea, certain of the patients presented other conditions known to complicate bacillary dysentery. Among these complications were arthritis, toxic myocarditis and intestinal bleeding. I⁵ have shown these conditions to be expressive of a specific hypersensitiveness to bacterial protein. The patients were allergic to the group of dysentery bacilli. It should be mentioned in this connection that some of these specifically hypersensitive patients gave in addition to a positive agglutination reaction for some strain of the dysentery bacillus a positive intradermal reaction with the dysentery bacterial protein. In desensitizing them I obtained the best results when the desensitizing substance was prepared from the homologous dysentery bacillus isolated from the stool by the method herein reported.

COMMENT

Duval's lactose fermenter seems to give rise to the most chronic form of bacillary dysentery. In many of my cases of years' standing the reaction of the blood is positive and the acidophilus method ultimately yields positive evidence of Duval bacilli in the stool. There are cases in which the reaction of the blood is positive, without true dysenteric symptoms, in which the acidophilus method has given negative stool cultures for any strain of *B. dysenteriae*. Again, according to my experience, in the type of case in which the Duval lactose fermenter is isolated by this method, no other strain of dysentery bacilli is present. This observation is significant in relation to the specific therapy and subsequent cure of the patients. In this connection I should like to point out the importance of isolating the bacilli in culture and preparing an autogenous vaccine for the specific purpose of desensitizing patients that are allergic.

A certain number of patients with bacillary dysentery were for the first time shown to present symptoms attributable to specific hypersensitiveness to bacterial protein. Only the isolation of the offending organism makes possible the preparation of a vaccine for the proper treatment of these patients by desensitization.

The preponderance of dysentery colonies over all others in the dejecta from the patients treated by the acidophilus method is not only interesting but significant. Before the acidophilus treatment, repeated examinations of the stools for dysentery bacilli resulted

negatively, while examination of the stools by the same technic after completion of the acidophilus procedure yielded a high percentage of dysentery colonies and in some instances almost a pure culture.

Until recently, many authorities have held that the Flexner strain of *B. dysenteriae* is the prevailing etiologic factor in sporadic bacillary dysentery.

This theory is undoubtedly explained on the ground that the bacilli isolated from the stools were not examined further than the differentiation from the true Shiga strain, which is done by the fermentation of mannitol. All mannitol fermenters are generally regarded as the Flexner type of bacillus. The agglutination reaction of the patient's blood, even when the Flexner strain is not responsible, is positive, though of course in low dilution. This is because of the biologic relation of all members of the dysentery group. Undoubtedly, in suspected cases of bacillary dysentery in which the agglutination test is made only with the Shiga and Flexner strains and the result is a low positive reaction, not high enough to rule out the ordinary common agglutinations for biologically related species, like the colon bacilli, the infecting bacillus is not one of these strains but some other. In using the agglutination test for diagnosis it is far better to employ a recently isolated culture of dysentery bacilli, preferably that from the suspected case. While it has heretofore been difficult in cases of chronic bacillary dysentery to recover the specific organism from the stool, the acidophilus method greatly facilitates the recovery of the specific causal excitant. With the offending micro-organism freshly isolated, the homologous agglutination is of diagnostic value. This is important because so often there is a poor agglutination reaction with the homologous stock culture. Long cultivation under artificial conditions causes, for some reason not understood, a loss in agglutinating properties. Even with typhoid this is often observed, and it is necessary to pass the bacillus through an animal in order that it may regain its agglutinating properties. A sharp-cut agglutination reaction occurs with the patient's blood when the bacillus used is freshly isolated and is the particular excitant of the disease. In many of the chronic cases of bacillary dysentery there was no reaction to any of the stock cultures or at best a low reaction to one, presumably the specific cause. In these cases, when the fresh isolation could be obtained and used as the agglutinating substance, the reaction was positive in a dilution that left no room for doubt concerning specificity.

I was the first to point out, in 1930, that the lactose-fermenting strain of *B. dysenteriae* causing sporadic dysentery both acute and chronic in the United States is identical with the strain discovered by Duval in 1904, both culturally and serologically.

SUMMARY AND CONCLUSIONS

Sporadic bacillary dysentery in the United States is caused by the lactose fermenter of Duval more often than by any other member of the dysentery group.

The diagnosis of this type of infection is made possible in many instances, especially in the chronic type of case, by the use of the acidophilus method herein reported.

By this new method the specific causal excitant is made possible of detection and isolation from the stool in cases in which the stools previously failed repeatedly to yield a positive culture.

Furthermore, in cases of chronic bacillary dysentery in which the agglutination reaction was only suggestive or was absent with any stock culture of dysentery

bacilli, the agglutination reaction was definitely positive with the dysentery bacillus freshly isolated from the stool in the homologous case.

With the isolation of the specific strain of *B. dysenteriae*, one is in a position to attempt the cure of the case. When there is an allergic state, such as I have shown exists in a certain percentage of the chronic cases of bacillary dysentery, it is necessary first to desensitize with varying dilutions of vaccine made from the homologous isolation. According to my experience it is difficult to treat satisfactorily the allergic patient with chronic bacillary dysentery, either with vaccine or with antidysenteric serum, before desensitization. In fact, the patients were made worse by the ordinary vaccine treatment. Because of the reaction in these refractory cases, I suspected that a state of allergy existed. This state was proved by subsequent investigation.

The recovery of the specific dysentery strain by the acidophilus method has made possible not only the specific diagnosis but, in cases of allergy, the desensitization and the subsequent treatment by immunization.

3503 Prytanja Street

ABSTRACT OF DISCUSSION

DR. JOHN H. MUSSER, New Orleans. This being a new method, I cannot speak from personal experience. I am happy that credit is given to Dr. Duval for the discovery of an organism which is generally known as the Sonne bacillus, for which discovery Dr. Duval has been almost completely forgotten. There are circumstances which make such a thing possible. A man who discovers an organism but whose interest in it slackens or disappears entirely does not deserve as much credit as a man who works vigorously with the method and makes it known to the medical world. Dr. Silverman's method undoubtedly is of considerable value both from a diagnostic and from a therapeutic point of view. Diagnostically it should help in a large group of indefinite diarrheas that are seen in the South, in which the symptoms are highly suggestive of a chronic dysentery and in which it is quite common to have an agglutination reaction which is not diagnostically of significance. There is no doubt whatever that the management of these cases depends on having what might be spoken of as the autogenous organism at hand. The value of this method of desensitization, the value of vaccines in the treatment of dysentery, is enhanced by having an autogenous preparation, and if this method makes this preparation possible, it will be a big step forward in the management and handling of these patients.

DR. JOSEPH FELSEN, New York. Dr. Silverman has made a contribution to the diagnosis of bacillary dysentery. I fully agree with him that Dr. Duval has received too little credit for his work on the late lactose fermenter which he described in 1904. I endeavored to correct this oversight, in a measure, by referring to the so-called Sonne bacillus as the Sonne-Duval organism. During the past five years I have noted a steady increase in the incidence of this type of dysentery in New York City, one outbreak having persisted in a children's hospital for many months. While many of the cases are quite mild, one is occasionally surprised by the severe, fulminating character of the disease even in adults. The disease appears to be adapting itself to a virgin soil. This corresponds, I believe, to Dr. Silverman's experience in New Orleans. It has been my privilege to describe seven new clinical forms of acute bacillary dysentery: asymptomatic, afebrile, constipated, neurotropic, appendicular form with acute distal ileitis, agranulocytoid and pneumonic. From the public health standpoint their recognition is important. From the clinical point of view their diagnosis is essential if we are to understand the pathogenesis of the chronic dysenteries (chronic ulcerative colitis, chronic distal ileitis), for the atypical acute forms are frequently overlooked. It is in the chronic type of dysentery, which follows about 10 per cent of the acute cases, that Dr. Silverman's method may prove most useful. In the chronic phase the recovery of the specific initial infecting organism is often very difficult. My routine procedure has been to examine at least six sigmoidoscopic crypt

aspirations with direct seeding of the material on culture mediums I believe that the old concepts of "colitis" will be radically revised in the light of the recent advances in the study of chronic bacillary dysentery. Repeated and careful bacteriologic studies of crypt material will reveal the true pathogenesis to be bacillary dysentery in a surprising number of cases. I again call attention to "sick carriers," for skilful use of the sigmoidoscope will reveal the presence of organic lesions. Double infections with *Bacillus dysenteriae* and *Endamoeba histolytica* and *Bacillus typhosus* or *paratyphosus* are relatively frequent. The ideal approach to the treatment of chronic ulcerative colitis and chronic distal ileitis is the prevention of bacillary dysentery.

DR. DANIEL NATHAN SILVERMAN, New Orleans. I agree with Dr. Felsen that if the acute cases were recognized there would be less chronic ones to diagnose, but, unfortunately though some of us do see the onset of bacillary dysentery within the first few hours or a day or two, we are unable to stem the tide, and they become chronic in spite of early diagnosis. I am not oblivious of the fact that Dr. Felsen has done an extensive piece of work in dysentery in this part of the world. In answer to his inquiry with reference to the discovery of the lactose fermenter, Duval isolated the organism in culture in epidemic form in children in Philadelphia in 1904, and in a subsequent article in *THE JOURNAL*, in 1904, reported finding the same organism in the adult.

EFFECTIVE CLINICAL DOSAGES OF THEELIN IN OIL

BASED ON A STUDY OF SIXTEEN
CASTRATE WOMEN

AUGUST A. WERNER, M.D., GREY JONES, M.D.
JOHN ROBERTS, M.D., G. O. BROUN, M.D.
CHARLES H. NEILSON, M.D.
AND
NORMAN O. ROTHERMICH, M.D.
ST. LOUIS

Diversity of opinion exists regarding the amount of estrogen necessary to produce the interval phase of the endometrium in castrate women. Some clinical investigators¹ believe that the administration of from 30,000 to 50,000 rat units is needed to obtain this result.

The experiments of Werner and Collier² in which thirteen castrate women were given intramuscular injections of theelin in aqueous solution showed that the growth phase could be produced by much smaller dosages than those just indicated and that approximately 2,800 rat units would initiate endometrial growth.

We believed that it would be of value to repeat this work, especially since theelin in oil was available. An investigation was decided on which included a series of separate experiments to run concurrently.

Among the points of interest to be determined were (1) the dosages of theelin in oil that will relieve symptoms resulting from castration, and the relation of such

relief to certain organic changes, (2) the dosages that will relieve symptoms and not cause uterine bleeding, (3) the differences between effective dosages of theelin in oil and in aqueous solution, and (4) the effects of definite dosages of theelin in oil on the breasts, the visible parts of the genitalia, the endometrium, the vaginal mucosa and the vaginal secretions.

Sixteen castrate women having their uteri intact were assembled, all of whom were castrates of more than six months' duration. Their ages varied from 17 years to 36 years. None of them had had theelin for

TABLE 1—Theelin Dosage in Five Groups of Castrate Women

Group	Number in Group	Theelin Single Dose in International Units	Total Theelin Received During 30 Days in International Units
A	3	500	5 000
B	3	1 000	10 000
C	4	1 500	15 000
D	3	2 000	20 000
E	3	2 500	25 000

at least two years, although five of them had been previously subjected to a course of theelin. Four of them would not permit curettement, and we were of the opinion that the youngest patient in the group should not be curetted.

It was the consensus that the dosages of theelin should be so regulated that the minimum dose should not, or should scarcely, produce endometrial growth, the medium dose should be such as to produce endometrial growth, and the maximum dose should be sufficient to produce bleeding or pseudomenstruation.

As a check on the dosages, intermediate dosages were given to a group of women between A and C and to another group between C and E (table 1).

Accordingly, they were arranged into five groups as shown in table 1.

METHODS

1 An individual study of the subjective symptoms of each subject by three members of the group.

2 Physical examination of the sex-related structures and curettement. On this occasion a specimen of vaginal tissue was secured for biopsy.

3 A rest period of fully three weeks for each curetted patient, during which time the patients received intramuscular injections of physiologic solution of sodium chloride every third day. Vaginal smears were taken at the time of each injection.

4 A second check on the subjective symptoms at the end of the three weeks rest period.

5 Theelin administration. Each patient received intramuscular injections of dosages as indicated in table 1 every third day until ten injections were given. Vaginal smears were taken at the time of each treatment.

6 Making of final curettement and obtaining of a chip of vaginal tissue four days after the last administration. At this time a vaginal smear also was taken.

7 A final study of symptoms. At no time during the experiment did any physician know what information the others had obtained.

RESULTS

Effect of Theelin on Subjective Symptoms—The evaluation of drugs and chemical substances used for therapeutic or experimental purposes on the human subject is always difficult. This evaluation must consist first of the change in the subjective symptoms of the patient. There are so many factors entering into sub-

jective symptoms and their determination that the value of these symptoms may not be safe for scientific conclusion

In this set of experiments the symptoms of the patients before the use of theelin and the subsequent effect of theelin are modified by (1) the fact that these patients knew they were the subjects of an experiment, (2) their evident desire for relief of their symptoms, (3) the fact that some of the patients had had injections before with relief of their symptoms, and (4) outside influences which aggravate the symptoms because of absence of estrogen

In taking the history of these sixteen women every effort was made to make the history as impersonal as possible. The women told their stories in their own way without leading questions. The history of these patients before any medication was given showed that all had practically the same symptoms, such as subjective nervousness, hot flashes, melancholia, irritability, excitability, basal headaches, numbness and tingling, dizziness, lassitude and fatigability, insomnia, loss of sexual desire, and dryness of the vagina

The history taken at the end of the control period showed the following facts

Subject 1 felt better but was still nervous

Subject 7 felt considerably better but still had depression

The other thirteen girls felt no change in their symptoms. Some of them reported that they felt worse

At the end of the theelin experiment all the patients were greatly improved. Many were entirely relieved of their symptoms. The changes produced were as follows

1 Nervousness, hot flashes, headaches, insomnia, numbness and tingling were practically gone

2 Depression and crying spells had all disappeared

3 In the main, energy, ambition and sexual desire had returned

4 A striking change in their symptoms consisted of a decreased dryness in the vagina with a normal mucous discharge

5 The married patients stated that the sexual life became quite normal and natural

All were aware of an increase in the size of the breasts and most of them noticed tingling and drawing sensations in the breasts and an increased sensitiveness of the nipples. All the women had a sensation of pelvic fullness, bearing down, needling pains and uterine cramps, accompanied by a feeling that they might menstruate. However, none of them had uterine bleeding during the injection period

The effect of theelin as used in these tests was pronounced. The effect of the size of the dose was not definitely and clearly worked out by this history, the smaller doses seemed as effective as the larger doses. The patients all stated that the disappearance of the symptoms came on gradually

Effect of Theelin on Gynecologic Features—Before Injections. All patients examined before treatment exhibited practically the same gross physical manifestations. The breasts were atrophic and flaccid and the nipples were small and nonerectile when mechanically stimulated. The external genitalia were considerably smaller than normal, the labia majora showed a loss of subcutaneous fat, the mucosae of the vestibula were dry and thin and a whitish yellow. The internal genitalia were considerably decreased in size, the vaginas were small and smooth and slightly sensitive to touch, the cervixes were small and hard, the uteri were

small, hard and retroverted, and their average dimensions were about $1\frac{1}{2}$ by 1 by 1 inches (37 by 25 by 25 cm). Speculum examination in each case revealed a small cervix with a pinpoint external os, the vaginal secretion was scanty in amount and the vaginal walls were thin and smooth and a light yellow

After the examination a piece of endometrium was removed by a small curet without anesthesia, and a piece of vaginal mucosa was removed from the posterior wall at a point 1 inch above the introitus. This was done after an infiltration of the part with procaine hydrochloride solution

After Theelin Treatment. The gross changes on examination were essentially the same in every patient. The breasts were definitely enlarged and the nipples erectile, the external genitalia were enlarged and appeared normal, the vulvar mucosa was moist and pink. The internal genitalia were all enlarged. In each patient the vagina seemed larger, the walls were soft and slightly irregular, the cervix was enlarged and soft in consistency, the corpus uteri was considerably larger than on previous examination. Some of the uteri were as large as 3 by 2 by $1\frac{1}{2}$ inches (76 by 51 by 37 cm) and were soft

Speculum examination showed a great increase in the vaginal secretion, the cervix was enlarged and the external os was patulous. The vaginal mucosa seemed thicker and it exhibited the usual pink coloration that one finds in noncastrated women who are examined before the menopause

After the examination another piece of uterine and vaginal mucosa was removed for biopsy. During the completion of this procedure, it was noticed that the cervical canal was larger and that the vaginal and uterine mucosae were thicker and more vascular than they had been before the injections of theelin

HISTOLOGIC REPORT

Gross Appearance of Tissues—Gross material was obtained for study from subjects 1, 2, 4, 5, 6, 9, 10, 11, 12, 14 and 16. Subjects 3, 7, 8, 13 and 15 employed in the experiment were not operated on for reasons given elsewhere. The biopsy material was in the form of uterine curettings and small bits of vaginal wall. Tissues from each of the women were obtained both before and after the administration of the drug. The uterine curettings were exceedingly scanty and small at the close of the experiment. The snips of vaginal wall showed no macroscopic changes that could be observed

All tissues were subjected to 10 per cent solution of formaldehyde for a period of twenty-four hours. An autotechnician was then employed for all solutions previous to embedding in order to eliminate, so far as possible, time factor variables. All were cut on the same rotary microtome at 5 microns and all were stained with hematoxylin and eosin, the pretheelin at one sitting and the post-theelin at another

Uterine Scrapings—Before Treatment. The microscopic examination of the scrapings removed before therapy revealed the picture of atrophy such as is seen in the castrate. For the most part the tissues consisted of short lengths of columnar or cuboid epithelium. Attached to these was little or no endometrial stroma. The cells of the superficial part of the mucosa were small, both nuclei and cytoplasm. The nuclei contained less chromatin than usual and the cytoplasm was clear. In most cases the nuclei were at about the midpoint in the cells. Generally this part of the mucosa had the appearance of an atrophic and inactive type of secretory epithelium

Case 9 presented changes not in accord with the others. This case gave the appearance of an abundance of endometrial stroma. However, the looseness due to edema and leukocytic infiltration spoke for an inflammatory reaction, probably due to infection.

In no case was there any hyperplasia of the administration of theelin in previous experiments.

After Treatment The microscopic preparations of curettings after theelin therapy were much larger and were composed of both surface epithelium and stroma. Generally the surface epithelium, instead of being arranged in rather straight lines as in the castrate atrophy, showed many invaginations as if forming glands. The glands were rather simple and their lumens contained no papillary projections. The epithelial cells were tall, being approximately three times the height of those in the untreated castrate. There was a proportional increase in both nuclei and cytoplasm. The nuclei were dark and practically always in a basal position. This with a granularity of cytoplasm spoke for secretory activity. The endometrial stroma was abundant and compact in most cases. Definite glands were present in most endometria. The formation of mucus was marked in the cases in which larger dosages were given (cases 9, 10, 11, 14 and 16). Case 12 had to be eliminated, since only cervical material was obtained on the final curettement. In case 9 all evidence of previous inflammation disappeared. The changes in the endometria in this experiment, both of castrate atrophy and of hyperplasia, following theelin administration, were in accord with the observations of Werner and Collier in previous experiments. Larger dosages however, were employed in their work.

Vaginal Wall—Before Treatment The pieces of vaginal wall removed at the start of the experiment, like the endometria, presented stratified squamous epithelium which suggested atrophy. The germinal cells of the basal zone were scanty and very small and their nuclei were quite pale. The remainder of the cells of this zone were widely spaced, and noticeably vacuolated and a large number contained no nuclei. The intra-epithelial zone of cornification was either entirely wanting (cases 5, 6, 11) or was almost negligible (cases 1, 2, 4, 9, 10, 12, 14, 16). When present, it lacked compactness and was frayed and its fine strands were widely separated. The superficial zone, being particularly subject to loss (probably mechanical) was wanting in a few cases, both before and after the administration of theelin. When present, its cells were reduced in number, were often nonnucleated and contained few cytoplasmic structures.

After Treatment The sections of vaginal wall after treatment with theelin revealed a very striking increase in total thickness of the stratified squamous epithelium. This appeared to be due to an active growth. Not only was the basal layer more cellular but the cells were actually larger. The cells of the germinal layer showed a proportional increase in both cytoplasm and nuclei. The nuclei were particularly deep staining owing to an increased chromatin content. The upper cells of the basal zone were much less vacuolated. This basal cell zone growth corresponds to that seen in the premenstrual phase as recently described by Traut, Bloch and Kuder.³ The intra-epithelial zone of cornification was present in practically all cases. Its width was probably not increased but its substance

was much more compact and more deeply staining. None of the frayed and separated appearance of the untreated castrate was found. The superficial zone of the stratified squamous epithelium was variable in thickness probably because of mechanical defects. The sections suggested some slight increase in width. The cells were broader and contained more cytoplasmic substance, and a much greater number were nonnucleated.

The subepithelial connective tissues were very vascular and leukocytic laden and penetrated deeply as papillae into the squamous epithelium.

VAGINAL SMEAR EXAMINATION

The study of the changes induced in the vaginal smears of castrate rats and mice as introduced by Allen and Doisy has been of fundamental importance in the biologic standardization of estrogens. Recently, largely through the work of Papanicolaou,⁴ the study of human vaginal smears has been suggested as a method of studying the cyclic changes associated with menstruation and the effects of treatment with estrogenic mate-

Fig. 1.—Uterine scraping of human female castrate 2 before beginning of the experiment.

rials. It therefore seemed advisable to make use of vaginal smears to determine the presence or absence of changes in the vaginal secretions following the dosages of estrogen that were employed in the present study. It should be stressed at the outset that we were seeking doses which would be effective in relieving symptoms and desired, if possible, to avoid excessive stimulation of growth in the structures of the genital tract. At the same time we were interested in the presence and extent of such changes as would occur in the various doses given.

Two of us have familiarized ourselves with the vaginal smear technique of Papanicolaou and have employed it throughout this study. We have studied a number of normal females and are able to confirm in general the cyclic changes that Papanicolaou observed in the human vaginal smear during the menstrual cycle.

4 Papanicolaou G N. The Sexual Cycle in the Human Female as Revealed by Vaginal Smears. *Am J Anat (supp)* 52: 519 (May) 1933. The Existence of a Postmenopausal Sexual Rhythm in Women as Indicated by the Study of Vaginal Smears. New York: Department of Anatomy, Cornell University Medical College. Papanicolaou G N and Shorr Ephraim. Action of Ovarian Follicular Hormone in Ovarian Insufficiency in Women as Indicated by Vaginal Smears. *Proc Soc Exper Biol & Med* 32: 585 (Jan) 1935. *Am J Obst & Gynec* 31: 806 (May) 1936.

The general plan of the study has already been described. The vaginal smears were collected daily in cases 1, 8 and 14. In all other cases smears were taken every third day. During the periods of theelin administration the smears were taken on the day on which theelin was administered. Since injections were given to each patient every third day in these sixteen cases, the smears represent the condition of the vaginal secretions three days after the previous administration of theelin. Material from the three weeks control period was available in each case for comparison with the smears of the treatment period. Usually at least one smear was available after the cessation of treatment.

The appearance of the vaginal smear of menopausal and untreated castrate patients according to Papanicolaou, while somewhat variable, is characterized in general by leukocytosis, prevalence of epithelial cells with large nuclei ordinarily found in the deeper layers of the vaginal epithelium, considerable mucus and a rich

Fig. 2.—Uterine scraping of castrate 2 at close of experiment after injection of 5,000 international units of theelin in oil.

bacterial flora. Some smears of castrate cases, however, show leukopenia, but the picture otherwise remains the same.

The changes observed in the castrate smear during treatment are as follows:

- (a) The number of leukocytes is decreased.
- (b) The number of epithelial cells characteristic of the deeper layers of the normal vaginal epithelium is decreased. These cells are rather small in size and have relatively large nuclei. Conversely, there is an increase in the number of large flat cornified epithelial cells with pyknotic nuclei.
- (c) The number of clumps or masses of epithelial cells is decreased, i. e., in the fully treated cases the cornified epithelial cells appear separate and discrete from one another. It is important to note, however, that during the earlier stages of treatment—a stage which Papanicolaou considers “inadequate treatment”—there may be a temporary increase in the masses and clumps of desquamated epithelium.
- (d) During the “early and inadequate” stages of treatment, Papanicolaou describes the mucus as increased and thick and viscid. When the full follicular phase is attained, the mucus is thin and clear.

(e) Bacterial flora, which is rich as a rule in the castrate smear, continues to be abundant during the “early and inadequate” stages of treatment but becomes scanty as the typical follicular phase is reached.

By the use of large doses of estrogenic material Papanicolaou produced a picture similar to that seen in the follicular phase of the menstrual cycle. Its characteristics are leukopenia and the presence of large flat, discrete, epithelial cells, largely cornified, with small pyknotic nuclei. Mucus, if present, is usually thin and does not enmesh the cells in huge masses. The bacterial flora becomes scanty so that the smear has a “clean” appearance in contrast to the “dirty” appearance of the castrate smear.

A full report of our studies of vaginal smears will appear elsewhere. The results may be summarized as follows. The subjects who received 5,000 international units during the treatment period showed no definite effect in the vaginal smears. The subjects receiving 10,000 international units showed a possible slight effect in two cases and no effect in one case. Of the four subjects receiving 15,000 international units, no effect was seen in one, a slight effect was seen in one and rather definite effects were seen in two. In the group receiving 20,000 international units some effect was seen in all three subjects, but it was well marked in only one. The group who received the highest dosage, namely, 25,000 international units, showed a rather definite effect in two cases and a slight effect in the third.

Our observations are confirmatory of those of Papanicolaou as regards the appearance of the untreated castrate smear. The types of changes noted as a result of theelin treatment are in general similar to those he described, namely, production of leukopenia in cases presenting an originally purulent smear, increased number of cells with pyknotic nuclei and increased secretion of mucus with a tendency to formation of clumps and masses of epithelial cells. The last he finds in women given doses of estrogen of somewhat similar magnitude to those we have used. We did not in any case produce what Papanicolaou has described as the full follicular stage in the vaginal smear. In order to produce this type of vaginal smear in castrates and women in the menopause, Papanicolaou made use of much larger dosages of estrogenic material than were given in any cases in this series. He stated that the daily dose required to produce this type of smear varied from 250 to 3,000 rat units. Our largest dosage was 2,500 international units every third day.

It is quite evident from the present study that changes in the vaginal secretion are a much less delicate index of the effectiveness of estrogenic material than is an examination of the uterine mucosa secured by curettage. In the smallest dosages employed the changes in the uterine mucosa were definite and striking. It is also quite obvious that symptomatic relief can be secured in dosages that are too small to produce definite changes in the vaginal secretion, since the group of subjects receiving the smallest dosage apparently secured as much relief of symptoms as those who received larger doses.

In view of these facts we feel that the question may legitimately be raised whether the objective of theelin medication in castrate and menopausal cases should be directed toward relief of symptoms or should be pushed to the point of restoration of the vaginal smear to the full follicular phase of the menstrual cycle as suggested by Papanicolaou. The possibility that over-

stimulation of the lining membrane of the genital tract by estrogen may possibly lead to the production of neoplasms has never been entirely eliminated. Papanicolaou himself states that large doses of estrogenic material continued over a long period of time are likely to give rise to profuse and debilitating bleeding when treatment is discontinued.

COMMENT

In this discussion the points of interest, as stated before, will be considered in order, the first being the dosage of theelin in oil that will relieve symptoms resulting from castration and the relation of such relief to certain organic changes.

Relief from the subjective symptoms of castration was had by all patients. However, it must not be supposed by any one that the authors of this paper consider that ten injections of theelin in the strengths used is adequate treatment. Castrates and many menopausal women will need repeated intervals of injections until they finally attain the endocrine adjustment characteristic of the postmenopausal period.

This experiment was conceived with the idea that the large dosages of estrogen advocated for treatment of various disturbances related to the sex life in women are unnecessary to attain the desired result. Its completion indicates that, in castrates, comparatively small dosages of theelin will relieve the symptoms that accompany absence of the ovaries. The factor of time or duration of treatment must always be considered.

The second point of interest was the dosages of theelin that will relieve symptoms and not cause uterine bleeding.

Proposition 2 and the last part of proposition 1 are interrelated and will be discussed together. It was our hope that we could find a dosage of theelin that would

were not curetted had uterine bleeding. Patient 13 began to bleed six days after cessation of the injections and bled for three days, and patient 15 began to bleed four days after and bled for one day. This is definite evidence that 20,000 and 25,000 international units of theelin in oil will cause uterine bleeding in the castrate woman, while dosages as low as 5,000 international units produce bleeding in castrate women who have been curetted. It is very doubtful that the curettements in the other patients influenced the uterine bleeding, for it did not begin until the fifth day in case 2, the sixth day in cases 1 and 4, the seventh day in cases 5, 6 and 11, the eighth day in cases 12 and 14, and the tenth day in case 16.

The third point of interest was the differences in effective dosages of theelin in oil as compared with those of theelin in aqueous solution, based on the previous experiments by Werner and Collier, in which they found that appreciable endometrial growth (not

Fig 3—Vaginal wall of castrate 2 before experiment

TABLE 2—Observations on Sixteen Castrate Patients During Experiment

Patient	Total Theelin Dosage in International Units	Uterine Bleeding
1	5 000	6 days after for 7 days
2	5 000	5 days after for 3 days
3	5 000	No
4	10 000	6 days after for 3 days
5	10 000	7 days after for 3 days
6	10 000	7 days after for 4 days
7	15 000	No
8	15 000	No
9	15 000	No
10	15 000	No
11	20 000	7 days after for 5 days
12	20 000	8 days after for 2 days
13	20 000	6 days after for 3 days
14	20 000	8 days after for 3 days
15	20 000	4 days after for 1 day
16	25 000	10 days after for 3 days

* 1 cc of physiologic solution of sodium chloride was injected intramuscularly every third day for three weeks followed by injection of theelin in oil every third day for ten injections. Patients thought that they were receiving theelin throughout the experiment. No patient had uterine bleeding, until after cessation of the injections of theelin and this bleeding was accompanied by the subjective symptoms that they experienced during normal menstruation before castration. Patients 13 and 15 who had uterine bleeding were not curetted. The five who did not have uterine bleeding felt that they might bleed for a period of about five to eight days after cessation of injections. No one experienced irritation or induration from theelin.

relieve the subjective symptoms of these patients and yet be sufficiently small not to cause endometrial growth and uterine bleeding. Reference to table 2 shows that eleven of the castrates had visible uterine bleeding after cessation of the injections of theelin. It was a bit surprising that none of the four women in the third or middle group bled while those above (except patient 3) and below did. A point of special interest is the fact that two women (patients 13 and 15) who

the complete growth phase) could be produced by approximately 2,800 rat units (about 14,000 international units) of theelin in aqueous solution, when administered over periods of from two to eight weeks.

In this experiment approximately the midinterval phase of the endometrium was produced by even the smallest dosage given, i e, 5,000 international units of theelin in oil.

When endometrial growth is used as the criterion to differentiate the effectiveness between theelin in aqueous solution and theelin in oil, it is seen that theelin in oil is much more effective, producing more rapid and greater growth when given in smaller amounts. The reason for the increased effectiveness of theelin in oil is perhaps the prolonged absorption rate of the oil solution as compared to that of the aqueous solution, with a more constant stimulative effect. Again, because of the rapid absorption of the aqueous solution, more of the theelin may be lost by excretion.

It will be recognized that the production of endometrial growth in castrate women and in women having primary amenorrhea are two separate and distinct problems. In castrate women the ovaries are absent but the endometrium is receptive to estrogenic stimulation. In primary amenorrhea, two biologic problems are conceivable: first, that in which the ovaries fail

to secrete a sufficient amount of estrogen to produce genital development and endometrial growth, and, second, that in which the ovaries, based on blood estrogen determinations, are apparently functioning normally, but owing to some inherent defect in the müllerian duct system normal estrogenic stimulation does not produce uterine growth and bleeding. It is in the last condition that large dosages of estrogen are necessary

Fig. 4—Vaginal wall of castrate 2 after injection of 5,000 international units of theelin in oil

The fourth question to be answered was the effect of different dosages of theelin in oil on the breasts, on the visible parts of the genitalia, on the endometrium, on the vaginal mucosa and on the vaginal secretions.

This question has been answered under the gynecologic report. The effect of theelin in oil on the endometrium and vaginal mucosa is shown in the accompanying illustrations and is described in the report on the histologic and vaginal smear examinations.

CONCLUSIONS

1 Theelin in oil stimulates development of the sex-related structures of the human female, producing changes in the breasts, gross appearance of the vagina, with increased mucous secretion, and growth of the endometrium and vaginal mucosa in dosages as low as 5,000 international units.

2 Definite changes in the vaginal smears were noted with dosages of theelin in oil as low as 10,000 international units. Vaginal smears would appear to be a less delicate index of theelin administration than uterine mucosal specimens. Relief of symptoms of castration was obtained with dosages as low as 5,000 international units, which is insufficient to produce the full follicular phase in the vaginal smears.

3 This experiment proves that dosages of 5,000 international units of theelin in oil when the element of time is considered, will mitigate or relieve the symptoms of castration but at the same time will stimulate development of the endometrium sufficiently to cause uterine bleeding when discontinued.

4 Theelin in oil is much more effective than theelin in aqueous solution. When administered intramuscularly in the human being smaller dosages and less frequent intervals of injection produce more rapid and more marked effect on the endometrium and vaginal mucosa.

5 The evidence seems conclusive that the large dosages of theelin advocated by some (from 30,000 to 50,000 rat units) as necessary to produce the interval phase of the endometrium are grossly excessive.

A TREATMENT FOR SUBLUXATION OF THE TEMPOROMANDIBULAR JOINT

LOUIS W. SCHULTZ, D.D.S., M.D.

CHICAGO

Subluxation of the temporomandibular joint is fairly frequent. Its causes include congenital weakness of the capsule or malformation of the condyles or both. The joint may be strained or injured during general anesthesia, yawning, attempts by children to insert large objects into the mouth, and positional pressures during sleep.

Heretofore the usual treatment has been merely rest. To safeguard a subluxating joint from undue motion for one whole year by bandaging is obviously impos-

Fig. 1—Section of subcutaneous tissue of dog three days after the injection of sodium psyllate showing the subacute reaction with infiltration of lymphocytes.

sible. Surgical treatment has been attempted with some success by the use of mattress sutures inserted laterally through the capsular ligament or by the removal of the

Prof. Otto F. Kampmeier, head of the department of anatomy in the University of Illinois College of Medicine, placed the facilities of his laboratory at the author's disposal, and Walter Shriner, M.S., M.D., and a medical student abstracted the bibliography and helped in the animal experiments.

meniscus Physical therapy has been employed Orthodontic appliances and prosthetic devices, pressure pads in front of the ears held in place for several months by a steel spring passing over the calvarium, wiring the jaws in occlusion and bandaging the jaws for months at a time—all these have been tried and found only partially successful Changing the bite has been and is practiced with some success when that is the cause

Fig 2—More highly magnified section of subcutaneous tissue of dog three days after the injection of sodium psylliate showing the transition of lymphocytes (?) into fibroblasts

I have developed a simple method of shortening and strengthening the capsule of the joint by injection Fibrogenesis in the capsule of the joint is the result to be attained

Pendse and Dutt¹ of India carried out extensive investigations with regard to the chemistry of the seed of psyllium or *Plantago ovata* They found that the seed has a large content of mucilage but does not contain any alkaloids or glucosides

ANIMAL EXPERIMENTATION

In view of Rice's² results with various sclerosing solutions, I decided to test some of the reagents, among them sodium psylliate,³ on the temporomandibular joint Sodium morrhuate, thuja solution and Mayer's solution were some of the other substances tried I shall present only the results obtained with sodium psylliate and the technique of employing it

The agent used must not be injurious to the joint or surrounding tissues, the therapeutic response should be painless, the solution should not be injurious if by

chance it enters the veins, the degree of fibrogenesis should be controllable and no untoward systemic reaction should follow

Considerable experimentation was necessary to find the most effective fibrogenic agent Figure 1 shows the subacute reaction in normal subcutaneous tissue three days after the injection of sodium psylliate Figure 2 portrays a more highly magnified section of such tissue illustrating more particularly the transformation of lymphocytes into fibroblasts

A series of from eight to ten injections per dog made every two weeks showed all joints in perfect functional and anatomic condition at autopsies made at biweekly intervals on this series of dogs Cartilage surfaces were smooth and glistening, as was the synovial membrane (fig 3)

In all injected joints the capsules averaged from 5 to 7 mm more in thickness than in the control specimens

Twelve dogs were given injections of from 1 to 2 cc of sodium psylliate into the temporomandibular joints at biweekly intervals for three months Under deep anesthesia the opening between the incisor teeth was measured on each occasion A loss of from 3 to 5 per cent of the original opening was noted Autopsy revealed normal joint cavities with a firm, fibrous capsule in all dogs

Fig 3—Section of synovial membrane of dog fourteen days after the last of eight injections of 1 cc of sodium psylliate at biweekly intervals it shows no evidence of a destructive process

Results of other experiments are as follows

1 Subcutaneous injections (from 5 to 20 cc) were made In from two to three weeks large areas of firm fibrosis resulted, with no discomfort and with no sloughing

2 From 1 to 2 cc of sodium psylliate injected into firmly healed, abdominal scars caused a small area of necrosis

² Rice C O Injection Treatment of Hernia Philadelphia F A Davis Company 1937

³ Furnished by the courtesy of G D Searle & Co

3 Injections of from 1 to 2 cc of sodium psyllate into the mental and infra-orbital foramina produced no effect. Motor nerves were tested with a similar absence of effect.

4 Injections of from 60 to 120 cc into the peritoneal cavity produced no effect either immediately or subsequently, as proved at autopsy from one-half to three months later.

Fig 4—Technic of injection of temporomandibular joint

5 Introduction of this agent into normal pleural cavities showed no gross effect on the pleura or lung at autopsy.

6 Five cc put into the gallbladder produced a firm generalized fibrous sheet over the immediately adjacent liver and over the biliary apparatus but had no other effect. The amount of fibrous tissue varied considerably in these dogs.

7 From 30 to 60 cc injected directly into the left ventricle of the heart on three successive days and at weekly intervals revealed no effect either immediately or at autopsy.

8 Scarifying and coating with sodium psyllate of stomach, intestine and liver and introduction of about 30 cc of the solution into the peritoneal cavity produced no adhesions in from two weeks to two months, as shown at autopsy.

Many hundred celloidin sections of the tissues subjected to the action of sodium psyllate were made and examined, all of which showed fibrogenesis, as indicated in the foregoing narrative.

In brief, the animal experiments demonstrated that

- 1 There was no alteration of the joint cavity, the fibrosis occurring in the ligaments.

- 2 There were no gross changes in the ligaments other than their thickening, and hence the strengthening of the chief factors that hold the joint within its cavity.

- 3 Subacute reaction followed thirty minutes after the injection of sodium psyllate.

- 4 There was infiltration of leukocytes at this time.

- 5 Two or three hours later a lymphocytic infiltration starts.

- 6 Fibrosis of this tissue starts in from four to six days.

- 7 Injections into the joint cavity caused some discomfort.

- 8 Large doses injected directly into the blood stream were followed by no symptoms.

- 9 Injections into the heart produced no recognizable effects.

- 10 No infection followed the treatment.

CLINICAL APPLICATION

The harmlessness of treatment with sodium psyllate and the quick results obtained convinced me that it was the agent of choice for my purpose.

Injection is made only after a complete history is obtained, including examination of the joint, the external auditory meatus, the drum head and the occlusion of the teeth. If indicated, the procedure is as follows: The ball of the index finger is placed in front of the tragus, and the patient opens the mouth wide enough to cause the head of the condyle to sublaxate, "click," or produce abnormal movement of the fibrocartilaginous disk. The needle is inserted into the joint cavity (fig 4) and from 0.25 to 0.5 cc of the solution is deposited inside the joint cavity. The injections are repeated weekly or biweekly on both joints until a sufficient

Fig 5—Above patient before injection. Note great protrusion of condyles. Below one week after the first injection of sodium psyllate. Both condyles are in position.

fibrosis is obtained. This occurs usually in from three to five weeks. The injections, therefore, number from three to four at the intervals stated.

The technic of injection should not produce more disturbance than the prick of the needle and a slight feeling of fullness at the time of the injection. Pain usually follows twenty or thirty minutes later, at which

time the patient may be given a sedative, or an anodyne may be applied to the parts involved

Since the area to be treated contains many important structures, such as the internal maxillary and internal carotid arteries, the middle and internal ear, the brain, the parotid gland and the facial nerve, the course of injection should proceed with due caution

During the past year I have treated more than thirty patients afflicted with temporomandibular subluxation by the method described, with results that approach entire satisfaction. Figure 5 illustrates the condition presented in one of these patients and the results attained

It appears logical to assume that the principle herein described, namely, thickening and shortening of the joint capsule by injection of a fibrosing agent, might be applied therapeutically to other joints. It is probable that the lesions of other joints most apt to be amenable to this form of treatment would likewise be subluxation or partial dislocation although it is barely possible that even recurring complete dislocations might respond favorably, particularly if numerous injections were performed

CONCLUSIONS

- 1 Stabilization of joints by injection therapy is successful
 - 2 Sodium psyllate is a dependable fibrosing agent
 - 3 Sodium psyllate is noninjurious to tissues generally
 - 4 In experienced hands it is relatively harmless, and office therapy is possible
 - 5 It produces no apparent systemic disturbances even when injected intravenously into animals
 - 6 The fibrosis obtained by the injection of the temporomandibular joint for subluxation persists long enough to restore the joint to normal function
 - 7 The method of treatment comes within the scope of the general practitioner

Clinical Notes, Suggestions and New Instruments

PURPURIC AND SCARLATINIFORM ERUPTION FOLLOWING SULFANILAMIDE

IRVING L. SCHONBERG, M.D., CLEVELAND

Since the advent of sulfanilamide as a therapeutic agent there will no doubt be many reports concerning reactions. The following is of clinical interest because of the fact that a toxic purpura first developed, which appeared following the use of sulfanilamide and recurred one month later as a scarlatiniform eruption as a result of a smaller dose of the same medication

REPORT OF CASE

A G, a Jewish woman aged 21, presented an erysipeloid dermatitis involving the vulva and extending to the adjacent surface of the thighs and also into the left inguinal area. The vulva presented a marked edema, considerable erythema and some vesiculation. The skin was infiltrated and tender and there was increased local temperature. The edema was non-pitting. The areas were sharply demarcated and slightly raised above the adjacent skin. The temperature was slightly elevated (100 F). An acute adenitis developed and it was necessary to incise the inguinal gland. Cultures were made from a thin serosanguineous fluid which exuded from the sinus and streptococci of the hemolytic type were found. The local treatment consisted of wet dressings of 1 per cent zinc sulfate-copper

sulfate solution. The inguinal sinus was douched with 1 per cent gentian violet solution. Drainage persisted for some time and the sinus failed to heal. There were recurrent attacks of edema and erythema of the vulva.

In view of the fact that streptococci were found on culture, it was deemed advisable to administer sulfanilamide. The usual dose of four 5 grain (0.3 Gm.) tablets every six hours was administered the first day and two tablets every six hours on subsequent days. On the fourth day an eruption developed over the entire body which was at first composed of erythematous wheals and macules. The temperature rose to 104 F. The drug was discontinued but the eruption progressed. Finally the urticaria disappeared and the patient presented a generalized purpuric rash composed of purplish macules that did not fade on pressure. Supportive treatment eliminated the purpuric eruption within a few weeks. The sinus healed and the edema and erythema of the vulva subsided completely.

Purpuric eruption on right forearm after administration of sulfanilamide

One month later an edema of the vulva again developed, which, although not as marked as the original condition, was similar in appearance. At this time there was a right inguinal adenitis. One 5 grain tablet of sulfanilamide was administered and four hours later a generalized scarlatiniform eruption developed. No distinct lesions of any type were present. The patient in addition suffered an acute edema of the eyelids, the lips, the larynx and the forehead, considerable difficulty in breathing, pain in the chest and a temperature again elevated to 104 F. Pruritus over the entire body was intense. Twenty-four hours later the temperature had subsided, the eruption was faint, and breathing was normal.

SUMMARY

This case illustrates that sulfanilamide is another drug which exhibits allergic manifestations. This patient, in whom a purpuric rash first developed following its use, presumably developed a hypersensitivity of her entire organism, so that one 5 grain tablet precipitated marked allergic symptoms. Extreme caution is advisable in resuming the use of the drug following any type of skin eruption. Fortunately the patient did not take more than one 5 grain tablet. A larger dose would probably have provoked a condition of extreme gravity.

Interest in the History of Medicine—Dr. Garrison's position in American medicine is unique. No one prior to his time had stimulated so widespread an interest in the history of medicine or reached into the consulting room and library of every serious student and practitioner in the United States. In the minds of American physicians from 1913 on, Garrison and medical history became synonymous. Garrison's 'Introduction to the History of Medicine' became their chief sourcebook.—Viets H. R. Fielding H. Garrison and His Influence on American Medicine, *Bull. Inst. Hist. Med.* 5:347 (April) 1937.

SULFANILAMIDE A PHOTSENSITIZING AGENT
OF THE SKINBEN A. NEWMAN, M.D. AND HERMAN SHARLIT, M.D.
NEW YORK

In spite of the intensive use of sulfanilamide in the last year as a chemotherapeutic agent in beta-hemolytic streptococcus infections, clinical reports have noted a relatively low incidence of untoward reactions. Our observations of more than 300 patients in the erysipelas wards of Bellevue Hospital (service of Dr. John Nelson), treated with sulfanilamide, are in substantial agreement with this. The occurrence of dizziness, mental confusion, lassitude and mild cyanosis was not uncommon with patients receiving large doses of the drug, but this in no way interfered with the therapy or its effects. Of this entire group, dermal reactions in the form of toxic erythema appeared in only one patient. This was a banal type of toxic erythema, evanescent and of nondescript character, and might well have been a consequence of the infection itself.

The more recent use of sulfanilamide in ambulatory cases of nonstreptococcal infection appears to supply the circumstances for a distinct and special type of dermal response to the presence of this drug in the skin. We herein report four such cases.

REPORT OF CASES

CASE 1—J. R., a white man, aged 26, attended the genitourinary clinic May 25, 1937, because of a gonorrheal urethritis of five days' duration. He was given 10 cc of prontosil¹ intramuscularly and sulfanilamide 20 grains (1.3 Gm) three times a day. May 30, the fourth day of medication, he took a "sun

Fig. 1 (case 1)—Early appearance of eruption twelve hours after exposure to sunlight. Note delimitation at waist line.

bath" for five hours, exposing all of his body above the waist line. The following morning the patient showed a dermal eruption and felt ill. He promptly reappeared at the clinic acutely ill and with a temperature of 103 F. The urethral discharge

From the Department of Dermatology and Syphilology, New York University Medical College and Bellevue Hospital, service of Dr. Howard Fox.

¹ The term prontosil has been used for a number of related substances. To avoid confusion the term prontosil used in this paper refers to the solution of the disodium salt of 4-sulfamido-phenyl-2-azo-7-acetyl amino-1-hydroxynaphthalene-3,6-disulfonic acid.

had disappeared the second day of therapy. The eruption was confined to the upper half of the body and ended abruptly at the waist in a sharp, distinct line. It consisted of scattered macular plaques, which on the chest and back had become one confluent sheet. On the sides of the chest, the neck, face and upper extremities the lesions varied from the size of a pea to that of the palm of the hand, and the majority of these lesions were macular, though some were slightly raised papules, a mixture as it were, of a scarlatiniform and morbilliform eruption. They were deep red with a dusky violaceous tinge.

Fig. 2 (case 1)—Eruption becoming more confluent. Note sharp delimitation at waist line.

The patient was immediately hospitalized and on the following day the eruption had become completely confluent, involving the entire upper half of the body. On the second day of hospitalization the temperature had become normal, the eruption began to fade and completely disappeared on the sixth day after his admission to the hospital.

The routine urine examination showed no abnormalities, and the blood count was normal. The Wassermann and Kahn tests of the blood were negative.

We continued to confine this patient to his bed with definite instructions to avoid direct sunlight. On disappearance of the eruption, sulfanilamide was again prescribed, 20 grains (1.3 Gm) at 8 a.m. and a similar dose four hours later. One hour after the administration of the second dose of the drug the patient experienced a tingling sensation in the skin and noted the appearance of a faint erythema. The following morning the eruption was at its maximum intensity and involved the complete and identical areas originally exposed to the sun and the site of the initial eruption. The character of the eruption differed in no wise from the initial one. It was accompanied by fever (to 104 F) and general malaise. In addition, however, an irregular mild erythema developed over the lower half of the left leg, an area not initially involved by exposure to sunlight or later exposed to it. All of this induced eruption disappeared in six days as did the constitutional symptoms.

The patient remained confined to his bed and strict prohibition of exposure to sun was continued. Now with an apparently normal skin the patient was exposed to an erythema dose of ultraviolet radiation on two skin sites, each 10 cm square: one site a previously involved one of the upper part of the back and the other a previously unaffected one on the thigh.

eruption was induced at either of these sites. Two days later sulfanilamide 20 grains (13 Gm) was administered to the patient at 8 a m and another like dose at 12 noon. At 10 a m, two hours before the second administration and before any eruption appeared, an erythema dose of ultraviolet radiation was given to a previously unaffected area over the right hamstrings. The following course of events ensued. At 1 p m the original site of eruption began to take on a scarlatiniform hue. The experimentally irradiated area showed no change at that time. By evening the original site was the seat of a diffuse scarlatiniform eruption, with the experimental area beginning to show signs of bluish erythema. The following morning the original site had faded to almost normality, with the experimental area going on toward the blue-red previously described as characteristic of this eruption.

CASE 2—C R, a white man, aged 30, a street pedler, appeared at the genito urinary clinic June 1, 1937, because of a urethritis of five weeks' duration. He was given 10 cc of protosil intramuscularly and sulfanilamide 20 grains (13 Gm) three times a day. Two days later, on his return to the clinic he had an eruption on the face and neck, extending down to a V over the sternum, in a line with his open shirt collar. The eruption on the face consisted of scattered, erythematous macules and papules, varying in size from a pea to a twenty-five cent piece (24 mm). On the neck the eruption consisted of a deep red plaque. That evening pinhead sized erythematous papules appeared in the antecubital fossae. He complained of intense itching. The eruption completely disappeared eight days after withdrawal of the medication.

CASE 3—J S, a white man, aged 25, unemployed, had a severe syphilis vulgaris of the entire bearded area of three years' duration. Previous treatment consisted of roentgen therapy, ointments of ammoniated mercury and chlorhydroxyquinoline and applications of aqueous solution of brilliant green. Experimental therapy with sulfanilamide was started June 3, 1937. He was advised to take 20 grains (13 Gm) three times a day for three days and then 15 grains (1 Gm) three times a day for two days. The patient reappeared at our office on the fifth day of medication complaining of a rash of twelve hours' duration. The eruption consisted of deep red, pea to dime (18 mm) sized scattered macules on the face and on the dorsa of the hands. He stated that he had been exposed to the sun for the entire previous afternoon but had been fully clothed. Itching was very mild. The syphilis vulgaris was unaffected.

CASE 4—O L, a white man, aged 22, unemployed, had a severe syphilis vulgaris of one and a half years' duration. His past treatment had included applications of various types of wet dressings, ointments of ammoniated mercury and chlorhydroxyquinoline and roentgen therapy. Experimental therapy with sulfanilamide was started June 3, 1937. He was advised to take 20 grains (13 Gm) three times a day for two days and 15 grains (1 Gm) three times a day for two days. Four days later the patient returned to our office, with an eruption said to be of twenty-four hours' duration. The eruption consisted of deep red macules and papules scattered over the face and neck, a diffuse maroon erythema with slight edema of both hands and a scattered pink erythema on the inner surface of the left thigh. The latter area, however, had not been exposed to sunlight. All the skin of both hands up to and including the wrist was involved, and the eruption was sharply demarcated at the cuff line. The patient complained of lassitude and a severe pruritus. He had been exposed to the sun the entire previous day but had been fully clothed. The eruption completely disappeared one week after the withdrawal of the drug. The syphilis vulgaris was unaffected.

SUMMARY OF CLINICAL APPEARANCE AND COURSE

These four patients receiving moderate doses of sulfanilamide had identical features in their histories and a similar development of a characteristic eruption. None were acutely ill at the time the drug was prescribed; they were ambulatory and they were all exposed to direct sunlight for five hours or more while taking the medication. In each case within twelve hours after exposure to the sun an eruption of the skin developed almost wholly confined to the parts exposed. The eruptions were similar and characteristic. They consisted of numerous scattered, irregularly grouped macular plaques, varying in size

from that of a pea to that of the palm of the hand. Some of the lesions were slightly raised above the skin. As the eruption progressed the lesions became more confluent, until the entire exposed portion was uniformly involved. The color of the fully developed eruption in each instance was striking. It was deep red with a violaceous tinge, the exact hue aptly described as maroon. No scaling accompanied either the evolution or the involution of the lesions. Moderate to severe itching was present in three of the four patients. Clinically the eruption was a toxic erythema which, on withdrawal of the sulfanilamide vanished completely in one week. Constitutional symptoms such as malaise, lassitude and elevation of temperature accompanied the development of the eruption, its degree, apparently, was measurable by the extent of the cutaneous surface involved.

COMMENT

Obviously sulfanilamide can photosensitize skin. We have as yet had no opportunity to study in detail the mechanism of this sensitization. The few experimental conditions set up about the study of case 1 would indicate (1) that threshold doses of the drug are necessary at the time of exposure to sunlight to effect an eruption, (2) that on withdrawal of both drug and sunlight the eruption will completely disappear before the sensitizing influence of the irradiation has been dissipated. Thus was evidenced by the fact that reactions can again be elicited in previously involved skin by further exhibition of the drug in the absence of added irradiation. The appearance in scattered, unexposed sites of nondescript erythemas simultaneously with the more spectacular eruptions in the exposed areas would suggest that, in addition to the manifest cellular background to the sensitizing mechanism involved, there may in some measure be a concomitant humoral disturbance able to induce cutaneous changes at a distance.¹

SUMMARY

1 A peculiar eruption induced by sulfanilamide and sunlight was reproduced experimentally in one patient, giving conclusive evidence that sulfanilamide was the photosensitizing agent.

2 We believe it incumbent on physicians when prescribing sulfanilamide to instruct their patients to avoid direct sunlight.²

SULFANILAMIDE AND THERMOTHERAPY IN GONOCOCCIC INFECTIONS

A PRELIMINARY REPORT

EDGAR G. BALLENGER, M.D., OMAR F. ELDER, M.D.
AND HAROLD P. McDONALD, M.D., ATLANTA, GA.

By thermochemothrapy is meant the use of artificial fever to supplement the use of chemical agents in the treatment of infections.

Our experience with a group of patients who received artificial fever in combination with sulfanilamide has convinced us of the value of such a plan of treatment. Patients chosen for thermochemothrapy at first were those who had failed to respond to artificial fever or those in whom the treatment with sulfanilamide had failed. When these agencies were administered simultaneously, however, it was soon seen that the combination of these remedies was more efficacious than when either was used alone. Urethral discharge and cloudy urine, due to the gonococcal infection, which had not responded to large doses of sulfanilamide, were seen to disappear in one or two days after thermochemothapeusis.

In these treatments 80 grains (5 Gm) of sulfanilamide was given daily for two days, then artificial fever was administered. The fever was carried as high as 103 or 104 F and maintained in this range for three or four hours. As has already been found, this amount of hyperpyrexia is not sufficient to cure a gonococcal infection. Since sulfanilamide had failed and since this moderate amount of artificial fever is not sufficient to cure such infections, the conclusion seems justified that the hyperpyrexia activated the sulfanilamide or increased the defensive body reactions in a manner not attained by these agencies administered separately.

1 Dr. Howard Fox gave his permission for us to present the cases from his service.

2 Since submission of this report six additional cases of similar photosensitization by sulfanilamide have been observed by the authors.

At first thermochemotherapy was administered every other day until three treatments were given. After the first artificial fever treatment the daily amount of sulfanilamide was reduced from 80 to 60 grams (4 Gm). Early in our work this was gradually reduced still further after the fever was discontinued. The well being of patients so treated soon led us to discontinue the sulfanilamide after the third treatment with fever.

Tests were made at once to determine whether or not gonococci could be found. After five patients were shown to be well after this short course of sulfanilamide and with three treatments with artificial fever, we were under the impression that at least some of these patients were well after the first treatment with fever. We then decided to give but one treatment with fever supplemented with sulfanilamide and see whether or not this was sufficient. In two out of three patients so treated the usual tests for gonorrhea gave negative results. The third patient appeared to be well for five days, the urethral discharge with gonococci then reappeared.

Since the plan of treatment with the combination of artificial fever with sulfanilamide was found to be efficacious in patients with resistant infection, we decided to employ it in patients who for domestic or business reasons had urgent need for immediate cure. So far we have had no failures in ten consecutive patients when three fever treatments were administered simultaneously with sulfanilamide in the doses previously mentioned. There was one failure, in a patient who had three treatments with hyperpyrexia. On investigation it was found, however, that on account of a disturbed gastro-intestinal tract he had not taken the sulfanilamide as directed. After his stomach disorder had disappeared he was given adequate doses of sulfanilamide and then was cured by one additional treatment with fever. This result clearly showed us the necessity of giving sulfanilamide in an adequate amount before inducing the fever.

Never in many years of urologic work have we seen resistant infections disappear with the regularity and the promptness that have followed our attacks with this plan of treatment with fever and sulfanilamide combined.

Elderly patients with cardiac involvement or those with impaired renal or hepatic function do not tolerate well either artificial fever or sulfanilamide.

In a later report we shall discuss infections with other organisms that ordinarily do not respond either to sulfanilamide or to artificial fever therapy, yet which have been cured by their combined use.

THIRD GENERATION SYPHILIS

JOHN C. CLARK, M.D., ASBURY PARK, N. J.

Third generation syphilis is extremely rare. "The rub comes in the establishing of the prenatal as distinguished from the possibly acquired syphilis of the second generation mother." I believe that this case establishes prenatal syphilis in the mother.

REPORT OF A CASE

Mrs. S. D., a Negress, aged 18, a primipara, presented herself to the antepartum clinic of the Monmouth Memorial Hospital, Long Branch, N. J., Aug. 19, 1936, with a three months pregnancy.

The history revealed that the patient was the first living child in her family, her mother having previously had fourteen pregnancies, terminating either in miscarriages or in stillbirths. The patient was followed by two infants who lived only a few months, and then by a sister who lived and at the present time is 15 years of age. Two more living children were born alternating with stillbirths, making a total of twenty-two pregnancies and four living children. The sister presents Hutchinson's teeth and a positive Wassermann reaction of the blood. The other two children are not available for examination at this time. The patient's husband presents no clinical evidence of syphilis, and the Wassermann reaction of the blood is negative.

The patient showed above the average intelligence. Her height was 5 feet (152 cm) and her weight 117 pounds (53 Kg).

Her teeth presented unmistakable evidence of prenatal syphilis in both Hutchinson's incisors and mulberry sixth year molars. There was also the classic facies of heredosyphilis, including the depression of the nasal bridge. A routine Wassermann test of the blood was reported positive.

Treatment was instituted and consisted of sixteen weekly injections of nearsphenamine, a total of 8 Gm.

March 15, 1937, the patient was delivered of a 6 pound (2,720 Gm) male child, apparently normal but in whom hemorrhages from the nose, mouth and anus occurred on the second day of life. The hemorrhages lasted three days but responded satisfactorily to a transfusion of 60 cc of the father's whole blood. The Wassermann reaction of the cord blood was reported positive, as was the blood obtained by jugular puncture on the tenth day.

Treatment of the child has consisted of acetarsone by mouth. He has made a satisfactory gain in weight and has been free from any other clinical manifestations of prenatal syphilis.

I feel that this is prenatal syphilis in the second and third generations, in the third generation the case was modified perhaps by antepartum treatment of the mother.

404 Asbury Avenue

HYPERSENSITIVITY TO SULFANILAMIDE

MONTÉ SALVIN, M.D., LOS ANGELES

The case I am reporting here seems to be an anaphylaxis like reaction of a patient to the new drug sulfanilamide. Because of the miraculous benefits reported by the use of this new discovery in streptococcal and gonococcal infections, physicians are using it in these and other types of infections, and no doubt any complication, untoward reaction or unusual effect produced by this drug is of interest to the medical profession.

REPORT OF CASE

History.—A man, aged 22, presented himself at my office with an acute urethral discharge, which was accompanied by burning on urination and frequency. The discharge was of two days' duration, and there was a history of exposure to gonorrhea six days previously. The patient stated that he had not had any previous trouble of this sort. The past history was essentially negative. He had always enjoyed good health, he was not subject to colds, and the family history was negative with regard to tuberculosis.

Examination revealed a thick yellowish discharge at the urethral orifice, and a smear of this stained by the Gram method showed many gram-negative intracellular and extracellular diplococci. The two glass test showed many shreds in the first but none in the second glass. A diagnosis of acute anterior urethritis was made.

Treatment consisted of directions regarding diet and general hygiene, and tablets of sulfanilamide were prescribed, the directions being to take two tablets (10 grains, or 0.65 Gm) after each meal and two at bedtime. The patient was advised not to take any saline cathartics and was told to report back in three days. No other treatment was given at this time.

The next evening the patient's mother telephoned me saying that her son was very ill and wanted me to visit him. Arriving at the house soon afterward, I found the boy lying in bed complaining of intense itching all over the body, accompanied by sneezing, shortness of breath and lacrimation.

Examination.—Physical examination at that time revealed a temperature of 101 F, a pulse rate of 96, and a blood pressure of 110 systolic, 55 diastolic. The patient was extremely uncomfortable. There was much swelling of the eyelids, lips and scrotum, with urticaria-like lesions of the face, the back of the ears, the inner margins of the elbows and knees and the abdomen. Urinalysis was negative except for 1 plus albumin and pus. The white blood cell count was within normal limits.

Careful questioning of the family revealed no allergic diseases and none of the relatives had ever suffered from hives, eczema, hay fever or asthma.

Treatment.—The patient was told to discontinue the sulfanilamide. A large dose of magnesium magma was given, and an injection of three drops of epinephrine was administered.

cutaneously The next day all the symptoms had disappeared except the urethral discharge Patch tests with sulfanilamide were positive Tests with many other sulfur and related compounds were all negative A small dose of 1 grain (0.065 Gm) brought on a subsequent attack with itching and sneezing The drug was then discontinued

The patient still has urethritis However, treatment is now being given by the old standard methods, namely, irrigations and the like

COMMENTS AND CONCLUSIONS

Hypersensitivity to a new drug occurred in a patient who had never had any history of hypersensitivity to any substance and whose family, both immediate and more distant, had had no allergic diseases Small doses produced subsequent attacks, and patch tests of the drug were positive while tests of related compounds were negative

A COMPARISON OF MANDELIC ACID
AND SULFANILAMIDE AS URI-
NARY ANTISEPTICS

CLINICAL LECTURE AT ATLANTIC CITY SESSION

HENRY F. HELMHOLZ, M.D.

ROCHESTER, MINN.

Within the past two years two drugs, mandelic acid and sulfanilamide, have been added to our armamentarium for the treatment of urinary infections Both represent advances over the therapeutic measures in use before their introduction The ketogenic diet was a definite therapeutic advance, and it made it possible to clear up infections in patients with urinary stasis that had previously remained immune to treatment The difficulties of taking the ketogenic diet were such, however, that Rosenheim¹ introduced another organic acid, mandelic acid, in place of beta-oxybutyric acid This was another step forward in the treatment of urinary infections Mandelic acid can be taken by mouth, and it is excreted unchanged in the urine

Beta-oxybutyric acid and mandelic acid act bactericidally in about the same concentration and in the same range of p_H Both require organic acid concentrations

TABLE 1—The Bactericidal Effect of 1 per Cent Mandelic Acid at p_H 5

Time of Taking Culture	Colonies Escherichia Coli per 0.5 Cc	Colonies Aerobacter Aerogenes per 0.5 Cc	Colonies Staphylo- coccus Aureus per 0.5 Cc	Colonies Strepto- coccus Faecalis per 0.5 Cc
Before incubation	3 600	1 680	4 000	12 800
1 hour after incubation	3 600	880	2 400	9 600
2 hours after incubation	1 280	30	1 200	3 000
4 hours after incubation	800	1	1 000	35
8 hours after incubation	0	0	0	0
24 hours after incubation	0	0	0	0

of from 0.5 to 1.0 and a p_H of the urine between 5.0 and 5.5, anything that prevents achieving these conditions vitiates the value of the treatment Reduced renal function, for example, prevents the secretion of a urine of a p_H as low as 5.5 and a urinary concentration

of the organic acids in the bactericidal range In infections with urea-splitting organisms, such as those of the Proteus group, the alkalinity of the urine is usually such that, in spite of the use of acid salts, the urinary p_H rarely approaches 5.5

Osterberg and I² have shown that mandelic acid acts bactericidally on all the common gram-negative bacilli found in urinary infection More recently I³ have studied the effect of this drug on Staphylococcus aureus and Streptococcus faecalis and, as shown in table 1, the bactericidal effect on these organisms is practically the same as on the gram-negative bacilli Because of the resistance of Streptococcus faecalis to sulfanilamide therapy, a series of five strains of this organism was tested out with concentrations of mandelic acid of 0.25, 0.5 and 1 per cent, acting at a range of p_H from 5.0 to 5.5 (table 2) The bactericidal effect was very closely comparable to that on Escherichia coli Clinical experience has borne out the efficacy of mandelic acid therapy in Streptococcus faecalis infections as indicated by our experiments in vitro

Given originally as sodium mandelate in combination with ammonium nitrate or ammonium chloride to acidify the urine, mandelic acid is now generally given in the form of the ammonium salt If the urine does not reach the necessary p_H of 5.5, ammonium nitrate can be given in addition The mandelate is almost quantitatively excreted in the urine, so that by knowing the amount given in twenty-four hours and the total daily output of urine, the concentration of mandelic acid in the urine can be kept at approximately 1 per cent The usual adult dosage is 12 Gm a day,

TABLE 2—The Bactericidal Effect of Mandelic Acid on Streptococcus Faecalis at Various Concentrations and p_H 's

Concentration of Acid per Cent	p_H of Urine	Strains				
		1	2	3	4	5
0.25	5.0	—	+	+	+	+
0.5	5.3	S	+	+	+	+
1.0	5.5	+	+	+	+	+

— organisms not killed + organisms killed S bacterostasis

that is, 3 Gm four times a day, taken after each meal and at bedtime The twenty-four hour quantity of urine should be kept at about 1,000 cc (1 quart) For children the dosage is proportionately smaller One gram of ammonium mandelate is prescribed for each hundred cubic centimeters of urine in the daily output, accordingly, for an output of 500 cc (1 pint), 5 Gm of the drug should be given

In addition to the proper urinary concentration of mandelic acid, it is necessary to have the proper acidity, and this should be determined daily This can be done by the patient with the use of chlorphenol red or nitrozone paper The former indicates proper acidity by a yellow color and insufficient acidity by a red color, the latter indicates the proper acidity by a yellow color and insufficient acidity by a green color If the necessary acidity is not reached by means of the administration of ammonium mandelate alone, ammonium chloride or ammonium nitrate in doses of from 0.5 to 2 Gm four times a day is given The rapidly successful treatment by mandelic acid of a patient with chronic infection of the urinary passages is seen in table 3 Of special

interest is the rapid clearing up of an infection with *Streptococcus faecalis* after a failure with intense sulfanilamide therapy (table 4)

Recently I have studied the bactericidal effect of the urine after the administration of sulfanilamide by mouth. I have been able to show that, with sulfanilamide in concentrations that are easily obtainable by oral administration of the drug, the urine is bactericidal for *Staphylococcus aureus*, *Escherichia coli*, *Aerobacter*

TABLE 3—Treatment of a Girl, Aged 3 Years, with Pyelitis of Four Weeks Duration
(Ammonium mandelate [15 Gm] four times a day)

aerogenes and organisms of the *Proteus* and *Pseudomonas* groups. In sharp contrast is the luxuriant growth of *Streptococcus faecalis* in urine that is strongly bactericidal for the other organisms. It was further noted⁴ that the same concentration of sulfanilamide was more effective in alkaline than in acid urine. After the administration of sulfanilamide the urine is usually alkaline, but it is important to determine that such is actually the case. Table 5 shows the increased bactericidal power of a specimen of urine of pH 6.0 when alkalinized to pH 7.5.

This action of sulfanilamide in alkaline urine is of great significance in the treatment of *Proteus* infections. In the presence of a very strongly alkaline urine, its marked bactericidal action on eight strains of the *Proteus* group of organisms gives hope for successful treatment of a group resistant to mandelic acid as well as to all other forms of therapy dependent on an acid urine. The uniform growth of five strains of *Streptococcus faecalis* in urine bactericidal for the other bacteria, however, sets the latter infection quite apart and represents a loophole in the therapeutic efficacy of sulfanilamide. Clinically we have found in a number of mixed infections that, on sulfanilamide

TABLE 4—*Streptococcus faecalis* Infection Cured with Mandelic Acid

therapy, the gram-negative bacilli disappear from the urine, leaving behind a pure culture of *Streptococcus faecalis*. In the case cited previously (table 4), we increased the dosage of sulfanilamide above the average in an attempt to influence the *Streptococcus faecalis* infection, but without any effect. Using mandelic acid, the infection cleared up in three days. Whether there are other organisms causing urinary infections which are specifically resistant, like *Streptococcus faecalis*, is still to be determined.

"Prontosil," a proprietary product related to Prontosil, or sulfanilamide, was first given by rectum, and later by intravenous injection as well as by mouth, in the treatment of urinary infections. Unshelm⁴ and Klein⁵ both reported excellent results in the treatment of the pyelitis of childhood. Unshelm stated that prontosil had no effect on the *Escherichia coli* in vitro. Our results at the clinic in the treatment of simple urinary infections of the bacillary type have been equally successful with sulfanilamide. I wish to call special attention to two cases of *Escherichia coli* and *Aerobacter aerogenes* infection which yielded rapidly to sulfanilamide therapy after a long and unsuccessful treatment with mandelic acid.

REPORT OF CASES

CASE 1—A girl, aged 4 years, had suffered from an infection with *Escherichia coli* for a period of two years, with stasis due to megalo-ureter. The blood urea was normal. Pus, grade 1, and innumerable *Escherichia coli* organisms were constantly found in the urine on culture. In a period of about two months this patient was given six courses of ammonium mandelate therapy. Because of difficulty in keeping the urine at a pH below 5.5, ammonium chloride or calcium chloride was given in doses of 1 Gm four times a day. During one period of nine days the ketogenic diet also was used. On several occasions a single sterile culture was obtained, otherwise, the cultures uniformly showed innumerable organisms per 0.5

TABLE 5—Effect of Reaction on Bactericidal Power of Sulfanilamide in Urine
(Free 57 conjugated 68 mg. per hundred cubic centimeters)

<i>Escherichia coli</i>	4,200	4,360	600	0
<i>Aerobacter aerogenes</i>	720	59	Innumerable	26
<i>Proteus ammoniae</i>	820	200	700	0
<i>Pseudomonas</i>	3,420	5,400	3,500	1,760

cc of urine. Following this trial with mandelic acid therapy the child was given 0.33 Gm of sulfanilamide five times a day. At the end of four days her urine was sterile. Medication was continued for three days longer, during which time cultures of the urine remained sterile. Cultures taken two days after discontinuance of the medication were still sterile. Five days after treatment was stopped, however, innumerable organisms were again present. Sulfanilamide was again administered and the urine was sterile for a period of nineteen days.

CASE 2—A boy, aged 3½ years, had an acute attack of urinary infection in August 1935. His temperature rose to 105 F. He was treated with various drugs until October 1936, but without success. At that time ammonium mandelate was administered for a period of two months, but the infection persisted. The same treatment was tried again for three weeks, beginning in January 1937.

On his admission to the clinic his urine contained pus grade 4, and cultures revealed *Escherichia coli* and *Aerobacter aerogenes*. An intravenous urogram, retrograde urogram and cystoscopic examination showed ureterectasis and pyelctasis and cystitis cystica. The patient was given 1 Gm of ammonium mandelate four times a day, and later five times a day (table 6). The urine was found to be sterile on culture at the end of eight days of treatment. At the end of eleven days administration the drug was discontinued and after twenty-four hours, cultures of the urine again contained innumerable gram-negative bacilli. Ammonium mandelate was again given, the dose being increased to 6 Gm a day. In spite of this increased dose and a range of pH from 5.0 to 5.5 the urine remained unchanged.

4 Unshelm E. Zur Behandlung der kindlichen Pyuria. Arch. f. Kinderh. 109: 65-84, 1936.
5 Klein E. Prontosil in der Kinderpraxis. Med. Klin. 2: 9-0941 (July 10) 1936.

after thirty days of treatment. Following this failure, sulfanilamide, in the dose of 0.33 Gm four times a day for the first four days and five times a day on the fifth day was given. On the second day the bacteria had been reduced in number to fifty per 0.5 cc of urine on culture and, on the fifth day, to only two per 0.5 cc of urine. On the sixth day the urine was sterile. After ten days of treatment the administration of sulfanilamide was discontinued and cultures of urine taken three and five days later were sterile.

The ketogenic diet and mandelic acid can be given only in the subacute and chronic stage of pyelitis, whereas sulfanilamide can be administered in the acute febrile stage. Sulfanilamide is also easier to administer than is mandelic acid. Acting best in an alkaline medium, sulfanilamide can be given along with sodium bicarbonate and sodium citrate, which, together with the forcing of fluids, we at the clinic have relied on for treatment of the disease in its acute stage. The dosage in infancy is from 5 to 10 grains (0.3 to 0.65 Gm) a day, for children from 2 to 4 years of age, 10 to 15 grains (0.65 to 1 Gm), for children from 4 to 8 years, 15 to 25 grains (1 to 1.6 Gm), and for children from 8 to 12 years, 20 to 30 grains (1.3 to 2 Gm) a day. The adult dosage, as given by Cook and Buchtel,⁶ is 30 grains (2 Gm) the first day, 40 grains (2.6 Gm) the second day, and 60 grains (4 Gm) the third day, then decreasing the dose to 40 grains again on the fourth day. They were successful in treating two patients with pyelonephritis whose blood urea was above 100 mg per hundred cubic centimeters of serum, during the course of treatment the blood urea came down close to normal figures.

SUMMARY AND CONCLUSIONS

The introduction of mandelic acid and sulfanilamide has greatly improved the chances of curing urinary infections. Mandelic acid is dependent for its action on a concentration greater than 0.5 per cent and a pH of the urine less than 5.5, so that it is not likely to be successful unless the function of the kidney

is normal or nearly so. The inability to reduce the pH of the urine of patients with *Proteus* infections makes mandelic acid therapy almost useless in the treatment of such infection. Its action on *Streptococcus faecalis*, however, makes it the antiseptic of choice for this type of infection. Sulfanilamide, because of its ease of administration and tolerance by the stomach, is the drug of choice, however, in the average case, and it has the added advantage that it can be used during the acute stage of the disease. Acting best in an alkaline urine, sulfanilamide should be extremely useful in treating infections of the *Proteus* group. Its striking ineffectiveness in the treatment of *Streptococcus faecalis* infections, however, is a definite handicap.

These two drugs, one acting only in an acid and the other best in an alkaline medium, supplement each other, and they should be used in the treatment of urinary infections according to the type or types of organisms causing them.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
HOWARD A. CARTER, Secretary

EVIDENCE REQUIRED BY THE COUNCIL ON PHYSICAL THERAPY FOR CONSIDERATION OF APPARATUS USED IN FEVER THERAPY

The Council on Physical Therapy will give consideration to apparatus designed, advertised and sold for the purpose of administering fever treatments. Manufacturers of such apparatus and appliances are asked to comply with the general requirements as stated in the booklet "Official Rules of the Council on Physical Therapy" and are requested to present the following additional information:

1 A full description of the construction and method of operation of the unit, including specifications, working plans, photographs, blue prints and also the patent number.

2 Temperature charts showing the time required to raise the rectal temperature of twelve patients from normal to at least 106° F.

3 Statement of the constancy with which any degree of rectal temperature may be maintained for five hours and evidence to support these claims.

4 Inclusion, in the data furnished, of the temperature and the relative humidity of the air within the chamber throughout the periods of treatment, if the apparatus comprises a chamber in which the body of the patient lies during treatment.

5 A report on any undesirable effects on patients with reference to:

- (a) Skin (danger of burns)
- (b) Heart (blood pressure and pulse)
- (c) Respiration
- (d) Relative comfort or discomfort
- (e) Incidence of delirium

6 Energy input required to operate the unit.

The Council on Physical Therapy will give careful consideration to:

- (a) The facility with which the condition of the patient's skin can be observed during treatment
- (b) The facility with which the patient's physical needs can be attended to during treatment
- (c) The facility and rapidity with which, in case of emergency, the patient can be withdrawn and restorative treatment administered

⁶ Cook, E. N. and Buchtel, H. A. The Use of Sulfanilamide (Prontylin) in Urinary Infections. Proc. Staff Meet. Mayo Clin. 12: 381-383 (June 16) 1937.

EVEREADY TABLE MODEL CARBON ARC LAMP, TYPE M-4, ACCEPTABLE

Manufacturer National Carbon Company, Inc., Cleveland

This table model carbon arc lamp, producing ultraviolet radiation, is designed to be used under the direction of a physician at the bedside, in the hospital or in the home. In outward appearance this lamp is similar to the Home Model Type M-1, which was accepted by the Council, Nov. 5, 1932. The difference lies in the omission of the single thickness Corex-D window.

Description—The lamp examined (Type M-4) is provided with a wire mesh, which intercepts nonselectively about 40 per cent of the radiation of all wavelengths. Accompanying the lamp were Eveready Therapeutic C carbon electrodes, which are "designed especially for erythema production." The sizes used are No. 68 for the lower and No. 610 for the upper electrode.

Eveready Table Model Carbon Arc Lamp Type M-4

On 115 volts alternating current the arc begins to operate quietly on about 128 amperes and in the course of about ten minutes burns out on 105 to 11 amperes. Using an ammeter in the circuit, and depressing the starting lever when the current decreased below 115 amperes, the radiometric and biologic (erythemogenic) tests were made with the arc operating on 118 to 125 amperes, or about 600 watts in the arc. If the lamp had been permitted to operate until it burned out, the integrated intensity would be about 20 per cent lower than the average used in the biologic tests. Other pertinent details regarding the lamp are given in THE JOURNAL, Nov. 5, 1932, page 1604, where a similar and Council accepted lamp is described.

Radiometric Tests—The ultraviolet radiation of wavelengths shorter than and including 3,132 angstroms were evaluated by means of a differential thermopile and filter radiometer, as recommended by the International Congress on Light. The measurements were made at a distance of 24 inches from the front of the wire mesh screen, or about 28 inches from the center of the arc.

The wire mesh transmits nonselectively about 60 per cent of the radiation of all wavelengths. The ultraviolet intensity of wavelengths 3,132 angstroms and shorter (to 2,400 angstroms) of the arc shining through the wire mesh was $412 \mu\text{W}/\text{cm}^2$. This is about eight times the requirement for acceptance as a therapeutic lamp (fifteen minutes' exposure) under the direction of a physician.

When the lamp is used with a Corex-D window, the intensity is about ten times that required by the Council for a sunlamp (one hour exposure) for home use without the direction of a physician.

Erythema Tests—In view of reports of severe burns received by users of various kinds of so-called Sun Lamps, tests were made of the time required to produce a minimum perceptible erythema (M. P. E.), which is a measure of skin tolerance and a necessary precautionary test to avoid burns over a large area. The skin of the person used in making the test is of average pigmentation and has been subjected to previous tests, hence, of known erythema reaction.

Exposures to the Therapeutic C carbon arc were made on the untanned inside upper arm, at the minimum acceptable distance—24 inches—from the wire mesh window, for one, two, three, four, five and seven minutes respectively. After three hours all exposures were visible, the one minute exposure being only faintly red.

After twenty-four hours the one minute exposure had disappeared and the five and seven minute exposures were painful burns. The two minute exposure was still visible (after two days) showing that the minimum perceptible erythema exposure

is a trifle less than two minutes. The calculated time of exposure for a skin of average pigmentation is 19 minutes.

At a distance of 3 feet the intensity would be reduced to one half, requiring an exposure of four minutes for a minimum perceptible erythema. The instructions state that in using these therapeutic C carbons the first exposures should be for three minutes at a distance of 3 feet. From the foregoing tests it appears that burns may ensue on a sensitive untanned skin, if the exposure is not accurately timed.

The conclusion to be drawn from these tests is that the ultraviolet intensity of the Type M-4 carbon arc provided with Therapeutic C carbon electrodes is ample, when used under the direction of a physician.

In view of the foregoing report on the performance of the Eveready Table Model Carbon Arc Lamp, Type M-4, the Council on Physical Therapy voted to include it in the list of accepted devices because it meets the specifications for acceptable professional lamps.

MAJESTIC PORTABLE SURGICAL UNIT ACCEPTABLE

Manufacturer Majestic Surgical Instrument Company, Chicago

The Majestic Electro-Surgical Unit is intended for use in the physician's office and in the hospital. Coagulating, desiccating and cutting currents are available as well as a ground free current for illuminating diagnostic instruments requiring from $1\frac{1}{2}$ to $2\frac{1}{2}$ volts. The unit is foot-switch operated. It comes in a leatherette carrying case and weighs about 27 pounds.

Majestic Portable Surgical Unit

A single tube Hartlev circuit is employed. The wavelength is 399 meters. The coagulating and cutting currents are protected by two condensers against feed-back. Two transformers are employed, one filament and one plate. The filament transformer supplies the current for the diagnostic light (as used in cystoscope or resectoscope examinations). This winding is static shielded as well as ground free, so that it may be employed in bladder diagnostic work. A high and low switch is provided for current adjustment. The machine may be used with or without the body plate electrode.

At full cutting capacity, the unit draws approximately 4 amperes from a 110 volt alternating current line. The transformer temperature rise and the rise within the cabinet taken at various levels are within the limits of safety prescribed by the Council. The parts used in the alternating current circuit are of standard manufacture.

The unit was tried out in a clinic acceptable to the Council for a period of several months. The cutting current generated by the outfit was reported better than the coagulating current, although both were satisfactory.

In view of the foregoing favorable report, the Council on Physical Therapy voted to include the Majestic Portable Surgical Unit in its list of accepted devices.

Council on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COUNCIL ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION AND WILL BE LISTED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED

FRANKLIN C BING Secretary

DIETENE

Manufacturer—The Dietene Company, Minneapolis

Description—A powdered mixture of skimmed milk powder, sugar, soluble calcium caseinate, cocoa wheat embryo, dried whole egg, dried brewers' yeast, salt, Karaya gum, concentrate of vitamins A and D from cod liver oil, seasoning and artificial flavoring (dried toffee extract, vanillin and coumarin)

Manufacture—The ingredients in formula proportions are mechanically mixed, screened and automatically filled into containers

Analysis (submitted by manufacturer)—Moisture 4.6%, total solids 95.4%, ash 5.2%, fat (ether extract) 4.0%, protein (N \times 6.38) 36.1%, crude fiber 0.6%, Karaya gum 1.2%, carbohydrates other than crude fiber and gum 48.3%, sodium chloride as NaCl 1.6%, calcium as Ca 0.86%, phosphorus as P 0.86%, iron as Fe 0.0045%

Calories—374 per gram, 106 per ounce

Vitamins—Assays show that the finished product supplies the following vitamins in units per hundred grams: vitamin A, 3,500 U S P units, vitamin B₁, at least 230 International units, vitamin G, 424 Bourquin-Sherman units, and vitamin D, 160 U S P units

Allowable Claims—Dietene is accepted as a food product intended primarily for use in connection with procedures for reducing weight. The dietary requirements for low calorie diets and the Council requirements for special purpose foods intended for incorporation in menus for reducing weight have been published (THE JOURNAL, Aug 8, 1936, p 431). Dietene in itself has no reducing properties, but it is a preparation which is rich in protein, calcium, phosphorus and vitamins A, B₁, G and D, all of which must be given particular attention in the selection of low calorie menus. Acceptance of this product does not mean that reducing without medical advice is approved. On the contrary, the Council emphasizes that reducing without the advice and supervision of a physician may be dangerous

PURITAN BRAND LARD

Manufacturer—The Cudahy Packing Company, Chicago

Description—Leaf lard which complies with government standards for that product

Manufacture—Kidney fat from government inspected hogs is hashed into a steam jacketed open kettle, which is equipped with a mechanical stirrer, the temperature is increased until the cracklings are well dried and settle out from the rendered fat. The melted fat is strained through clean muslin to remove fine cracklings, automatically filled into clean tin pails and solidified, or solidified and packed in paper cartons

Analysis (submitted by manufacturer)—Moisture 0.10%, total solids 99.9%, free fatty acids as oleic acid 0.25%, iodine value 58, melting point (closed capillary) 46-48 C, solidifying point of fatty acids (titer test) 40-41 C, saponification value 194-196, color (Lovibond 5¼" col max.) 20Y-2R, smoke point (open cup) 365-375 F, rancidity (Kreis reaction) negative, keeping quality (hours at 208 F) six-eight

Calories—9 per gram, 255 per ounce

CLIX SHORTENING

Manufacturer—The Cudahy Packing Company, Chicago

Description—Hydrogenated lard

Manufacture—Dry, rendered lard from government inspected hogs is refined with sodium bicarbonate to remove fatty acids and treated with hydrogen gas in the presence of reduced nickel catalyst at elevated temperature and pressure. After the iodine number has been lowered sufficiently, the catalyst is completely

removed by double filtration. The filtered fat is treated with steam at high temperature and under vacuum as a deodorizing process. The product is then solidified, homogenized and filled into containers

Analysis (submitted by manufacturer)—Moisture, not over 0.05%, total solids 99.95%, free fatty acids as oleic acid, not over 0.03%, iodine value (Wijs method) 59.60, rancidity (Kreis reaction) negative, melting point (closed capillary) 47-49 C, solidifying point of fatty acids (titer test) 38-39 C, saponification value 194-196, color (Lovibond 5¼" col) not over 5Y0, 2R, smoke cup (open cup) min 435 F, inert gas incorporated 4-8%, keeping quality (hours at 208 F) ten-fifteen

Calories—9 per gram, 255 per ounce

LIBBY'S HAWAIIAN PINEAPPLE JUICE

Libby, McNeill & Libby, Chicago, manufacturers of Libby's Hawaiian Pineapple Juice, has agreed to maintain its advertising within the claims recognized by the Council on Foods and the product is therefore reaccepted. The method of manufacture has been described in THE JOURNAL (Dec 8, 1934, p 1779)

Analysis (submitted by manufacturer)—Moisture 87.1%, total solids 12.9 Gm per hundred cubic centimeters, ash 0.5 Gm per hundred cubic centimeters, protein (N \times 6.25) 0.5 Gm per hundred cubic centimeters, reducing sugars before inversion, as invert sugar, 9.6 Gm per hundred cubic centimeters, reducing sugars after inversion, as invert sugar, 11.1 Gm per hundred cubic centimeters, crude fiber 0.05 Gm per hundred cubic centimeters, carbohydrates other than crude fiber (by difference) 11.1 Gm per hundred cubic centimeters, titratable acidity, as citric acid, 0.7 Gm per hundred cubic centimeters

Calories—0.46 per cubic centimeter, 13.1 per ounce (avoirdupois)

Vitamins—Contains vitamin A and is a good source of vitamins B₁ and C. Chemical titration indicates a vitamin C content of 0.12 mg of ascorbic acid per gram, 3.3 per ounce. Equivalent to 2.4 International units per cubic centimeter, 66 per ounce

Claims of Manufacturer—The canned pineapple juice retains in high degree the nutritional values of the fresh fruit juice

STOKELY'S UNSTRAINED VEGETABLE SOUP WITH CEREAL AND BEEF BROTH

Manufacturer—Stokely Brothers & Company, Inc., Indianapolis

Description—A canned combination of tomato juice, beef broth, unstrained finely cut potatoes, carrots, water, unpolished rice, whole grain barley, celery, barley and rice flour, cabbage and spinach, slightly seasoned with salt

Manufacture—Selected carrots and potatoes are washed, peeled and diced. Fresh spinach, cabbage and celery stalks are inspected, trimmed, washed and finely cut. Unpolished rice and whole grain barley are cooked. Juice is extracted from fresh tomatoes. Canned juice is used when fresh tomatoes are not available. Each juice is heated without exposure to air to conserve the vitamins. The beef broth contains per pint the meat extractives from approximately one pound of lean beef and a portion of bone. Formula proportions of the ingredients are mixed, heated to 98 C without exposure to air, and filled into enamel-lined cans which are sealed and processed for sixty-five minutes at 116 C

Analysis (submitted by manufacturer)—Moisture 86.4%, total solids 13.6%, ash 2.2%, sodium chloride (NaCl) 1.8%, fat (ether extract) 0.1%, protein (N \times 6.25) 1.6%, crude fiber 0.8%, carbohydrates other than crude fiber (by difference) 8.9%, reducing sugar as dextrose 1.5%, sucrose 0.5%, pH 5.0

Calories—0.43 per gram, 12 per ounce

Vitamins—The natural vitamin content is retained in large measure in the manufacturing process by the use of equipment and procedure which exclude incorporation of air, the vegetable material is exposed only to steam

Claims of Manufacturer—A supplementary unsieved food for infants, retaining in high degree the natural flavor, mineral and vitamin values of the raw products. Requires only warming for serving

FEVER THERAPY

During the past two years, interest in the production of fever by physical means has greatly increased. Since the gravity of the procedure cannot be overestimated, the administration of fever therapy should be in the hands of a competent, well trained organization. The personnel should include at least one qualified physician who remains in attendance throughout the treatment and a skilled nurse-technician who has had special training in the field to administer the treatments.

Physicians intending to use this therapeutic measure should select patients with as much discrimination as they use in determining those who are to undergo major surgical operations. Raising of the body temperature to 105 and 106 F and maintaining it at that temperature for several hours is a most serious procedure, requiring the utmost vigilance on the part of the attendants for the safety of the patient. Naturally these treatments cannot be considered simple office procedures.

Several methods have been used for administering fever treatments by physical means. Among those in most general use are radiant heat cabinets, luminous heat cabinets and short wave diathermy cabinets. Electric blankets, sleeping bags, hydrotherapy, hot water baths and blankets have been used successfully by many specialists.

In view of the activity at the present time on the part of the manufacturers to supply the profession with equipment for producing fever by physical means, the Council on Physical Therapy has adopted the report "Evidence Required by the Council on Physical Therapy for Consideration of Apparatus Used in Fever Therapy," printed elsewhere in this issue of THE JOURNAL.¹ The most acceptable device would seem to be of the cabinet type, so arranged that the patient may be observed during the treatment and his physical needs attended to readily and conveniently. The only accurate

way of keeping close check on the temperature of the patient is by using the rectal thermometer. Hence, means should be provided to read the temperature conveniently. The unit must be so constructed that the patient may be withdrawn with facility, in case of emergency, and restorative treatment administered. The Council emphasizes the convenience and safeguards attached to apparatus as fully as it does the physical claims made for such apparatus. The paramount question is not so much one of the most suitable method of raising the body temperature as of the safety to the patient with any particular method.

EXPERIMENTAL TRACHOMA IN MONKEYS

Conjunctival scrapings from trachoma patients are noninfectious for dogs, rabbits, guinea-pigs, rats or other laboratory animals. Four years ago, however, Julianelle¹ discovered that such conjunctival material causes a folliculosis if instilled into the eyes of monkeys. This experimental folliculosis usually lasts less than a year, though a few cases are on record in which the infection persisted for from two to three years in monkeys. Julianelle found that only about half of the cases of human trachoma are thus transferable and that approximately half of the monkeys are resistant to this experimental infection. On recovery from the experimental disease there is no demonstrable acquired anti-trachoma immunity in the monkeys.

Hetler and James² subsequently found that monkeys maintained on diets deficient in vitamin A, on inadequate proteins or on other food deficiencies are not more susceptible than normal monkeys to this experimental eye infection. In fact, their data suggest that monkeys in a state of malnutrition are more resistant to experimental trachoma than are monkeys maintained on adequate diets.

All attempts to isolate and identify the trachoma-producing agent in human conjunctival scrapings have thus far failed.³ Numerous bacterial species have been isolated. Inoculation of the bacteria thus cultivated, either individually, pooled or in conjunction with Berkefeld filtrates of conjunctival material, is invariably without pathogenic effects on monkeys.

These failures suggest that the agent causing trachoma is not bacterial. Methods, therefore, have been sought to free infectious conjunctival material from all bacterial contaminants. The most successful method to date is intratesticular inoculation into rabbits. Pooled conjunctival material from trachoma patients is collected in infusion broth and injected in 0.5 cc doses into the testicles of normal rabbits. From one to two weeks later the inoculated testicle is removed.

¹ Evidence Required by the Council on Physical Therapy for Consideration of Apparatus Used in Fever Therapy, this issue, p. 1041.

aseptically and emulsified in a sterile mortar. The resulting emulsion is almost invariably free from demonstrable bacteria but is still highly infective if introduced into the conjunctival sac of monkeys. Bacteria-free infectious material produces no demonstrable inflammatory reaction in rabbit testicles. The presumably specific trachoma-producing agent usually remained active in the rabbit testicle for from one to two months.

Attempts to cultivate the infectious agent have thus far proved unsuccessful. Minced rabbit kidney, minced chick embryo, the developing chick egg, and various tissue fragments in homologous plasma have been repeatedly tried. More than a thousand such trials have failed to show evidence of multiplication. Numerous characteristics of the presumptive virus, however, have been determined. Exposure to from 45 to 50 C for fifteen minutes regularly inactivates infectious material. Monkey infectivity is usually lost as a result of three or four days' storage at room temperature. Glycerin is not an effective preservative for this agent. Two per cent cocaine, 2 per cent silver nitrate, 0.25 per cent phenol, 1:1,000 antimony and potassium tartrate or 1:100,000 gentian violet each kills or otherwise inactivates the virus in from three to four hours. Blood from patients with trachoma contains no demonstrable neutralizing or inactivating antibodies.

There is no apparent correlation between the presence or absence of epithelial inclusions with rhesus infectivity. Conjunctival scrapings containing numerous inclusion bodies are not necessarily infectious. Material lacking all demonstrable inclusions is at times highly infectious. Epithelial inclusions have never been found in monkeys successfully inoculated with trachoma material or in infected rabbit testicles.

UTILIZATION OF VITAMIN A AND CAROTENE

The intimate relationship between the plant pigment carotene and the indispensable accessory food factor known as vitamin A is well founded. Carotene is absorbed from the intestinal tract and is changed into vitamin A in the body. The vitamin A potency of plant material is largely due to carotene, whereas that of animal products is to a greater or less extent accounted for by vitamin A itself. Chemically it is reasonably well established that the molecule of the hydrocarbon beta-carotene gives rise to two molecules of the primary alcohol vitamin A. The two compounds exhibit definite differences in chemical and physical properties, yet their effect in the organism is so similar that the accepted international standard for vitamin A is 0.6 microgram of beta-carotene.

Although both these compounds are soluble in fats and in the so-called fat solvents, an increasing mass of evidence indicates that the extent of absorption is rather

widely different. One of the early demonstrations¹ of the difference between carotene and vitamin A in the organism rests on the effect of liquid petrolatum on the absorption of these compounds, apparently vitamin A itself is satisfactorily utilized in the presence of liquid petrolatum, whereas carotene is not absorbed from the intestine when liquid petrolatum is present and can be recovered in the feces. Somewhat later Greaves and Schmidt² showed experimentally that, when the bile was shunted from the small intestine to the colon, symptoms of vitamin A deficiency were not alleviated by orally administered carotene, whereas under the same conditions vitamin A itself was effective. Similar results obtained with jaundiced animals support the view that, whereas vitamin A can be absorbed from the intestine in the absence of bile, the presence of this body fluid is essential to the utilization of carotene given by mouth. Another study³ with normal animals fed large doses has shown that vitamin A is better absorbed than carotene. In a study of some Indian foods containing vitamin A and carotene, De⁴ compared the amount ingested with that excreted in the feces to secure the extent of absorption. Vitamin A itself was almost completely absorbed, whereas only 45 to 65 per cent of the carotene ingested disappeared from the intestine. Whether or not all the carotene which disappears from the intestine and is not recovered in the feces is absorbed remains more or less uncertain, yet the calculations of De on the basis of his investigation would indicate that this assumption is correct. Thus the fate of vitamin A and of carotene in the mammalian gastrointestinal tract is not entirely the same.

The most recent evidence bearing on the point under discussion is of further interest because the observations were made on several species. Guilbert, Miller and Hughes⁵ used cattle, sheep and swine in their studies of the minimum vitamin A requirement to prevent night blindness. Carotene was provided by alfalfa and by crystalline carotene, vitamin A was administered as cod liver oil. After careful evaluation of the potencies, these adjuvants were fed on the weight basis. The results show that hemeralopia is prevented in these species by from 6 to 8 micrograms of vitamin A as such or by from 25 to 30 micrograms of carotene per kilogram of body weight, indicating again the superiority of vitamin A per unit of weight when given by mouth. With the advent of more highly purified vitamin concentrates in some cases and of synthetic vitamin crystals in others, therapeutic use of these food factors may now approach quantitative dosage more closely than ever. Not only should the requirement be known within practical limits, but attention should be

given to the peculiar behavior of the various factors in the gastro-intestinal tract as well as after absorption. It would seem that the biologic assay still has practical value in pointing out the virtues and drawbacks of some of the food factors in relation to the mode of administration.

Current Comment

SAFE PROCESSES FOR INSTITUTIONAL CANNERS

Two years ago THE JOURNAL called attention to the problem of safety in the home canning of foods.¹ Complete eradication of *Clostridium botulinum* from home canned products is largely a matter of education of the housewife to the necessity of pressure cooking for the "nonacid" products. These are all products in which the hydrogen ion concentration is more alkaline than p_H 4.5. The "acid" products include chiefly tomatoes and citrus fruits. The revised Farmers' Bulletin 1762, issued by the Department of Agriculture,² provides an inexpensive and reliable guide for the proper processing of home canned foods. Recommendations for the canning of foods on an institutional scale are provided in a newly revised publication³ from the Research Laboratory of the National Canners Association. A perusal of this bulletin emphasizes once more the highly technical nature of present day adequate canning procedures. Suitable precautions should be observed by institutional canners who pack seasonal products for consumption by inmates of hospitals, asylums and prisons. Successful canning of acid foods such as tomatoes can be easily attained. Destruction of pathogenic organisms in such products may be accomplished by processing in boiling water long enough to attain a temperature at the center of the container of about 200 F. The nonacid foods, however, are more subject to spoilage by heat-resistant organisms which develop anaerobically in the can unless the food has been subjected to a heat treatment adequate to insure their destruction. Probably the most dangerous pathogenic anaerobe known is *Clostridium botulinum*, and commercial heating processes are calculated to be severe enough to destroy the spores of this organism. Sometimes it is necessary to subject a food product to a more prolonged heat treatment in order to prevent spoilage by other organisms which are even more resistant to destruction by heat than the pathogenic bacteria. Typical commercial processing times for the large size (No 10) cans at 240 F are forty-five minutes for beets and carrots, fifty-five minutes for peas and 180 minutes for cream style corn. These wide variations in the time required for heat processing are due to the differences in the rates at which heat penetrates into these various products. Other factors which determine the time of heat processing and which are adequately discussed in this brief guide book are the

temperature in the center of the container at the start of the process and the weight of the product in the can. It is interesting to note that with some products the position in which the can is heat processed in the retort is important. Spinach and similar greens that tend to stratify must be processed with the can in a horizontal rather than in a vertical position. Cans of asparagus must be heated with the spears in a vertical position. Other factors stressed in the bulletin and worthy of mention are strict observance to sanitation in the plant and prompt and rapid cooling of the cans to prevent later spoilage by thermophilic organisms. Bulletins of this type which provide full information about proper canning procedures are valuable safeguards to public health, and the canning industry is to be commended for its support of such publications. Directors of institutions which make a practice of preserving foods in metal containers would do well to give careful attention to the technical details provided in this bulletin.

SPIROCHETES IN THE PLACENTA

Since placental blood is often seronegative, even in known syphilis, any test that will lead to the positive detection of the disease in doubtful cases is of great importance. Recently Dorman and Sahyun¹ of the American University of Beirut, in Syria, examined 145 placentas by means of a modified Levaditi silver impregnation technic and demonstrated spirochetes that corresponded morphologically to *Spirochaeta pallida*. The placentas examined were chosen because of a suggestive history, a positive serum reaction, stillbirth, prematurity, placenta praevia, abortion, cesarean section or any other suggestive lesion. By using twin block sections, one for paraffin inclusion and the other for silver impregnation, these investigators were able to select from the paraffin sections stained with eosin and hematoxylin the areas most likely to contain the spirochetes. Their method was to find blood vessels showing mild periarteritis and endarteritis, which is known as Warthin's criterion. In the corresponding block treated with the silver method, foci were observed which took a pale yellow stain and were surrounded by a dark, powdery deposit. The organisms were found in and around these foci, usually near the amniotic surface of the placenta. In nineteen of the 105 "positive" placentas the spirochetes were "numerous," in fifty-one "moderate" and in thirty-five "few." Yet in 53 per cent of the mothers no external stigmas of syphilis could be found. Sixty-one per cent of the mothers had been delivered of full-term living children in previous pregnancies, the others had histories of abortions, stillbirths, neonatal deaths, premature labors or fetal abnormalities. Thirty of the mothers had had varying amounts of antisyphilitic treatment during this pregnancy. Even in some of these the spirochetes could be demonstrated in the placenta. This method should be confirmed and the spirochetes positively identified as *Spirochaeta pallida*.

CARE OF THE INDIGENT SICK

Changes in the administration of medical service are usually urged for the benefit of the indigent, in modern governmental plans these are the last persons considered. Sickness insurance, "medical cooperatives," group hospitalization and all the prepayment schemes offer nothing to the unemployed or indigent. They have no funds to contribute, no wages from which deductions can be made for the support of organizers, administrators, solicitors or propagandists. The indigent have until recently been left to the care of salaried physicians, most of whom were political appointees. The quality of the services was long a public scandal. Organized medicine, almost alone, demanded decent medical service for the poor. When millions became indigent, abuses were so multiplied that they could no longer be overlooked and some of the professional proposals were adopted. Wherever organized medicine was consulted, the poor chose their physicians and service was supervised to insure good standards. The gratuitous services of practicing physicians have always been the main source of supply for medical service to the indigent. Physicians seldom complained of this burden. More recently they have welcomed aid from public funds or private philanthropy when this was not accompanied by the kind of lay control which depreciates the value of medical service. Most proposals for new schemes of medical service to the indigent would begin by depreciating the quality of the service. Fortunately, most of these schemes have never materialized. Just about 90 per cent of the plans that have actually gone into operation and have supplied any additional service to the poor have been proposed, directed and operated by organized medicine.

SALT, DIARRHEA AND INTESTINAL FLORA

Numerous observers have reported intestinal disturbances in animals deprived of inorganic salts. According to Eppright and her co-workers,¹ diarrhea produced in rats by salt deprivation is associated with a replacement of the normal intestinal flora by irritating or potentially toxic bacterial species. With normally fed rats or with rats on a synthetic ration plus adequate salt (i.e., the Mendel salt mixture) *Bacillus acidophilus* is the dominant intestinal micro-organism. About 300,000,000 viable acidophilus bacteria per gram are found in the feces under those conditions. Micro-organisms of the coli-proteus or streptococcus groups are usually absent or are present in only small numbers. On changing to a low salt diet, however, acidophilus bacilli gradually disappear and are replaced by micro-organisms of the coli-proteus and streptococcus groups. Within fourteen days this new intestinal floral balance is usually established. Calcium and phosphorus added to the low salt ration causes a suppression of the abnormal coli-proteus flora and a reappearance of the normal acidophilus counts. Neither calcium nor phosphorus alone, however, is sufficient. *Bacillus acidophilus* given by mouth to rats is not retained on a low salt diet, this fact suggests that success in implanting *Bacillus acidophilus* in man is due to the large amounts

of calcium and phosphorus contained in acidophilus milk. Eppright found that sodium and potassium chlorides are not effective as correctives of low salt diets. Nor will withdrawal of sodium or potassium ions from the Mendel salt mixture lead to an appreciable change in the normal intestinal flora.

GIANT CELLS IN MEASLES

The frequent finding of characteristic giant cells in the lymphatic tissues during the prodromal stages of measles has stimulated renewed interest in the etiology of this disease. The pathologic anatomy of measles has been confined in great measure to a study of the skin exanthem, Koplik's spots and lung complications. But in 1911 Alagna¹ reported the presence of peculiar collections of nuclei, resembling those in the megakaryocyte, without distinct protoplasm found in the enlarged faucial tonsils of children dying at the height of the exanthem. These observations were unheeded until 1931, when Warthin² and Finkeldey³ simultaneously and independently rediscovered the giant cells in the tonsils, and 1932, when Finkeldey⁴ saw them in the vermiform appendix. These observations have been substantiated by Davidsohn and Mora,⁵ Herzberg,⁶ Fischer,⁷ Schultze,⁸ Hathaway,⁹ and more recently Wegelin.¹⁰ The giant cells, irregular in shape, are about 100 microns in diameter and may contain as many as seventy to a hundred chromatin rich nuclei, which are often pyknotic and fragmented and which occur as grapelike masses in the center of the cell. The cytoplasm is basophilic, in places finely granular or foamy. Phagocytosis of lymphocytes and nuclear remains is occasional. The cells are found in the germinal centers, in the lymphoid tissue between them, or subepithelially and occur in the adenoids, the spleen and the peribronchial, retroperitoneal, peripancreatic and mesenteric lymph nodes in addition to the tonsil and appendix. Davidsohn and Mora state that they are rarely seen in lymphoid tissue draining regions of severe inflammation. They are found most abundantly during the prodromal stage and less during the active disease, a fact that harmonizes, interestingly enough, with the studies by Tunnichiff, Duval, Hibbard and others of a green-producing diplococcus, which is isolated from measles patients most easily in the prodromal stages. Warthin thought that the giant cells arose by amitotic division from hyperchromatic cells resembling lymphocytes in the germinal centers. Their presence is thought to be a specific reaction against invasion to the measles virus.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES NEW HOSPITALS EDUCATION AND PUBLIC HEALTH)

ARIZONA

Personal—Dr. Ruiland W. Hussong, health officer of Phoenix, has resigned, effective September 1, to enter private practice, according to *Southwestern Medicine*.—Dr. Stanley L. Moleski, Grand Rapids, Mich., has been appointed health officer of Yuma County on a full time basis. He succeeds Dr. Calvin A. Eaton, Yuma, who held a temporary part time appointment.

Harlow Brooks Clinical Conference—The second Harlow Brooks Memorial Navajo Clinical Conference was held at Sage Memorial Hospital, Ganado, September 3-4. Speakers included:

Dr. Fred H. Albee, New York: Importance of the Liver at the Top of the Femur and Its Surgical Reconstruction.
Dr. E. Payne Palmer, Phoenix: Cancer Among the American Indians.
Dr. Thomas G. Orr, Kansas City, Mo.: Treatment of Appendicitis and Its Complications.
Dr. Richard H. Pousma, Rehoboth, N. M.: Observations on the Work Being Done in European Clinics.
Dr. Edwin Forrest Boyd, Los Angeles: Mistaken Diagnosis.
Dr. Victor S. Randolph, Phoenix: Collapse Therapy in Tuberculosis.
Dr. Joseph M. Greer, Phoenix: Some Phases of the Work for Crippled Children in Arizona.
Dr. Clarence E. Yount, Prescott: Emergency Treatment of Fractures.
Dr. Arthur C. Carlson, Jerome: Open Reduction of Fractures.

New General Hospital for Care of Indians—A new \$450,000 base hospital for Navajo and Hopi Indians is scheduled for completion November 5 at Fort Defiance. There will be private rooms, wards, isolation wards, a maternity unit, and a nursery with facilities for fourteen patients. According to Dr. William W. Peter, Window Rock, medical director of the Navajo-Hopi areas, the hospital will provide for 130 patients.

The new general hospital for Indians

without overcrowding. The Navajo-Hopi reservation of 25,000 square miles is the largest of 199 Indian reservations in twenty-two states. It has a total population of about 45,000 Navajos and 3,000 Hopis. In this area there are ten hospitals with 344 beds and three sanatoriums with 129 beds. For these thirteen institutions and attending field work there are twenty-one physicians, seventy-three nurses and 195 other employees. Of these 289 medical employees, 148 are Indian and 141 are white. The supporting appropriations from federal funds this year amount to \$530,408. Formerly, when administratively there were five Navajo agencies, each with a superintendent, the medical personnel and programs were organized separately. With the consolidation in 1933 into one Navajo agency, the medical work was also unified. There is now only one medical service embracing all hospitals, sanatoriums and funds under the administrative supervision of a medical director. Through having a larger medical and nursing personnel and more extensive laboratory, medical and surgical equipment than are available in the smaller hospitals, the new base hospital at Fort Defiance is to serve the entire Navajo-Hopi area through receiving difficult cases maintaining a central laboratory service, training new appointees and by occasional area clinics and refresher courses. According to *Southwestern Medicine* the old hospital will be converted into a tuberculosis sanatorium.

CALIFORNIA

Society News—Dr. Howard F. West, Los Angeles, addressed the San Diego County Medical Society, September 14, in San Diego, on "Deficiency States Arising in the Course of Chronic Disease".—Dr. Irvin Abell, Louisville, Ky., President-Elect, American Medical Association, will discuss "The Responsibilities of the Profession" before the Los Angeles County Medical Association, September 30.

Regulate Use of Sulfanilamide—An executive order issued August 26 by Dr. Jacob C. Geiger, director, San Francisco Department of Health, emphasizes the criteria to be followed by clinicians in the department and its institutions in the use of sulfanilamide in certain infections, especially in children. Concerning the drug, the order states:

There must not be any indiscriminate use.
There must be a clear indication for its use.
The ordinary care and routine treatment must have been used and found inefficient.
Patients must be carefully watched for evidence of (1) liver injuries (2) blood cell injuries and (3) cyanosis.

It was stated that the drug may be rapidly excreted and that recovery from such injuries are prompt. In other words this drug must be administered with care as to dosage in relation to body weight, and only by physicians who have all the laboratory facilities for careful observation of the patient.

DISTRICT OF COLUMBIA

Hospital News—Dr. Vincent J. Dardinski, professor of anatomy and director of the department of anatomy, Georgetown University School of Medicine, has been appointed full time pathologist and director of the laboratories of the University Hospital. Dr. John R. Cavanagh, associate clinical professor of medicine at the university, will become director of the outpatient department of the hospital, and Dr. Frank S. Horvath, associate professor of clinical medicine, will be assistant director and supervisor of student instruction in the outpatient department.

Personal—Dr. John B. Nichols, president of the Medical Society of the District of Columbia in 1912, was honored recently on his completion of thirty-five years of service as medical director of the Acacia Mutual Life Insurance Company.—Dr. William DeKleine, medical director of the American National Red Cross, recently received the honorary degree of doctor of science from Hope College, Holland, Mich., from which he was graduated in 1902.—Dr. Carl C. Dauer, formerly assistant professor of preventive medicine, Tulane University Graduate School of Medicine, New Orleans, has been appointed assistant epidemiologist of the District health department.

ILLINOIS

Bacillary Dysentery at Dixon State Hospital—Thirty deaths and 225 cases of bacillary dysentery have occurred at the Dixon State hospital for mental defectives since the first of the year, the newspapers reported September 10. At that time eighty-one persons were under quarantine and all the 3,200 patients in the hospital were being examined for symptoms and signs of the disease.

INDIANA

Personal—Dr. Henry G. Steinmetz, assistant superintendent of the Logansport State Hospital for the last three years, has been appointed supervisor of health in the sixth district, composed of Monroe, Lawrence, Brown, Morgan and Johnson counties, with headquarters at Indiana University, Bloomington.

Fifty Years of Practice—The Fourth District Medical Society and the Tri-County Medical Society (Jackson, Jennings and Bartholomew counties) gave a dinner, August 4, at the Muscatatuck State Park Inn, in honor of Dr. William H. Stemm, North Vernon, who has completed fifty years in the practice of medicine. A watch was presented to Dr. Stemm and also to Mrs. Stemm. The speakers included Drs. Charles E. Gillespie, Seymour, Herman M. Baker, Evansville, president-elect of the state medical association; George E. Denny, Madison, James K. Hawes, Columbus; Evan C. Totten, Madison, and Edmund D. Clark, Indianapolis, president of the state association, and Senator Thomas A. Hendricks, Indianapolis, executive secretary of the state medical association. A graduate of the Medical College of Ohio, Cincinnati, Dr. Stemm once served as mayor of North Vernon and, in 1914, as president of the Jennings County Medical Society. He was president of the state medical society in 1918-1919 and has also served as counselor of the fourth district.

IOWA

Activities of Speakers' Bureau—Four graduate courses are being given this fall by the speakers' bureau of the Iowa State Medical Society, one on cancer at Cedar Rapids, one on general therapeutics at Algona, and one on endocrinology and metabolism at Waterloo and Shelton. The bureau will also present a series of lectures on medicine and health to the students of Luther College at Decorah and Wartburg College at Waverly. The course at Luther College will carry through the year, with one talk every three or four weeks, while the talks at Wartburg College will be given twice a week during October.

KENTUCKY

Personal—Dr Derric C Parmenter, formerly of Greenup and recently in charge of public health work in Greenup County, has been appointed health officer of Breathitt County, with headquarters at Jackson. Dr Randolph Compton, Louisville, has been appointed in Greenup County—Dr Raymond E Wehr, Bedford, has been transferred from Johnson County to Trimble County as health officer.

Society News—Dr Douglas E Scott, Lexington, addressed the Harrison County Medical Society, Cynthiana, recently, on "Treatment of Specific Urethritis"—Dr R Hayes Davis, Louisville, addressed the Grant County Medical Society, Wilhamstown, recently, on "Functional Diseases"—Dr Irvin Abell Jr, Louisville, addressed the society recently on "Pitfalls in the Diagnosis of Acute Appendicitis"—Drs Walter E Vest and Frank C Hodges, Huntington, W Va, addressed the Pike County Medical Society in Pikeville recently on "Dyspepsia in Diagnosis" and "Pathologic Forms of Appendicitis" respectively—Dr Richard R Elmore, Louisville, among others, addressed the Jefferson County Medical Society, Louisville, September 20, on "The Value of Blood Sedimentation Tests"—Dr Chapman S Moorman addressed the Louisville Urological Society, September 21, on "Care of the Prostatic Patient."

LOUISIANA

Personal—Dr James T Nix, director since 1936 of the Louisiana State University Graduate School of Medicine New Orleans has been appointed dean, according to the New Orleans *Times-Picayune*, August 21. He graduated from Tulane University of Louisiana School of Medicine, New Orleans, in 1910—Dr Walter W Pombouéuf, Bastrop, has been appointed health officer of Claiborne Parish, succeeding Dr Harry R Marlatt, Homer, resigned. The change was effective August 1, it was reported.

MICHIGAN

Examination of Applicants for Marriage—The new law in Michigan requiring examination of persons applying for licenses to marry will become effective October 29. It is announced. Under the law, applicants will be required to submit to medical examination including blood tests, not more than fifteen days before applying for a license. A health certificate will be required before county clerks may accept license applications, it was stated.

Status of State Psychopathic Hospital Changed—By a recent enactment of the state legislature, the status and name of the state psychopathic hospital, Ann Arbor, have been changed. The unit will henceforth be known as the Neuropsychiatric Institute of the University Hospital and will function as an integral part of the University Hospital. According to the University Hospital *Bulletin* there is to be a change in the type of patients to be admitted to the institute in that it will no longer be a hospital for committed patients but in the future all admissions are to be voluntary and, in the main non-psychotic persons.

MISSOURI

Annual Fall Clinical Conference at Kansas City—The fifteenth annual fall clinical conference of the Kansas City Southwest Clinical Society will be held at the Municipal Auditorium, Kansas City, October 4-7. Guest speakers will include:

- Dr Fred M Smith Iowa City Concerning the Problem of Gallbladder Disease
- Dr Richard H Jaffe Chicago Pathology of Jaundice
- Dr Owen H Wangenstein Minneapolis Significance of Mechanical Factors in the Genesis of Acute Appendicitis
- Dr Paul B Magnuson Chicago Backache
- Dr Alfred E Barclay Oxford England Practical Importance of Mechanics in Digestion
- Sir George Lenthal Cheatle London England Cystic Diseases of the Breast
- Dr Robert A Strong New Orleans Significance of Vomiting in Infancy
- Dr Otto H Schwarz St Louis Prevention and Treatment of Eclampsia
- Dr Herman L Kretschmer Chicago Present Status of Transurethral Prostatic Resection in the Treatment of Bladder Neck Obstruction
- Dr Bernard L Wyatt Tucson Ariz Role of the General Practitioner in the Field of Arthritis
- Dr Frederick A Collier Ann Arbor Mich Surgery in Diabetes
- Dr Richard B Cattell Boston Diagnosis and Management of Surgical Diseases of the Biliary Tract
- Dr Arnold S Jackson Madison Wis The Injection Treatment of Hernia
- Dr William D Gill San Antonio Texas Paranasal Sinuses and Their Relation to Ocular Diseases
- Dr Max Cutler Chicago Tumors of the Breast—Diagnosis and Treatment

There will be a public health meeting Monday evening with the following speakers: Rev Burriss Jenkins Kansas City, on "The Layman's View of the Medical Profession," Dr Strong,

"Preventive Pediatrics" and Father Alphonse M Schwitalla, S J, St Louis, "The Patient and His Doctor." In addition to the general sessions there will be symposiums on industrial surgery, the heart circulation, lungs, urology and syphilis, obstetrics, gynecology and pediatrics, surgery, medicine, and proctology. The round table luncheons will be addressed Tuesday by Dr Barclay, the theme of his discussion to be "It is very, very wrong to doubt. What nobody is sure about." Wednesday, Dr George B Norberg, Kansas City, Mo., "Some of the Old and Some of the New" and Dr Kretschmer, "Tumors of the Kidney" and Thursday, Dr Ferris Smith, Grand Rapids, Mich., "Evolution of Plastic Surgery," and Dr Collier, "The Administration of Fluid." At the meeting of the Kansas City Society of Ophthalmology and Otolaryngology Thursday, Dr Smith will conduct a round table on "Management of Chronic Sinus Disease with Direct and Differential Diagnosis and Therapeutic and Surgical Treatment" and Dr Gill, a diagnostic clinic, in the evening they will speak on "Nasal Fractures" and "Fractures About the Orbit" respectively.

NEBRASKA

New Health Unit—A new health unit was to be established in Lincoln County, August 1, with headquarters at North Platte and with Dr Donald M Harris, Omaha, as director. The unit is to be financed with federal funds.

Society News—At a meeting of the Madison Six County Medical Society, Norfolk, July 20, the speakers were Drs Edgar V Allen and Lawrence M Randall, Rochester, Minn., on "Diseases of the Peripheral Blood Vessels" and "Irregularities of Menstruation and Menopause" respectively—At a meeting of the Cedar, Dakota, Dixon, Thurston and Wayne Counties Medical Society at Wayne August 3, Drs Archibald F O'Donoghue and Walter Scott, Sioux City, Iowa, spoke on backache and Dr Thomas R Gittins, Sioux City, on headache.

NEW YORK

Society News—Dr Otto Alois Faust, Albany, addressed the Medical Society of the County of Albany, September 22, on "High Calcium Values in Tetany of the New-Born"—The midyear meeting of the New York State Association of Public Health Laboratories will be held at the state laboratory in Albany, October 29.

One-Day Pneumonia Institutes—As a part of the pneumonia control program sponsored by the New York State Department of Health, the Medical Society of the State of New York is collaborating with the department and with the medical schools of the state in offering a series of one-day institutes for physicians on diagnosis and treatment, with special emphasis on serum therapy. Fifty physicians can be accommodated at each institute from the counties surrounding the cities in which they are given. The dates are as follows: Syracuse, October 12, Rochester, October 19, Buffalo, October 25, Albany, November 9, and New York, November 23. No fee will be charged, and the health department will reimburse expenses of those attending up to \$20 each. The institutes will consist of the following features: addresses by authorities on the disease; demonstrations of administration of serum, the taking of blood cultures and sensitivity tests; demonstration of the use of oxygen; informal discussions of individual problems; ward rounds on clinical material if available at the time; sound motion pictures illustrating serum treatment and nursing care. Dr Thomas P Farner, Syracuse, chairman of the state society's committee on medical education, is in charge of arrangements for the institutes.

New York City

Professor Sourdille to Lecture—Prof Maurice Sourdille of the faculty of the school of medicine at Nantes, France, will deliver an illustrated lecture on "New Technics in the Surgical Treatment of Severe and Progressive Deafness from Otosclerosis. Indications, Choice of Method and Results, A Report of More Than 300 Operations," before the section of otolaryngology of the New York Academy of Medicine at a special meeting October 6. The lecture will be in English.

Society News—Dr Russell M Wilder, Rochester, Minn., will address a clinical session of the New York Diabetes Association of the New York Tuberculosis and Health Association, October 15, on "Pathogenesis and Etiology of Diabetes"—Dr Jay Arthur Myers Minneapolis addressed a joint meeting of the Medical Society of the County of Queens and the Queensboro Tuberculosis and Health Association, September 22, on "Tuberculosis in Childhood"—A symposium on "Inflammatory Diseases of the Bronchi" will be presented at the eleventh clinical session of the Tuberculosis Sanatorium

Conference of Metropolitan New York, October 13, by Drs John Alexander, Ann Arbor, Mich., John D. Kernan and Oscar Auerbach.

Dinner to Dr. Snow—Friends of Dr. William F. Snow, general director of the American Social Hygiene Association are sponsoring a testimonial dinner for him at the Waldorf Astoria, October 1. The dinner will mark the fortieth anniversary of Dr. Snow's entrance into Cooper Medical College, now Stanford University School of Medicine, San Francisco. He was a member of the faculty of Stanford for many years and was epidemiologist and later executive officer of the California State Board of Health. He was appointed head of the social hygiene association in 1914. Dr. Snow was instrumental in the organization of the National Health Council and was its president from 1927 to 1934. He has also served as president of the Conference of State and Provincial Health Authorities of North America. During the World War Dr. Snow saw active service as a lieutenant-colonel in the Army Medical Corps and served as secretary of the General Medical Board of the Council for National Defense. Among other activities he was from 1924 to 1928 chairman of a committee of the League of Nations to study traffic in women and children.

NORTH CAROLINA

University News—Dr. Walter Reece Berryhill, formerly associate professor of pathology, physiology and physical diagnosis at the University of North Carolina School of Medicine, Chapel Hill, has been appointed assistant dean, associate professor of medicine and physician-in-chief to the university infirmary. James C. Andrews, Ph.D., formerly assistant professor of physiologic chemistry at the University of Pennsylvania School of Medicine, Philadelphia, has been made professor and head of the department of biological chemistry. Other appointments include those of Dr. Harold W. Brown of the U. S. Public Health Service, recently stationed at the malaria research laboratory, Savannah, Ga., as professor of public health and Dr. Russell L. Holman, New York, as assistant professor of pathology. Dr. Holman has been instructor in pathology at Columbia University College of Physicians and Surgeons. The appointment of Dr. William deB. MacNider as dean was announced in THE JOURNAL, August 21, page 594. Plans for a new building for the medical school and the division of public health, financed by a legislative appropriation and a PWA grant amounting to \$400,000, were announced.

NORTH DAKOTA

A Case of Anthrax—Newspapers recently reported a case of anthrax in a hospital at Mandan, said to be the first ever reported to the state department of health. It was said that four cows belonging to the patient had died of the disease.

OHIO

State Association Sponsors Graduate Lectures—The Ohio State Medical Association will begin a new project of regional graduate lectures October 21 in Findlay, with lectures on heart disease by Drs. Roy W. Scott, Cleveland, and William H. Bunn, Youngstown. The course for the first region will consist of eight sessions of two lectures each given at intervals of two weeks alternately in Findlay and Defiance. Lecturers for the later sessions have not been announced. All members of the association may attend and there will be no registration fee. The lecture project, which was arranged by a committee on education created by a revision of the constitution and by-laws of the association in 1936, will extend over five years. Identical courses will be given at different times each year in six regions of the state. The time will be divided among the various fields of medicine and surgery, and a natural sequence from one session to another and one year to another will be provided. Certificates of attendance will be issued at the end of the five-year course to members who have attended a certain percentage of lectures. Members of the committee on education are Drs. Clyde L. Cummer, Cleveland, chairman; Carl A. Wilzbach, Cincinnati; William Kelley, Hale, Wilmington; Harry S. Noble, St. Mary's; and Russel G. Means, Columbus. The subcommittee on regional postgraduate lectures is composed of Drs. Cummer, Noble, James M. Pierce and Cecil Striker, Cincinnati; Sterling H. Ashmun, Dayton; Louis N. Jentgen, Columbus; and Robert T. Allison Jr., Akron.

OKLAHOMA

Society News—The Four Counties Medical Society (Pottawatomie, Seminole, Hughes and Pontotoc counties) convened in Shawnee recently with the following speakers: all of Ada, A. Linscheid, Ph.D., president of the Central State Teachers' College on "General Education as Related to the Practice of

Medicine," Dr. William F. Dean, "Heart Disease in the Aged" and Dr. Robert E. Cowling, "Right Unilateral Pain in the Abdomen." Dr. Samuel A. McKeel, Ada, president of the Oklahoma State Medical Association, also spoke.

Faculty Appointments at Oklahoma University—The following appointments to the faculty of the University of Oklahoma School of Medicine, Oklahoma City, have been announced:

Berry Campbell, Ph.D., National Research Council fellow in comparative anatomy, Western Reserve University School of Medicine, Cleveland, to be assistant professor of anatomy.

Albert J. Sheldon, A.M., Johns Hopkins University School of Hygiene and Public Health, Baltimore, assistant professor of bacteriology and interim.

Francis C. Lawler, Emory Laboratory of Cancer Research, St. Luke's and Children's Hospital, Philadelphia, assistant professor of bacteriology.

Irvin S. Danielson, Ph.D., teaching fellow in biologic chemistry, Harvard University Medical School, Boston, assistant professor of biochemistry.

Dr. Arnold J. Lehman, instructor in pharmacology, Stanford University School of Medicine, San Francisco, assistant professor of pharmacology.

Dr. Ome Owen Williams, instructor in pathology, University of California Medical School, San Francisco, assistant professor of pathology.

PENNSYLVANIA

Personal—Dr. Elmer Highberger Jr., recently of Saranac Lake, N. Y., has been appointed medical director of the Grand View Sanatorium at Oil City. —Dr. William W. Bolton, Lansdowne, has been named director of the division of syphilis and genito-infectious diseases in the state department of health, succeeding Dr. Edgar S. Everhart. —Dr. Edward B. Shellenberger, who recently retired from the staff of the Danville State Hospital, was honored with a testimonial dinner given by the hospital staff in August.

State Medical Meeting in Philadelphia—The eighty-seventh annual session of the Medical Society of the State of Pennsylvania will be held in Philadelphia, October 4-7, at the Bellevue-Stratford. Guest speakers for general and section meetings include:

Dr. Thomas B. Turner, Baltimore, "The Biology of Syphilitic Infection."

Dr. Frank H. Lahey, Boston, "Duodenal Ulcer—Its Nonsurgical and Surgical Management."

Dr. Foster Kennedy, New York, "The Nervous Relationship of the Gastro-Intestinal Tract."

Dr. Russell L. Cecil, New York, "General Treatment of Pneumonia."

Dr. John Staige Davis, Baltimore, "The Use of Relaxation Incisions When Dealing with Scars."

Dr. Leroy A. Schall, Boston, "Laryngectomy—Its Place in the Treatment of Cancer of the Larynx."

Dr. Lewis Webb Hill, Boston, "Atopic Dermatitis in Infancy and Childhood."

Dr. Louis W. Sauer, Evanston, Ill., "Prevention and Treatment of Whooping Cough."

Dr. Joseph G. Hopkins, New York, "Common Fungus Infections of the Skin."

Dr. Oswald S. Lowsley, New York, "Further Experience with a New Principle in Kidney Surgery."

Dr. Jonas S. Friedenwald, Baltimore, "Clinical Studies in Slit Lamp Ophthalmoscopy."

There will be symposiums on behavior problems in childhood and on the common cold and round table conferences on allergy of the respiratory tract, anemia in infants and childhood bronchiectasis, nephritis in children, acid-base imbalance and care and feeding of the new-born.

WISCONSIN

The Hall of Health—The State Medical Society of Wisconsin at its annual meeting in Milwaukee sponsored an exhibit on medicine and public health for the public, called the "Hall of Health," September 11-17. The exhibit was arranged by the society's council on scientific work of which Dr. William S. Middleton, Madison, is chairman and Dr. Eben J. Carey, Milwaukee, is director of exhibits. Thirty-seven displays were included, employing many mediums and sponsored by numerous organizations. Marquette University School of Medicine had exhibits on embryology, blood vessels and cancer. The Wisconsin Anti-Tuberculosis Association, prevention of tuberculosis, the state board of health, state laboratory and the University of Wisconsin Medical School, laboratory diagnosis of disease. Wisconsin Crippled Children Division, prevention of deformities. Wisconsin Pharmaceutical Association, a modern pharmacy. The Camp Transparent Woman and the sculptural reproduction of Sir Luke Fildes' painting "The Doctor" were on view. The state dental society and the Marquette University Dental School emphasized care of the teeth. The state board of health illustrated its activities and the Medical Society of Milwaukee County explained its work. Exhibits prepared by the American Medical Association provided information on syphilis, cosmetics, posture, mechanical nostrums and "patent" medicines. Cancer was the subject of exhibits by the Wisconsin division of the Women's Field Army of the American

Society for the Control of Cancer, the American College of Surgeons and the department of pathology at Marquette University School of Medicine. The annual exhibit of physicians' hobbies arranged by the woman's auxiliary of the Medical Society of Milwaukee County was a part of the "Hall of Health." Other subjects treated included tooth ring analysis, mental hygiene, foods, occupational therapy, medical education, medical examinations, sight saving, nursing, Bright's disease, burns, anesthesia and rays.

GENERAL

Infantile Paralysis Funds from the President's Birthday Celebrations—The treasurer of the national committee for the birthday bills held January 29 in honor of President Roosevelt for aid in fighting infantile paralysis recently reported that about \$340,000 will be presented to the Georgia Warm Springs Foundation as its share in the funds raised this year from the parties. As of July 28 the treasurer, Mr. Keith Morgan, New York, said that 3,591 local committees had sent their remittances, most of which represented the 30 per cent of the proceeds of the balls, though some committees sent all their funds. Mr. Morgan resigned as treasurer of the committee to become vice president of the Warm Springs Foundation.

Silver Jubilee of Clinical Orthopaedic Society—The twenty-fifth annual meeting of the Clinical Orthopaedic Society will be held in Chicago, October 14-16, with headquarters at the Palmer House. Clinical sessions will be held at Cook County, Billings, Illinois Research, St. Luke's hospitals, and Thorne Hall at Northwestern University. An informal dinner will be held Thursday evening at the Palmer House and the annual banquet Friday evening. The meeting is in honor of Dr. John Lincoln Porter, Evanston, Ill., who founded the society twenty-five years ago when it was known as the Central States Orthopedic Club. In his honor, the John Lincoln Porter Lectureship in Orthopedic Surgery has been established, the first lecture to be given this year by Dr. Willis C. Campbell, professor of orthopedic surgery, University of Tennessee School of Medicine, Memphis, on "Malunited Fractures." Guests of the society during the meeting will include Drs. George E. Bennett, associate professor of orthopedic surgery, Johns Hopkins University School of Medicine, Baltimore; Arthur Bruce Gill, professor of orthopedic surgery, University of Pennsylvania School of Medicine, Philadelphia; and Philip D. Wilson, clinical professor of orthopedic surgery, Columbia University College of Physicians and Surgeons, New York.

American Public Health Association—Health Education Institute—The sixty-sixth annual meeting of the American Public Health Association will be held in New York, with headquarters at the Hotels Pennsylvania, New Yorker and McAlpin, October 5-8. The preliminary program includes the following speakers:

- Dr. Halbert L. Dunn, Washington, D. C., The Adaptation of the International List of Causes of Death to the Changing Needs of the Medical Profession and Public Health Groups
- Dr. Henry B. Elkind, Boston, Is There an Epidemiology of Mental Disease?
- Dr. Wade H. Frost, Baltimore, Familial Aggregation of Infectious Disease
- Dr. Royd R. Sayers, U. S. Public Health Service, Syphilis Control in Industry
- Dr. Thomas M. Rivers, New York, Lymphocytic Choriomeningitis
- Dr. Frank G. Boudreau, New York, International Cooperation in Hygiene
- Dr. Gaylord W. Anderson, Minneapolis, Present Status of Scarlet Fever Prevention

A public meeting will be held Friday afternoon, the speakers to include Mr. Homer Folks, New York, on "The Social Significance of the Health Center," and Dr. Iago Galdston, New York, Individual Preventive Medicine." At a session on public health education Thursday, Mr. Myron Weiss, New York, associate editor of *Time*, will speak on "The Box-Office Appeal of Health Movies." The winner of the Sedgwick Memorial Medal Award will be announced Tuesday when an address will be delivered by Dr. Livingston Farrand, former president of Cornell University, Ithaca, N. Y. Other organizations meeting at this time include the American Association of School Physicians, Association of Women in Public Health, American Association of State Registration Executives, biometric section of the American Statistical Association, Conference of State Sanitary Engineers, Public Health Association of New York City and National Society for the Prevention of Blindness.

The fifth Health Education Institute to be conducted by a committee of the public health education section of the association, will be held October 3-5. The program aims to give the

major objectives and principles of community health education and to provide information about techniques involved and the application of these methods in specific public health activities.

Academy of Ophthalmology and Otolaryngology—The forty-second annual convention of the American Academy of Ophthalmology and Otolaryngology will be held in Chicago at the Palmer House, October 10-15, under the presidency of Dr. Lee Wallace Dean, St. Louis. The meeting will begin with a joint session Monday morning, October 11, at which Dr. Harris P. Mosher, Boston, will be the guest of honor and will make an address. There will also be a symposium on physical therapy presented by Drs. Arthur U. Desjardins, Rochester, Minn.; John S. Coulter and Sanford R. Gifford, Chicago; and John L. Myers, Kansas City, Mo. Mornings thereafter will be devoted to instructional courses. In addition to individual courses with a large number of instructors there will be three special courses on histopathology of the eye, histopathology of the ear, nose and throat, and anatomy of the eye and orbit. The scientific sections, ophthalmology and otolaryngology, will meet separately on alternate afternoons, with the following speakers, among others:

- Dr. Louis Bothman, Chicago, Refractive Errors in the Same Eyes While Under the Influence of Homatropine, Scopolamine and Atropine
- Olof Larssell, Ph.D., and Dr. Ralph A. Fenton, Portland, Ore., Lymphatic Transmission of Bacteria to the Lung
- Drs. Frank R. Spencer, Boulder, Colo., and William C. Black, Denver, Malignant Diseases of the Nasal Accessory Sinuses with Review of Nine Cases
- Dr. Austin A. Hayden, Chicago, Audiometers and Hearing Aids—Minimum Standards
- Dr. Julius Friedenwald and Miss Clara M. McKee, Baltimore, Uveitis Due to a Filtrable Virus
- Dr. Albert N. B. Lemoine, Kansas City, Mo., Eye Manifestations of Endocrine Disturbances
- Dr. Varaztad H. Kazanjian, Boston, Plastic Repair of Deformities About the Lower Part of the Nose Resulting from Loss of Tissue

The Thursday afternoon session will be a panel discussion of "Septic Thrombophlebitis of the Sigmoid Sinus," with Dr. Lee Wallace Dean, St. Louis, president of the academy, as chairman. Tuesday evening there will be a joint session with the American Speech Correction Association. Dr. and Mrs. Dean will hold the annual president's reception Sunday afternoon, October 10, in the Red Lacquer Room of the Palmer House in honor of Dr. and Mrs. Mosher, members of the academy and their guests. The annual banquet and dinner dance will be Wednesday evening and "an evening of diversion" will be presented Thursday evening. Alumni dinners will be held Tuesday evening. Friday will be devoted to a golf tournament at Olympia Fields.

FOREIGN

International Trachoma Meeting—During the meeting of the International Council on Ophthalmology in Cairo, Egypt, December 8-14, there will be a meeting of the International Organization Against Trachoma. Subjects to be discussed include microbiologic etiology, pathology and treatment of trachoma and special reports on the disease in various countries. The French Line, Compagnie Generale Transatlantique, 610 Fifth Avenue, New York, recently announced several trips in connection with these congresses to Alexandria and upper Egypt, Palestine and Syria. Information will be sent on request to physicians interested in the trips.

Society News—The International Hospital Association at its meeting in Paris July 11 voted to hold its 1939 congress in Toronto, Ont., the time and place to be decided later. The French League Against Rheumatism has arranged an "International Day on Rheumatism" to be held in Paris in connection with the exposition, October 9. The subject of discussion will be radioactive medication in the therapy of rheumatism and gout. A meeting will be held in the morning at L'Hopital Antoine and in the afternoon at the Faculty of Medicine. Information may be obtained at the Secretariat of the League, 23 Rue du Cherche-Midi, Paris VI.

Cholera in China War Zone—It is reported that cholera is epidemic in the war zone in China, 1,018 cases having been reported in Shanghai up to September 17. *Science* reported September 10 that Dr. Howard F. Smith, chief quarantine officer of the U. S. Public Health Service quarantine station at Manila, had gone to Hong Kong to take charge of the situation as it concerns the United States and to assist local health authorities in control measures. Dr. Smith cabled that there had been 802 cases, with 427 deaths, in the Hong Kong area up to August 24. Ships bound for the United States from the Orient are ordered to stop at Honolulu for inspection if there is any unusual illness aboard and west coast quarantine stations have been notified to be on the alert to detect cases or carriers promptly.

The Risks of Explosion in Anesthesia

In recent years, cases of explosion during the use of anesthetics have been recorded from time to time in this country and in America. The *British Medical Journal* has published a useful review of the subject. In the *British Journal of Anaesthesia*, Coste and Chaplin have published some investigations made to discover under what conditions anesthetic vapors become explosive. They found that a mixture of ethyl chloride and air is inflammable when the proportion of the former lies between 5 and 20 per cent and that in the case of ether vapor and air a concentration of from 2 to 8 per cent can be ignited. If ether vapor is mixed with nitrous oxide the risk of explosion is doubled, as any concentration of ether between 15 and 16 per cent is inflammable, much the same is true of oxygen and ether. Vapor produced by bubbling oxygen, with or without nitrous oxide, through ether in Boyle's machine or Shipway's apparatus produced a very inflammable mixture, even if the gases were passed through the chloroform bottle as well, it was still possible to explode the mixed vapors. On the other hand the risks of explosion in open ether anesthesia were found to be very slight. Samples of air taken at a distance of 2 inches from the patient's mouth contained too small a percentage of ether to ignite. Both ethylene and acetylene proved explosive when mixed with oxygen for purposes of anesthesia and cyclopropane too was a source of danger.

Of more importance to the anesthetist is the spark which may explode the anesthetic mixture. A red hot cautery or a diathermy electrode is an obvious danger. Less obvious dangers are electric light bulbs on esophagoscopes or bronchoscopes. If the insulation is faulty, a spark may arise. A hot dental needle has produced an explosion though its temperature was below that required to produce red heat. Static electricity is another source of danger and has attracted attention in this country and America. The mere movement of blankets over metal operating tables may produce considerable static voltages. The rubber wheels of trolleys provide sufficient insulation to allow dangerous charges to accumulate. It has been recommended to prevent this by earthing the metallic equipment by a light chain trailing to the floor of the operating room. Another method, which is being investigated by the National Physical Laboratory, is the use of electrically conducting rubber for tires, tubing and breathing bags.

A Study of the Mode of Action of Radiation

The Medical Research Council has published a report entitled "Some Quantitative Aspects of the Biological Action of X and Gamma Rays," by Dr. C. M. Scott, who has reviewed the literature of the subject and made experiments on the action of γ -rays on the isolated frog's heart and on the eggs of *Calliphora erythrocephala* (the common bluebottle fly). The rapidity of advances in the radiotherapy of malignant disease has outstripped scientific knowledge, so that this method is largely empirical. The measurement of the doses of radiation is of great practical importance but is much more difficult than measurement of the dosage of drugs. One of the chief points brought out by this report is the extraordinary variations which living cells display as regards their susceptibility to radiation. Thus the radiation required to kill the adult fruit-fly (*Drosophila*) is several thousand times greater than that needed to kill its eggs. The general argument running through the report is that any explanation of the mode of action of radiation on cells must take into account this variation in sensi-

tivity, and many attractive theories regarding the action of radiations break down in face of this difficulty. The evidence marshaled by Dr. Scott supports the view that the fundamental action of radiations is on the nucleus of the cell and thereby on the processes of growth.

The destructive effect on the cell produced in radiotherapy differs entirely from that produced by other agents, such as cold and chemical substances. These destroy all living tissues indiscriminately. So do α and gamma rays in doses of the order of 100,000 roentgens. But doses of the order of 1,000 roentgens, i. e., of the therapeutic order, have a selective action on the nuclei of dividing cells. No physicochemical explanation of this action can be given, it is a biologic action that stands alone. It is a graded action, depending on dose and ranges from completely reversible inhibition of growth to an inhibition which results in the death of the cell.

APPARENT STIMULATION AFTER IRRADIATION

The question whether irradiation has another type of biologic action, namely, an accelerating one on cellular activities, particularly on cellular division, has been often debated. Many surgeons hold that a tumor which has been given an insufficient dose of radiation may grow much more rapidly and that metastases may form more readily. This has been called "the stimulant action of radiations." After reviewing the evidence, Packard concluded that "radiations do not directly stimulate normal activities of the cell, their primary effect is always an injury from which the cell may recover perfectly." According to this view, any acceleration of normal cell processes is temporary and is followed by retardation. But long continued exposure is a different matter. It is well known that malignant tumors arise in the skin of radiologists who have been exposed to small doses of radiation over periods of years. In 1932 Ross described a case in which a radium needle accidentally became embedded in the interventricular septum of a woman's heart. Three years afterward a malignant tumor developed in the liver near the site of the needle. Malignant tumors have also been experimentally produced in animals by prolonged irradiation. In the human skin such tumors are always preceded by obvious injuries, chronic inflammation and atrophy, for example. It may therefore be questioned whether the tumor is due to a direct action of the rays on the cells or is a result of the chronic inflammation and therefore only an indirect result.

THE TIME FACTOR

Clinical evidence shows that cells can tolerate a larger amount of radiation administered in small doses over a long period than they can tolerate in one big dose or in a few big doses administered over a short period. For any given dose of radiation the longer the time over which its administration is spread, whether by reducing its intensity or by administering in fractions, the less its effects. But in the treatment of deep seated tumors the tolerance of the skin has to be considered and this limits the intensity that can be used. Hence in all the methods the radiation is spread over a long time. The destruction of a tumor by a very short exposure to an intense radiation, say 500 roentgens per minute would probably also destroy the skin. On the other hand with a long exposure of feeble intensity, say 0.5 roentgens per minute a dose of 2,500 roentgens would destroy the tumor without injuring the skin. The capacity of normal tissues to recover from the effects of radiation fortunately is greater than that of neoplasms.

The Distribution of Gas Masks

Experiments in the distribution of gas masks are about to be made at the government factory in Blackburn, where masks of the officially approved type are being made at the rate of 500,000 a week. Sites have been selected for twelve of the thirteen gas mask storage depots to be established throughout

the country. There are three depots for storage in the London district, each with room for 3,000,000 masks. Others are to be established at Nottingham, Liverpool, Manchester, Coventry, Bristol, Reading, Cambridge, Gatshead and Galashiels. The principal task now facing the Air Raid Precautions Department is arranging for the transfer of the masks from the main storage depots to regional centers, whence they will be sent in batches of about 30,000 to the buildings from which distribution to individuals will be carried out in the event of emergency. The final distribution will be made under the supervision of air raid wardens, of whom it is hoped there will eventually be 300,000. Metal containers for the masks are being made at the government factory and mouthpieces by the various rubber firms. When completed they are stored in nitrogen to protect the rubber. They are made in three sizes, the smallest for young children. Babies present a special difficulty, which is causing some concern. Devices have been designed to protect without frightening them.

Is It Necessary to Modify Hypertonic Saline Solution?

Drs Wilmoth and Le Pelletier, at the June 30 meeting of the Académie de chirurgie, read a paper entitled *Is It Necessary to Modify the Hypertonic Saline Solution as Now Employed in Surgery?* At a previous meeting (April 28) Dr Okinczyk had reported two cases in which the subcutaneous injection of 500 cc of physiologic solution of sodium chloride by the drop method was followed by a high temperature and pulse rate, dry tongue, marked pallor and oliguria. A similar case had been observed by Dr Jean Quenu.

Wilmoth and Le Pelletier's patient, a man of 28, had been treated for a gastric ulcer during the three years preceding his admission to their service. Based on the x-ray examination, a diagnosis of duodenal ulcer was made by the authors and confirmed at operation (subtotal gastric resection). An eventration occurred on the fifth postoperative day, following several attacks of hiccup. The abdominal incision was resutured and on the evening of the same day 20 cc of a 10 per cent saline solution was given intravenously, and 40 cc of a 20 per cent solution by rectum. This was repeated on the following day. The abdominal distention, which had been quite marked, was greatly improved, but a severe diarrhea lasting three days followed, accompanied by evidence of intense dehydration. Death took place on the fifth day after operation. A total of 4 Gm of sodium chloride had been given intravenously and 16 Gm by rectum. The examination at the time the diarrhea and dehydration first appeared revealed a hyperchloremia and a moderate acidosis.

It is well known that following extensive operative procedures the most frequently humoral modifications which have been noted are (a) a hypochloremia due to fixation of chlorine in the traumatized tissues, (b) an increase of polypeptides in the blood and (c) the appearance of an acid which corresponds to the decrease of the alkali reserve and an increase of the globulin and plasma chlorine ratio. These changes are the chief indication for giving a hypertonic saline solution after operation.

The authors warned, however, against the use of a saline solution of greater than 10 per cent concentration, because even at that strength there is a marked purgative action. As Gosset, Binet and Petit-Dutaillis have shown, the use of a 10 per cent solution is very efficacious in cases of postoperative abdominal distention due to a paresis of the intestinal musculature. The use of a 20 per cent saline solution, however, is followed by too much purgation and dehydration.

Splenectomy for Hypertrophic Cirrhosis of Liver

The value of splenectomy in hypertrophic cirrhosis of the liver was the subject of two papers read at the July 2 meeting of the Société médicale des hôpitaux. In the first paper, Noel Fiessinger and M Gaultier reported a case of hypertrophic hypersplenomegalic hepatic cirrhosis in a man aged 41, without apparent etiology and presenting clinically a hemorrhagic ascitic syndrome. A study of the hepatic functions having shown a marked improvement following treatment, splenectomy was deemed indicated to prevent recurrence of gastrorrhagias. These have not recurred during a period of two years after the operation and the hepatic functions have practically become normal. Only a very hard large liver persists accompanied by a slight increase of rose bengal retention, which is, however, less than before the operation. Even though a neoplasm (seminoma) of the testis with pulmonary metastases exists at present, there has been no change in the functional equilibrium of the liver. Bergeret, Caroli and Audeot in 1934 were quoted as having studied twenty-two cases. Their conclusions were that splenectomy was indicated only in cases of cirrhosis which developed slowly, accompanied by moderately or very large spleens, in patients relatively young and in the absence of a history of alcoholism and syphilis. Carnot, Harvier and Caroli reported a case in which splenectomy had been performed in 1931 by Bergeret for hypertrophic cirrhosis with marked splenomegaly, ascites and recurrent gastric hemorrhages. The operation was followed by striking recession of symptoms. Cases reported by other French authors were cited to show the great value of splenectomy, which, according to Fiessinger and Gaultier, is indicated only in cases in which the splenomegaly is evident, provided functional liver tests show that such a procedure is safe.

In the second paper, Bergeret and Caroli first reported the end results in the case cited by Fiessinger and Gaultier, in which splenectomy had been done in 1931. The patient was a young man who had been under observation since 1927 for a hepatosplenic cirrhosis of unknown etiology. There were marked enlargement of the liver, poor general condition, repeated intestinal hemorrhages, and ascites. Operation was deemed indicated as a last resort, after blood transfusions had been given. There had been such a decided improvement after the operation that the patient had been able to resume work. Although the ascites had not recurred, an intestinal hemorrhage appeared three years after operation. Since the latter, only occasional transitory attacks of pruritus and pain had been noted. Although during the first two years there had been an apparent decrease in the size of the liver, it is still large, with its lower border at the level of the umbilicus. The authors consider the splenectomy as only a palliative measure in this case.

Although splenectomy is generally held to be indicated only in the hypertrophic or cryptogenic forms of hepatic cirrhosis, a case of splenectomy was reported in which there was a distinct history of alcoholism with a small "hob-nailed" liver. The spleen was very large and the intestinal hemorrhages so frequent that a gastro-enterostomy had been performed on the basis of a diagnosis of gastric or duodenal ulcer. The splenectomy was done in May 1935. Thirteen months later the patient had a slight intestinal hemorrhage but is now (July 1937) apparently in good condition.

Biliary Peritonitis

Two cases of biliary peritonitis without demonstrable perforation of the bile passages were reported by Dr Brugcas of Shanghai, China, at the June 30 meeting of the Académie de chirurgie. The first patient was a man, aged 25, who had been taken suddenly ill with severe epigastric pain accompanied by vomiting, headache and profuse perspiration. The upper part of the abdomen was rigid and tender on palpation. A diag-

nosis was made of perforated gastric or duodenal ulcer, although there was no preceding history of such a lesion. When the abdomen was opened, a greenish bile-stained liquid escaped. Examination failed to reveal any perforation of the stomach, duodenum or bile passages. The gallbladder contained about 80 cc of a turbid greenish fluid, but no calculi were found in this organ or in the bile ducts. Cholecystectomy was performed, followed by uneventful recovery.

In the second case the onset was similar but more protracted. A marked icteric tinge of the sclerae and urine was noted on admission. In the absence of previous symptoms indicative of a gastric or duodenal ulcer, a preoperative diagnosis of biliary peritonitis following cholecystitis was made. When the abdomen was opened a large quantity of greenish fluid was found, which on culture mediums showed the presence of many colon bacilli. The same was true of the contents of the greatly distended gallbladder. No calculi or perforation of any portion of the bile ducts or gallbladder was found. Uneventful recovery followed a cholecystostomy. Dr. Brugas did not believe that removal of the gallbladder was indicated unless there was evidence of a gangrenous area in its wall. In both of the patients an acute cholecystitis without calculi had existed. No cultures of the peritoneal or gallbladder fluid was made in the first case.

Congress of French Alienists and Neurologists

The forty-first Congress of French Alienists and Neurologists was held at Nancy, June 30-July 5. The first paper was a biologic study of alcoholic delirium by Dr. Barques of Agen. Laboratory studies show that the acute mental manifestations in chronic alcoholism are usually not accompanied by albuminocytologic changes in the cerebrospinal fluid. In an occasional case hyperalbuminosis and less often a slight leukocytosis may be found. The effects of alcohol are more marked on the cerebral tissue than on the meninges. As regards the urine there is a slight inconstant albuminuria, frequently a glycosuria and urobilinuria, as well as an increase in the uric acid content. These urinary changes are only transitory. The blood changes are the most important, there being a hyperglycemia and an increase in blood urea which parallels the severity of the clinical symptoms.

All these indicate a syndrome of hepatic insufficiency involving all the hepatic functions in a more or less serious manner. The delirium is in direct relation to it, being the effect of the chronic intoxication.

A second paper was on primary cerebellar atrophy, by Dr. Noël Peron of Paris. He regarded such cases as slowly progressive disorders due to a "fragility" which was not of fetal origin (like the familial atrophies), but appeared at a later period and were anatomically systematized, as first described by Andre Thomas and then by Dejerine. Clinically, he placed in the first group the olivopontocerebellar atrophy of Thomas and Dejerine. The onset is slow and progressive in persons over 50. The cerebellar syndrome first affects the functions of locomotion, especially of the lower extremities, so that the patient is unable to stand or walk. The upper extremities are involved a little later. There are also marked disturbances in writing and speech, accompanied by a condition of mental asthenia, followed by dementia.

In a second group the author placed the late cerebellar atrophies, with predominant cortical involvement. They appear late in life and develop slowly. Static and equilibrium disturbances are prominent features. Walking becomes impossible without aid and retropulsion is frequent. The lower extremities are almost exclusively involved, kinetic disturbances of the hand being very slight.

A negative sign of great value is the absence of other neurologic symptoms. Whereas in the first group the evolution of the disease is usually from two to three years, in the second one it is much slower, from ten to twenty years.

In general, the diagnosis of cerebellar atrophy is difficult. It must be differentiated from (a) cerebellar syndrome due to vascular lesions, (b) tumors of the cerebellum and posterior fossa, (c) infectious lesions of the cerebellum and its meninges, (d) sclerosis in plaques, and (e) cerebellar atrophy of the familial type.

New Dean of Medical School

The pathologist Prof. Lucien Cornil, who is head of the department of pathology in the medical school at Marseilles, has just been elected dean of the faculty as successor to Professor Imbert.

Gas-Proof Shelters in Public Hospitals

During the past few years, efforts have been made in the public hospitals of the department of the Seine in which Paris is situated, not only to take care of gassed individuals but also to provide shelter for patients who cannot be transported during gas attacks in times of hostilities. In Paris itself the director of the Assistance publique, Dr. Mourier, and Professor Tanon, head of the department of hygiene in the medical school, have completed the installation of gas-proof shelters for nontransportable patients, as well as the organization of facilities for the treatment of those suffering from the effects of inhalation of poison gas in war.

Studies of the Rupturability of the Capillaries

Dr. Sack, senior physician of the Medical Clinic, recently pointed out in the Freiburg Medical Society that the tests heretofore in use for the rupturability of the cutaneous capillaries are extremely inaccurate. He has devised an improved apparatus by means of which negative pressure of from 0 to 700 mm of mercury, regulated at will, can be applied to the skin. The procedure is this: After negative pressure of given strength has been applied to a cutaneous area for a certain time, from two to five blood dots will appear, the rapidity with which this phenomenon takes place corresponds to the force of the negative pressure; the slighter the pressure the greater will be the time that elapses prior to the appearance of the blood dots, and the greater the pressure the shorter the time. In scurvy, for example, a diminished negative pressure is sufficient to effect a rapid production of typical cutaneous hemorrhage, if vitamin C is then administered the resistance of the vessels will be considerably heightened at the end of some five weeks, namely, under a pressure of the same strength the time intervals in which the characteristic hemorrhages are produced will be considerably longer. Vitamin C thus exerts a specific influence on the resistance of the capillary vessels of the skin. Conversely, if histamine, for example, is administered the rupturability of the capillaries is observed to be greater only ten minutes after subcutaneous injection of 1 mg of the substance. Studies of the action of calcium (in different doses and variously administered) established no deviations from the norm. A therapeutic effect of calcium in hemorrhagic diathesis is therefore not demonstrable by this means. Furthermore, it is interesting to note that capillary resistance is influenced, that is, increased, by the application of cupping glasses. What underlies this effect is not yet understood.

The Vitamin Content of Flour and Bread

The Leipzig nutrition-physiologist Professor Scheunert has investigated the vitamin content of flour and bread from both wheat and rye. The customary German milling scale served as a basis for these experiments. Rye was observed to contain less vitamin B₁ but more vitamin B than wheat, 100 Gm. of wheat contained 130 international units of vitamin B₁ and 100 Gm. of rye contained 100 international units. Each hun-

dred grams of wheat contains 50 growth units of vitamin B₁, and each hundred grams of rye 571 such units. The vitamin B₁ and vitamin B values depreciate with the production of bran in the milling process, in this respect there are notable differences between wheat and rye. In wheat the vitamin B₁ content is lowered some 30 per cent by an 82 per cent milling, and more thorough milling causes even greater depreciation. In white wheat flour of 60 per cent milling only 24 international units of vitamin B₁ is to be observed. With rye the decline proceeds more slowly, after the minimal milling (94 per cent) the flour still contains the same vitamin B₁ value as the whole grain. This value is reduced some 15 per cent by an 82 per cent milling and 25 per cent by a 75 per cent milling. After even slighter millings, rye exhibits a considerable depreciation of the vitamin B₁ value. Rye flour of 65 per cent milling contains only 48 international units per hundred grams and flour of 40 per cent milling only 24. The vitamin B₁ content of flour is not impaired by the baking process. The only breads that present high vitamin B₁ values are the whole grain bread with germinal factor and breads of, respectively, 94 per cent and 82 per cent millings. Some of the B₁ values per hundred grams in various breads: breads of 82 per cent milling, wheat breads 67 international units, rye breads 59, breads of 75 per cent milling, wheat breads 24 international units, rye breads 50, the white breads show a yet smaller content, 16 international units. With respect to vitamin B values, the wheat is somewhat more deficient than the rye and here too, on account of the extraction of bran, the B content in wheat flour is more readily depleted than that of rye flour. The B content of whole wheat is 50 growth units, that of rye 57, wheat flour of 82 per cent milling contains 33 units, and similar rye flour still contains 50 units. The same value is found in rye flour of 75 per cent milling, whereas in wheat flour of similar milling no appreciable amount of vitamin B can be observed. The lighter rye flour on the contrary still contains demonstrable B values. The same applies to breads both rye and white. Accordingly, whole grain flour and breads as well as flour and breads in which larger proportions are utilized (namely, those which will contain the greatest proportion of bran) are an important factor in the nation's supply of vitamins B₁ and B.

Germany's First Encephalitis Clinic

According to the National Health Bureau's statistics there were 274 fatalities from lethargic encephalitis in Germany during 1934, 515 from epidemic encephalitis and 267 from acute anterior poliomyelitis. In the same year 1,414 patients received hospital care for epidemic encephalitis, 592 of these patients were newly admitted during the year. The morbidity from the foregoing diseases seems to have increased in recent years.

Five years ago a Bulgarian botanist suggested the use of the root of *Atropa belladonna* and an extract of an aromatic bitter (*Calamus*—sweetflag) to improve encephalitis. The queen of Italy heard of this discovery, through her daughter, the queen of Bulgaria, and set about introducing the therapy into Italy, in which country the herbs are abundant. Professor Ferrarini of Rome developed a therapeutic procedure. A first encephalitis clinic was opened at Rome for the purpose of pushing these investigations further. Similar clinics were next established in Turin and Milan. According to the official reports, several thousand patients were treated at these institutions, 18 per cent of these cases, it was stated, were brought to clinical cure, 41 per cent ameliorated, 38 per cent ameliorated to a less extent and only 3 per cent remained uninfluenced. The outcome depends on the severity of the disease. The therapy includes a stay of some two months in the hospital and an after-treatment period of equal length.

Early in August a clinic patterned on the Italian institutions was opened in Cassel (central Germany). High government

officials participated in the dedication of this hospital, which was styled "Queen Elena Clinic." The president of the National Health Bureau took this occasion to relate how a representative of the bureau, commissioned to study the Italian clinics, had been so impressed with the successes achieved that he subsequently recommended the establishment of a similar institution in Germany. The queen of Italy subsequently consigned to Germany supplies of the medicine. The queen also appointed an eminent physician to collaborate with the Germans in the use of the drug.

AUSTRALIA

(From Our Regular Correspondent)

Aug 11, 1937

Beginnings of State Medical Service in Australia

With the aim of providing all people, irrespective of the locality in which they are situated or their financial position, with the best medical attention and hospital accommodation when necessary with adequate supervision from a public health point of view, the government of Tasmania is appointing ten physicians who will be attached to the staff of the department of health. The department of health in Tasmania is now making a survey of the medical services available in the country districts, and when this work is completed the location of each medical officer will be decided on. The most important duty of the medical officers will be to attend the sick and injured in their respective districts. The facilities of the existing "bush nursing" centers will be used by them and extended as opportunity offers. Preventive medicine will also receive attention, and the duties of medical officers of health will devolve on the new appointees. They will enforce the public health regulations regarding sanitation, dairying milk supplies, the isolation and treatment of infectious diseases and the control of quarantine. Lectures on preventive medicine will be given to appropriate organizations, such as parents and countrywomen's associations. Provision for study leave is included in the terms of appointment. The policy of the government in Tasmania is to concentrate the major curative resources at the base hospitals already established. Smaller hospitals would render valuable services as clearing and casualty stations and for accommodation of minor cases. A more highly developed ambulance service will make transport from the smaller hospitals in outlying districts to the larger hospitals. Two bacteriologic and pathologic laboratories are already established, and smaller ones will be established in other centers. Medicines will be supplied from a central dispensary with depots in each district.

Record Low Infant Mortality Rate in Adelaide

What is believed to be a world's record for a low infant mortality rate has been established in Adelaide, South Australia, over the past twelve months. Whereas the lowest infant death rate for the past nine years had been 55 for every thousand births, for the year ended March 31, 1937, the mortality rate for Adelaide has been 23. It is possible that this is a freak rate, but it is a happy indication of the trend. In South Australia last year the infant mortality was 311. Queensland's rate for the same year was 362. South Australia for the past year, with a figure of 311, has now beaten New Zealand, which occupies second place with 3215. New Zealand was the previous holder of the world's record. A factor that is considered to be important in this low mortality rate is the emphasis on, and the provision of, extra milk for expectant mothers in necessitous circumstances. The South Australian government issues to mothers an additional daily pint and a half of milk. There is a very efficient Mothers' and Baby's Health Association in South Australia, which carries out an educational campaign and provides the means for adequate supervision of expectant mothers. Serious epidemics of sum-

mer diarrhea are becoming less frequent. A factor in this is considered to be the bituminization of the highways. The decrease in the number of horses and stables in recent years has minimized the fly nuisance. Other activities contributing to this happy result are the close supervision of the milk supply by the Metropolitan County Board under the Food and Drugs Act, the efficient work of the many maternity homes, and the activities of the local boards of health. In view of the rapidly falling birth rate in Australia, such a reduction in the infant mortality rate provides a measure of comfort to those who justifiably are apprehensive for the future of the race.

Plans for an Institute of Medical Research

Parliamentary approval has been given to the establishment in the near future of an institute of medical research in Adelaide, South Australia. The institute will be under the control of a committee representative of the management of the Adelaide hospital, and the university. The director will be Dr. Weston Hurst, who arrived from England last year to take up the position. Half the annual salary of £1,500 will be paid by the government and half by the university. In the new institute will be housed a laboratory of clinical science and the university departments of bacteriology and pathology. It will group together the pathologic and bacteriologic activities of the medical school. The site chosen for the new institute will be convenient to the wards of the Adelaide hospital on the one hand, and the university departments of anatomy, physiology, biochemistry and chemistry on the other. The institute will also be near the nutrition laboratory of the Council for Scientific and Industrial Research. It is expected that the institute will be the clearing house for medical science in South Australia. Another function of the institute will be the collection and compilation of medical records over a sufficient time to give the history of the more important human disorders as they occur in Australia, having special regard to race, occupation, nutrition and climate.

The Mystery of Growth

Given a normal pituitary and thyroid function, with a proper supply of vitamin B, amino acids, ample food supply and physical exercise during the years between 5 and 20, the stature of a race may be increased to the optimum of Greek perfection. This statement was the keynote of the Sir Charles Clubbe memorial oration delivered at the University of Sydney by Prof. J. C. Meakins, professor of medicine at McGill University. Professor Meakins had been invited to Australia by the New South Wales postgraduate committee and his lecturing services were also utilized in other states. It was obvious that Professor Meakins in his oration had attempted an impossible task, but in confining his attention to the alterations of the stature of mankind he considered that the factor of environment seemed to be much more important than that of heredity in the determination of stature. In the environment, the most important factors were physical activity, the character and quality of the food supply, and the effects of parasitic and other diseases. Tall races are not necessarily superior to shorter, either in physical endurance or in mental capacity. Exercise and physical training up to the twentieth year have a direct influence on stature. Comparison of various races of differing stature shows striking differences in the consumption of milk, milk products and meat to a degree that is considered to be significant. Improvement in the dietary is responsible for the increased growth of Chinese children who have migrated to Hawaii.

Graduate Education in New Zealand

In an editorial published in the *New Zealand Medical Journal* for June the absence of any permanent arrangements for graduate education in New Zealand was deplored. Graduate work was defined not only as study preparatory to the taking of

higher degrees but as that which is necessary to keep the practitioner in touch with the trends of medical practice. Reading alone is not considered adequate for these purposes. It is the established custom in New Zealand for medical men to do their graduate study abroad. New Zealand is an isolated country, and it was considered that machinery should be created whereby advantage could be taken of the infrequent visits of distinguished teachers, such as the recent visit to Australia of Dr. J. C. Meakins, professor of medicine at McGill University. A suggestion is made that a large hospital outside the already existing medical school at the University of Otago at Dunedin should be developed as a graduate hospital. It is considered that the claims of pregraduate education are already paramount in institutions already devoted to that work. The *New Zealand Medical Journal* is at present published only every two months. Exception may be taken to the editorial in the *New Zealand Medical Journal* as regards the separation of undergraduate and postgraduate medical education, especially in the beginning stages of the latter type of education. Australian experience has shown that the association of postgraduate education with existing medical schools has been of benefit to both. For instance, in Queensland the founding of the new medical school of the University of Queensland, and the association of postgraduate education with the university this year has enabled an extension of the course to a fortnight. Previously it had occupied only a week. Full use, moreover, was made of the services of the professors and teaching resources of the medical school. In New South Wales the university medical school is the pivotal point of graduate education.

Medical Board Overruled by Court

An interesting legal decision was given in Melbourne in July whereby a ruling of the medical board of Victoria, which refused to register a German doctor, was reversed by a state court. Dr. Moritz Meyer, a physician and surgeon practicing in Germany, was obliged to leave that country because of restrictions imposed by the German government on the practice of medicine by persons of non-Aryan descent. He had left Germany in October 1935. At that time he was a doctor of medicine of the University of Leipzig, and from April 1920 to October 1935 he had practiced medicine and surgery in hospitals in Berlin and Dresden, and also privately in Dresden. On leaving Germany he had gone to England and Scotland, where he became, by examination, a licentiate of the Royal College of Surgeons of Edinburgh, of the Royal College of Physicians of Edinburgh, and of the Royal Faculty of Physicians and Surgeons of Glasgow. He had decided to practice his profession in Victoria and had been led to believe that his qualifications entitled him to registration there. The medical board of Victoria had refused his application for registration on the grounds that there was not sufficient evidence of the required courses of study and that the board, moreover, was expressly forbidden to recognize a course in a foreign university, school of medicine or college. Dr. Meyer appealed to the court, and Mr. Justice Lowe in a judgment held that the applicant was entitled to registration and to receive from the medical board a qualification. The medical board of Victoria expressed doubt as to whether a court was entitled to overrule a decision of the board's and proposes to contest the decision.

The Campaign Against Company Pharmacy

The pharmacists of New Zealand and the different Australian states have put up a valiant fight against the threatened "trustification" of pharmacy. This opposition was occasioned by the contemplated introduction of a branch of an organization known in Great Britain as "Boots the Chemists." In New Zealand, although two of the "Boots" shops are already operating, the government has held up any further extension for twelve months in order that the existing practice of pharmacy may reorganize itself to provide a service comparable to

that of "company" pharmacy. In Queensland the labor government altered the pharmacy act so as to prevent any further extension of company pharmacy in that state, and any existing company is now prohibited from changing its name or opening new branches. A commission of inquiry is sitting in New South Wales, and at the moment any extension of company pharmacy will be at the risk of those concerned. Existing legislation in Victoria prohibits company pharmacy, and any attempt to evade the present act will be met by amending legislation. The Tasmanian pharmacy act prevents companies from operating, and no amendment would be countenanced. The premier of South Australia states that he is opposed to the "chain store" system of trading in pharmacy. In Western Australia the government has promised to introduce amending legislation next session to close the door against any extension of company pharmacy. It is evident that the weight of parliamentary opinion in Australia and New Zealand is definitely against the exploitation of the pharmaceutical profession by commercial concerns. In the meantime, pharmacists are endeavoring to improve still further the service which they are rendering to the public.

Sudden Loss of Consciousness as Cause of Automobile Accidents

Dr F Van Loon lectured on "Sudden Inhibition of Consciousness as a Cause of Automobile Accidents" before the Societe juridique de psychiatrie. The inhibition of consciousness to which the author refers may occur in normal persons. E Bramesfeld and H Jung investigated this problem and found that the phenomenon is usually conditioned by one of the following factors: (1) monotony of the road, (2) regularity of the rows of trees along the roadside, (3) too great familiarity with the route, (4) idle conversation, (5) enervating heat, (6) fatigue or somnolence of the driver and (7) intoxication due to alcohol or hypnotics. Each of these factors involves either a deficiency of stimuli or the repetition of identical stimuli. Mention should also be made of the depressive influence of night and the monotonous sound of the motor, both likewise etiologic factors. These transitory depressions are not to be confused with genuine sleep, such as overtakes exhausted drivers.

An accident case recently disposed of in a Rotterdam court illustrates the great need for this differentiation. According to the record, both court and witnesses appeared quite unfamiliar with momentary loss of consciousness as a cause of accidents. A driver traveling a good straight highway on an afternoon in June suddenly for no apparent reason swerved to the left and struck three children who were riding bicycles. One of these children received fatal injuries. Charged with criminal responsibility for the accident, the defendant was unable to account for his erratic driving and asserted that his first intimation that anything was amiss came with the shock of the collision. Medical and neurologic examination failed to disclose any physical basis for the loss of control. Sole pathologic determinations were hypertension and a history of adolescent chorea. The road was straight, unencumbered by any obstacle and well known to the defendant, who declared that he always attempted to drive carefully and disclaimed any tendency to become somnolent at the wheel. Van Loon, as expert witness, testified that in his opinion the accident was not imputable to any technical deficiency on the part of the defendant but to a momentary inhibition of consciousness. The court was not altogether in accord with the doctor's opinion, although in view of the relatively light sentence imposed the impression was conveyed that the expert's interpretation had to a certain extent influenced the decision. This problem is one of great interest and a sound knowledge of its implications can be

obtained only by a systematic study of every accident for which momentary inhibition of consciousness could conceivably be responsible.

The Destruction of Rats in Amsterdam

According to the director of the city health department, destruction of rats in Amsterdam has been successfully carried on. The director's report first takes up the advantages and disadvantages of the use of various bacterial preparations in the fight against rats. In the first and second campaigns, squillitic preparations were generally used. Subsequently tests were made with a number of utilizable substances in order to determine which were the more effective, one preparation would be distributed in a certain quarter of the city, another preparation in a different quarter and so on. The results were largely confusing. Squill bulbs are difficult to handle in packets. The results obtained were most diverse, in general it was established that the poison made the rats so ill that they could be easily caught and destroyed. In the second campaign a squillitic paste was tried in place of the bulb packets. The cost of these campaigns exceeded 24,000 florins, the greater part went for the pay roll. There were 402,522 packets distributed.

The director's conclusions may be summarized as follows:

- 1 Deratization of a large city is possible.
- 2 Squill preparations, if distributed in large quantities, are an excellent rat poison.
- 3 For large scale destruction, liquids or pastes are superior to other types of preparation.
- 4 Although squill preparations are more costly than squill bulbs, they give quite unequal results. Moreover, handling of the bulb packets for purposes of deratization is more difficult than that of paste or liquid preparations.
- 5 The successes achieved with all or any of these preparations are only temporary.
- 6 Deratization should be a regular and unrelenting procedure. If the advances are to be preserved, a plan for a continued active campaign must be adopted.
- 7 Conditions that serve to create breeding places for rats must be systematically reduced.
- 8 The cooperation of the public in a campaign is of the utmost importance.

The Psychiatric Element in Criminal Jurisprudence

Dr J S M Van Geuns, in a lecture before the juridical society of psychiatry, said that the expert opinion of the psychiatrist exerts a great influence on the court's decision. He not only aids the examining magistrate by his knowledge and experience but gives his opinion as to what sentence ought to be passed on a defendant who presents psychic abnormalities. The psychiatrists draw the particular attention of the courts to defendants of unsound mentality. The expert medical report in a criminal case should fulfil certain special conditions: it should contribute to the record a clear picture of the defendant's mental condition and of the relation of this condition to the offense with which he is charged. The psychiatrist should state whether or not the offender is to be punished and what penalty, if any, ought to be imposed. There are times when a judge, in order to solve certain specific problems, will require information on various psychologic points of order. The judge may, for example, stand in need of expert opinion to clarify the testimony of questionable witnesses. If a judge accepts as competent the testimony of a person less than 16 years old, an article of the criminal code stipulates that the reasons for believing such testimony should be set forth in the court's decision. Other cases that involve psychologic questions will often require the services of an expert, for example, the question of what bearing reflexes and automatisms may have on the premeditation of a crime. The speaker cited several instances in which the judge, despite the legalistic soundness of his reasoning, has erred. Moreover, direct and cross examination of defendants and witnesses should be freed from all elements of coercion or leading. Van Geuns's address is a convincing argument for the desirability of collaboration between psychiatrist and jurist.

Marriages

WILLIAM PRITCHARD JORDAN, Powellsville, N C, to Miss Mary Margaret Schlanser in San Francisco, June 15

CHARLES M. BOWMAN, Albion, Ind., to Miss Mary Isabel Cook of New Harmony, in Fort Wayne, June 19

RALPH HOWARD EDSON, New York, to Miss Leona Virginia Pierce of Upper Montclair, N J, June 19

WILFRED J. NOWLIN, Farmer City, Ill., to Mrs. Neva Whitford Jones of Champaign, in Chicago, June 15

BALLARD NORWOOD JR., Virginia, Va., to Miss Gwendolyn Beatrice Wheeler of Oxford, N C, June 25

HENRY WALKER JERNIGAN, Atlanta, Ga., to Miss Ruth Adelaide Carr of Malden, Mass., April 24

ALGERNON R. FIKE, Spartanburg, S C, to Mrs. Josephine F. De Pue of Tampa, Fla., May 22

ALBERT HAZEL ZEALY JR., to Miss Susan Moore Collier, both of Goldsboro, N C, June 19

SHERMAN F. GILPIN JR., to Miss Kathryn Hannah Lawser, both of Philadelphia, June 19

ROBERT DE VANE CROOM JR., Maxton, N C, to Miss Rosa Currie of Clio, S C, June 8

LELAND S. HARRIS to Miss Alma Bloch, both of Yakima, Wash., June 11

PHARES YATES GREENE to Miss Melba Hunt, both of Apex, N C, June 19

RALPH O. PETERSON to Miss Viola Gellin, both of Chicago, June 24

Deaths

Daniel Fiske Jones © Boston, Harvard University Medical School, Boston, 1896, member of the House of Delegates of the American Medical Association in 1921, member and past president of the American Surgical Association, member of the Southern Surgical Association, Society of Clinical Surgery and the New England Surgical Society, served during the World War, fellow and formerly regent of the American College of Surgeons, consulting surgeon to the New England Hospital for Women and Children, Beth Israel, and Massachusetts General hospitals, Boston, Union Hospital, Fall River, Brockton Hospital, Brockton, Addison Gilbert Hospital, Gloucester, Sturdy Memorial Hospital, Attleboro, Leominster Hospital, Leominster, and the Elliot Hospital, Keene, N H, honorary consulting surgeon to the New England Deaconess Hospital, member of of board of overseers of Harvard University, aged 69, died, September 11, of hypertensive heart disease

Pope Webb Oden, Shreveport, La. University of Nashville (Tenn.) Medical Department, 1910, member of the Louisiana State Medical Society, fellow of the American College of Surgeons, served during the World War, otologist, rhinologist and laryngologist to the T. E. Schumpert Memorial Sanitarium and on the staff of the Shriners' Crippled Children's Hospital, aged 50, died, June 27, in the John Sealy Hospital, Galveston, Texas, of hypertensive heart disease and myocardial fibrosis

Onslow Allen Gordon, Brooklyn, Dartmouth Medical School, Hanover, N H, 1885, member of the Medical Society of the State of New York, past president and formerly assistant treasurer, treasurer and vice president of the Medical Society of the County of Kings, fellow of the American College of Surgeons, past president of the Brooklyn Surgical Society, senior surgeon to St. Mary's Hospital, aged 85, died, July 4, at his summer home in Lake Keoka, Maine

Clarence Julius Manly © Colonel U S Army, retired, San Francisco, Louisville (Ky.) Medical College, 1897, veteran of the Spanish-American War, entered the medical corps of the U S Army as a captain in 1903, served during the World War as a colonel, was awarded the distinguished service medal, retired in 1935 by operation of law, fellow of the American College of Surgeons, aged 65, died June 27, in the Letterman General Hospital of coronary occlusion

Frederick Martin Albers © Brooklyn Long Island College Hospital, Brooklyn, 1905, fellow of the American College of Surgeons, attending surgeon, Victory Memorial Hospital, member of the attending staff of the Bay Ridge Sanitarium, member of the courtesy staff of the Flower Hospital New York Prospect Heights and Brooklyn Maternity hospitals, Brooklyn, aged 55, died July 11, of hypertension

George Stephen Skiff, Gainesville, N Y, University of Buffalo School of Medicine, 1887, member of the Medical Society of the State of New York, health officer of Gainesville, past president of the Medical Society of the County of Wyoming, on the staff of the Wyoming County Community Hospital, Warsaw, aged 72, died, June 27, of carcinoma of the kidney and gastric ulcer

Edgar Franklin McClendon © Plainview, Texas, St. Louis College of Physicians and Surgeons, 1890, past president and secretary of the Hale-Floyd-Briscoe-Swisher Counties Medical Society, on the staff of the Plainview Sanitarium and Clinic, aged 70, was shot and killed, June 25, by a prisoner, whom he had been called to treat in the county jail

George Lincoln King Sr. © Alliance, Ohio, Cleveland Medical College, 1895, past president of the Stark County Medical Society, member of the American Academy of Ophthalmology and Oto-Laryngology, for six years a member of the board of education, on the staff of the City Hospital, aged 72, died, July 8, of heart disease

Henry Wieder Salus, Johnstown, Pa., Medico-Chirurgical College of Philadelphia, 1905, member of the Medical Society of the State of Pennsylvania, owner and director of the Salus Private Hospital and medical director of the Municipal Hospital, was president of the Civil Service Commission of Johnstown, aged 58, died, July 17, of pneumonia

M. David Haspel, New Orleans, Tulane University of Louisiana Medical Department, New Orleans, 1905, member of the Louisiana State Medical Society and the American Academy of Ophthalmology and Oto-Laryngology, aged 55, on the staffs of the Baptist Hospital and the Charity Hospital, where he died June 26, of heart disease

Roderick Byington, Summit, N J, Columbia University College of Physicians and Surgeons, New York, 1900, member of the Medical Society of New Jersey, member of the board of education and public school physician, on the staff of the Overlook Hospital, aged 64, died, June 2, of cerebral thrombosis and arteriosclerosis

Henry J. Sommer © Hollidaysburg, Pa., Jefferson Medical College of Philadelphia, 1893, member of the American Psychiatric Association, past president of the Blair County Medical Society, medical superintendent of the Blair County Hospital, aged 65, died, July 11, at Altoona, of uremia and bronchopneumonia

Charles Seward Jadis MacNeil, Malden, Mass., Baltimore Medical College, 1909, member of the Massachusetts Medical Society, on the staffs of the Malden (Mass.) Hospital, Melrose (Mass.) Hospital and the New England Sanitarium and Hospital, Melrose, aged 57, died, June 29, of pneumonia

Daniel Stephen Rice, Stevens Point, Wis., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1897, member of the State Medical Society of Wisconsin, on the staff of St. Michael's Hospital, aged 73, died, May 26, of cerebral hemorrhage

Andrew Bogert Vanderbeek Jr., Paterson, N J, Columbia University College of Physicians and Surgeons, New York, 1933, member of the Medical Society of New Jersey, aged 32, died, June 22, in the Fort Sanders Hospital, Knoxville, Tenn., following an operation for ruptured appendix

Coite Long Sherrill © Statesville, N C, North Carolina Medical College, Charlotte, 1914, fellow of the American College of Physicians, served during the World War, chief of the medical service of the H. F. Long Hospital, aged 49, died suddenly June 24, of coronary occlusion

John William Lindner, New Orleans, Tulane University of Louisiana Medical Department, New Orleans 1903, at one time instructor of surgery at the Loyola Post-Graduate School of Medicine, formerly visiting surgeon to the Charity Hospital, aged 55, died July 17, of coronary thrombosis

Woolam Ira M. Smith, Nacogdoches, Texas, Atlanta (Ga.) Medical College, 1886, member of the State Medical Association of Texas, past president of the Nacogdoches County Medical Society, on the staff of the City Memorial Hospital, aged 77, died June 21

Stephen Benjamin Malone, Sandersville, Ga., Atlanta College of Physicians and Surgeons 1904, member of the Medical Association of Georgia, served as a member of the city council and city health officer, aged 59, died, June 25, of cerebral hemorrhage

Louis William Atlee, Philadelphia, Jefferson Medical College of Philadelphia, 1882, member of the Medical Society of the State of Pennsylvania, veteran of the Spanish-American War for many years on the staff of St. Agnes Hospital, aged 77, died, July 7

Edward Lee Wedemeyer, Waco, Texas, University of Texas School of Medicine, Galveston, 1897, member of the State Medical Association of Texas, past president of the McLennan County Medical Society, aged 67, died, June 2, of heart disease

Thomas Edward Cavanaugh, Wauwatosa, Wis., Rush Medical College, Chicago, 1904, aged 62, on the staffs of the Misericordia Hospital and St Joseph's Hospital, Milwaukee, where he died, June 17, of arteriosclerosis, gangrene and hypertension

Judson M Griffin, Detroit, Pulte Medical College Cincinnati, 1877, at one time registrar and professor of dermatology at the Detroit Homeopathic College, for many years on the staff of the Grace Hospital, aged 81, died, July 3

Isadore L Green, Watertown, N Y, Hahnemann Medical College and Hospital, Chicago, 1886, Harvey Medical College, Chicago, 1895, aged 91, died, July 14, in the House of the Good Samaritan, of chronic nephritis and arteriosclerosis

Wladimir Nikolas Lankovsky, Los Angeles, University of Tomsk Faculty of Medicine, Russia, 1901, at one time instructor in the College of Medicine and Surgery of the University of the Philippines, aged 84, died, June 12

Alvin Ernest Walters, Zanesville, Ohio, Starling Medical College, Columbus, 1896, served during the World War, aged 63, on the staff of the Good Samaritan Hospital, where he died, June 28, of carcinoma of the prostate

Charles Marion Womack, Lawrenceburg, Tenn., University of Nashville Medical Department, 1902, member of the Tennessee State Medical Association health officer, aged 64, died, June 28, in a hospital at Nashville

S Powell Sebastian, Greensboro, N C, Leonard Medical School Raleigh, 1912, aged 60, on the staff of the L Richardson Memorial Hospital, where he died, June 24, of injuries received in an automobile accident

John Adam Roberts, Oklahoma City, Rush Medical College, Chicago, 1890, also a druggist, aged 77, died, June 25, in the Holy Family Hospital, Manitowoc, Wis., of a skull fracture due to an automobile accident

Paul James Mahone, Seattle College of Physicians and Surgeons, Baltimore, 1907, member of the Washington State Medical Association, served during the World War, aged 55, died, June 30, of heart disease

Jacob S Kjelland, East Ellsworth, Wis., Medical Department of Hamline University, Minneapolis, 1898, served during the World War, aged 67, died, June 14, of chronic myocarditis and chronic nephritis

Edwin Lewis Bradbury, Neillsville, Wis., Rush Medical College, Chicago, 1899, member of the State Medical Society of Wisconsin, county physician, aged 75, died, May 13, of carcinoma of the prostate

Irving Camp Miner, Cleveland, Western Reserve University Medical Department, Cleveland, 1894, member of the Ohio State Medical Association, aged 77, died, June 25, of cerebral hemorrhage

Frank Jerome Hall, Takoma Park, Md., College of Physicians and Surgeons, Baltimore, 1897, past president of the board of education of Dallas, Texas, aged 64, died, June 23, in Washington, D C

Austin Charles Wright, Los Angeles, University of Michigan Department of Medicine and Surgery, Ann Arbor, 1881, at one time a member of the state legislature of Arizona, aged 76, died, June 20

George Ashton Babbitt, Medina, Ohio, Long Island College Hospital, Brooklyn, 1875, aged 85, died, July 1, in the Community Hospital, Berea, of injuries received in an automobile accident

James Samuel Sanders, Chester, Mass (licensed in Massachusetts in 1898), school physician, aged 82, died, June 28, in St Luke's Hospital, Pittsfield, of diabetes mellitus and gangrene of the right leg

Charles Schomberg Elliot, Halifax, N S Canada, Bellevue Hospital Medical College, New York, 1891, served with the Canadian Army during the World War, aged 72, died, June 1

Jacob Marion Stooksbury, Shawnee, Okla. Chattanooga (Tenn.) Medical College, 1893, member of the Oklahoma State Medical Association, aged 68, died, June 24, of cerebral hemorrhage

Emma Theresa Fryer, Philadelphia, Western Pennsylvania Medical College, Pittsburgh, 1905, aged 56, died, June 24, in the Philadelphia General Hospital, of carcinoma of the sigmoid

Eleanor A Harthill, Tuscaloosa, Ala., Wisconsin College of Physicians and Surgeons, Milwaukee, 1902, aged 75, died, June 19, following an operation for removal of a substernal thyroid

Andrew Warwick Duke, Center, Texas, Barnes Medical College, St Louis, 1900, past president of the Shelby County Medical Society, aged 65, died, June 3, of bronchopneumonia

Charles Hicks Howell, Meeker, Okla., College of Physicians and Surgeons, Dallas, Texas, 1905, served during the World War, aged 68, died, June 26, of chronic myocarditis

Alfred Ernest Bovell, Gloucester, Va., Howard University College of Medicine, Washington, D C, 1909, aged 65, died, June 26, of pneumonia, at Trinidad, British West Indies

Welby L Sullivan, Memphis, Tenn., Georgetown University School of Medicine, Washington, D C, 1894, aged 74, died, June 27, of coronary occlusion and myocarditis

George Edgar Stovall, Columbia, La., Memphis (Tenn.) Hospital Medical College, 1909, aged 53, died, June 23, in a hospital at Shreveport of hypertensive heart disease

Joseph Ernest Auger, St Chrysostome, Que., Canada, M B, Laval University Medical Faculty, Montreal, 1906, and M D, in 1907, aged 56, died, June 28, of peritonitis

James Lawrence McAleney, Portland, Maine, Medical School of Maine, Portland, 1895, aged 68, died, in June, of sarcoma of the thigh and coronary thrombosis

Fred M Wilbur, Galesburg, Ill., Barnes Medical College, St Louis, 1903, aged 60, died suddenly, June 23, of carcinoma of the esophagus and paralysis agitans

Hazleton Spencer, Mexico, N Y New York Homeopathic Medical College and Hospital, New York, 1898, aged 68, died, June 25, of coronary sclerosis

Joseph Morse Caley, Philadelphia, Hahnemann Medical College and Hospital of Philadelphia, 1889, aged 77, died, July 5, at the Hahnemann Hospital

William Lee Hill, Lexington, N C, College of Physicians and Surgeons, Baltimore, 1893, aged 73, died, June 10, of senile dementia and malnutrition

Reuben Jay Atwood, Chicago Chicago Medical College, 1890, served during the World War, aged 72, died, July 2, of carcinoma of the lip

Katherine Iris Howard Degan, San Francisco, University of California Medical Department, San Francisco, 1885, aged 72, died, June 13

Theodore S Howard, Chilhowee, Mo., St Louis Medical College, 1876, also a druggist, aged 86, died, June 23, of carcinoma of the prostate

Alonzo Leonidas Winfield, Richmond, Va., Medical College of Virginia, Richmond, 1911, aged 61, died, June 22, of diabetes mellitus

Bernard John Funk, Herbert, Sask., Canada, Manitoba Medical College Winnipeg, 1915, aged 51, died, June 19, of bronchopneumonia

Lydia Howell La Baume, Pacific Beach, Calif., Woman's Medical College, Chicago, 1885, aged 89, died, June 16, of arteriosclerosis

Paul H Fairchild, Passaic, N J Bellevue Hospital Medical College, New York, 1890, aged 69, died suddenly, June 8, in New York

George Ben Perkins, Farmington, Mo., Missouri Medical College, St Louis, 1893, aged 72, died, June 8, of pulmonary tuberculosis

Robert H Bryson, Ora S C, Medical College of the State of South Carolina, Charleston, 1897, aged 65, died, June 26

Frederick Samuel Harper, Hamilton, Ont., Canada, University of Toronto Faculty of Medicine, 1910, aged 49, died, June 15

James L Gibson, Lynden, Ont., Canada, Queen's University Faculty of Medicine, Kingston, 1893, aged 70, died, June 10

Frederick Mills Binkley, Los Angeles University of Tennessee Medical Department, Nashville, 1888, aged 78, died, June 7

Myron Albert Newman, Los Angeles Hahnemann Medical College and Hospital of Philadelphia, 1906, aged 59, died, June 19

Thomas S Hitt, Indianapolis, Starling Medical College, Columbus, Ohio, 1873, aged 91, died, June 29, in St Petersburg, Fla

George Gordon, Wardsville, Ont., Canada University of Toronto Faculty of Medicine, 1867, died, May 30 at Newbury

Bureau of Investigation

MISBRANDED "PATENT MEDICINES"

Abstracts of Notices of Judgment Issued by the Food and Drug Administration of the United States Department of Agriculture

[EDITORIAL NOTE The abstracts that follow are given in the briefest possible form (1) the name of the product, (2) the name of the manufacturer, shipper or consigner, (3) the composition, (4) the type of nostrum, (5) the reason for the charge of misbranding and (6) the date of issuance of the Notice of Judgment—which may be considerably later than the date of the seizure of the product]

Pinerva Pine Needle Rub—Pinerva Laboratories Inc, Milwaukee Composition Essentially volatile oils including pine needle oil (8 per cent by volume), alcohol (75 per cent) and water For rheumatism neuritis gout, etc Fraudulent therapeutic claims—[N J 24096 November 1935]

Pinerva Balsam Pine Needle Bath Tonic—Pinerva Laboratories, Inc Milwaukee Composition Essentially volatile oils including pine needle oil (31 per cent by volume) a sulfonated oil ammonium sodium and potassium compounds sulfates and 35 per cent of water For nerves and heart disorders rheumatism etc Fraudulent therapeutic claims—[N J 24096 November 1935]

Herb Nu Tonic—Helen Schymanski Edwin B Becker Dr Peter B Schyman and S M S Laboratories Inc Chicago Composition Essentially plant drug extracts including a laxative with glycerin and water Cure all Fraudulent therapeutic claims—[N J 24102 November 1935]

Sweet's Comfrey Liniment—Sweet Mfg Co Inc Pittsburgh Composition Essentially alcohol (71.5 per cent), water acetone ammonia red pepper and volatile oils including wintergreen clove camphor and sassafras Fraudulent therapeutic claims—[N J 24104 November 1935]

Terraline Creosote—Hillside Chemical Co Newburgh N Y Composition Essentially partially purified fluorescent petroleum oil with creosote For pulmonary disorders etc Fraudulent therapeutic claims—[N J 24109 November 1935]

Rosenberg's Improved Great Century Oil—Great Century Medicine Co Lititz Pa Composition Essentially wintergreen hydrocarbons similar to gasoline and a red coloring material For rheumatism neuralgia, headache etc Fraudulent therapeutic claims—[N J 24112 November 1935]

Sweet's Kur A Kol Tablets—Sweet Mfg Co Inc Pittsburgh Composition Essentially quinine sulfate calcium carbonate and starch For la grippe catarrh etc Fraudulent therapeutic claims—[N J 24104 November, 1935]

Ivey's Vigor Aid—Ivey Medicine Co Oklahoma City Composition Essentially potassium iodide extracts of plant drugs including a laxative with alcohol glycerin, sugar and water Cure all Fraudulent therapeutic claims—[N J 24094 November 1935]

Clifton's Brazillian Herbs—Clifton Drug Co, Girard Ill Composition Powdered plant drugs including aloe and other laxative drugs and salicylic acid For stomach and kidney disorders etc Fraudulent therapeutic claims—[N J 24093 November 1935]

Amlita—Amlita Laboratories Philadelphia Composition 26 grains of aminopyrine to each tablet For dysmenorrhea Fraudulent therapeutic claims—[N J 24119 November 1935]

Microsan Mosene—Microsan Mosene Laboratories Inc and Mrs Carrie S Wright trading as Corine Ricks and Corine Ricks Los Angeles Composition A watery solution of drug extractives a mercury salt and glycerin For tuberculosis Fraudulent therapeutic claims—[N J 24124 November 1935]

Cereal Meal—Cereal Meal Corporation St Louis Composition Essentially wheat bran wheat shorts linseed meal and agar agar Misbranded because of the claim contains no drugs whereas agar agar is defined as a drug in the United States Pharmacopoeia also because of fraudulent representations that it was an effective remedy treatment and cure for constipation and its effects and for indigestion etc—[N J 24502 March 1936]

Brewster's Germ Destroyer (Brewster's G D)—J R Brewster trading as Brewster Laboratories Nashville Tenn Composition Essentially a light petroleum oil a saponifiable oil and a small quantity of turpentine oil For tuberculosis asthma cancer etc Not a germicide as represented Fraudulent therapeutic claims—[N J 24503 March 1936]

Brewster's Throat Wash—J R Brewster trading as Brewster Laboratories Nashville Tenn Composition Essentially a fixed oil light petroleum oil a small amount of turpentine oil and a trace of ferric chloride For tonsillitis chronic throat trouble etc Fraudulent therapeutic claims—[N J 24505 March 1936]

Brewster's Throat Eaz—J R Brewster trading as Brewster Laboratories Nashville Tenn Composition Essentially a light petroleum oil a fixed oil a small amount of turpentine and a trace of potassium iodide. Cough and croup cure and female regulator Fraudulent therapeutic claims—[N J 24505 March 1936]

Brewster's Liver Tonic—J R Brewster trading as Brewster Laboratories Nashville, Tenn Composition Essentially a fixed oil and light petroleum oil For nervous indigestion stomach disorders and preventing tuberculosis Fraudulent therapeutic claims—[N J 24503 March 1936]

Blo Prepared Salt—William C Yergin trading as The Temple Salatrum Co Butler, Ind Composition A pink crystalline powder containing common salt small amounts of magnesium, calcium iron manganese and potassium compounds phosphate sulfate carbonate silica and indide For faulty metabolism cancers ulcers tumors Bright's disease epilepsy paralysis appendicitis tuberculosis typhoid fever diabetes, etc Fraudulent therapeutic claims—[N J 24504 March 1936]

Yerkes White Liniment—Yerkes Chemical Co Inc Winston Salem N C Composition Essentially an emulsion containing fatty acids ammonia (19 per cent) turpentine chloroform (33 per cent) alcohol (35 per cent by volume) and water Fraudulent therapeutic claims—[N J 24510 March 1936]

J W D Blood Purifier—James W Dorman trading as Dorman Chemical Co Concord N C Composition The liquid essentially arsenic potassium and sodium compounds a small amount of salicylic acid and water, cinnamon flavored white pills essentially extracts of plant drugs including aloe podophyllum and scammony a compound of mercury and volatile oils including peppermint and cloves blue pills essentially methylene blue oil of sandal and capsicum mass gelatin capsules oil of sandal a salicylate and a fatty oil For impure blood stomach heart and kidney disorders pellagra etc Fraudulent therapeutic claims—[N J 24515 March 1936]

Stekete's Worm Destroyer In Syrup—George E Stekete trading as Stekete's Family Medicines Grand Rapids Mich Composition Essentially small amounts of potassium sodium, calcium iron salts oil of worm seed anise oil plant drug extract sugar and water Fraudulent therapeutic claims—[N J 24516 March 1936]

Dewees Carminative—R G Dunwoody trading as R G Dunwoody & Sons Atlanta Misbranded because quantity or proportion of the morphine and alcohol present was not declared on the label—[N J 24517 March 1936]

Stardom's Health Diet—Hollywood Diet Corporation Chicago Composition Essentially water soluble material including dextrin (43 per cent), protein (13.5 per cent) fat including cocoa butter (6 per cent) plant material and inorganic constituents including salt an inconsequential proportion if any of vitamin D For obesity Fraudulent therapeutic claims—[N J 24519 March 1936]

Calso Water—Calso Co San Francisco Composition Essentially a carbonated solution of calcium magnesium and sodium salts including phosphate chloride and bicarbonate For acid conditions in the body Fraudulent therapeutic claims—[N J 24526 March 1936]

Palmer's Lotion—Solon Palmer, New York Composition Essentially mercuric chloride (0.3 per cent) water and denatured alcohol with a trace of perfume For eczema pimples etc Fraudulent therapeutic claims—[N J 24529 March 1936]

Palmer's Lotion Soap—Solon Palmer New York Composition A small proportion of a zinc compound no mercuric chloride For removing skin blemishes etc Fraudulent therapeutic claims—[N J 24529 March 1936]

Kerene—Welty Co Chicago Composition Deodorized kerosene for all hair and scalp disorders asthma catarrh coughs pneumonia rheumatism worms etc Fraudulent therapeutic claims—[N J 24533 March 1936]

Etsam—R M Evans trading as Etsam Mfg Co Hathoro Pa Composition Essentially magnesium and ammonium hydroxides and carbonates alcohol (28 per cent by volume) and water flavored with volatile oils such as lavender and lemon For stomach liver and gallbladder disorders nightmare appendicitis etc Fraudulent therapeutic claims—[N J 24534 March 1936]

Dalginine Capsules—Fred F Wanner & Sons Philadelphia Composition Approximately 182 grains of aspirin and 181 grains of phenacetine per capsule Misbranded because the quantity of these was misstated—[N J 24535 March 1936]

Sanovapor Dexene—Sanovapor Laboratories Inc Huntington W Va Composition A watery solution of sulfur dioxide For diabetes and its complications including boils eczema gangrene cataract optic atrophy deafness delirium etc Fraudulent therapeutic claims—[N J 24537 March 1936]

Germ X—American Lanolin Corporation Lawrence Mass Composition Essentially sodium hypochlorite common salt sodium carbonate sodium hydroxide and water For skin disorders influenza etc Not a germicide as represented Fraudulent therapeutic claims—[N J 24540 March 1936]

Grainalfa—Laboratory Products Co Providence R I Composition Essentially water sugars and plant extracts including wintergreen and peppermint oils Tonic and tissue builder Fraudulent therapeutic claims—[N J 24546 March 1936]

Calafin Liquid—Calafin Co Inc Los Angeles Composition Essentially potassium iodide arsenic opium alcohol and water For asthma hay fever etc Fraudulent therapeutic claims—[N J 24547 March 1936]

Allimin—Vitalin Products Co Chicago Composition Pills containing plant extracts including garlic For high blood pressure hardening of the arteries stomach and kidney troubles Fraudulent therapeutic claims—[N J 24549 March 1936]

THE USE OF CHEMICALS AS NASAL SPRAYS IN THE PROPHYLAXIS OF POLIOMYELITIS IN MAN

To the Editor—The value of nasal spraying with chemicals has yet to be established as useful for preventing infantile paralysis in man. The conservative physician will so advise his patients and await the results of a competently conducted controlled study.

The new classic experiments on monkeys that were carried out simultaneously by Armstrong and Harrison, Schultz and Gebhardt and Olitsky and Cox are well known (Armstrong, Charles, and Harrison, W T. Prevention of Experimental Intranasal Infection with Certain Neurotropic Viruses by Means of Chemicals Instilled into the Nostrils, *Pub Health Rep* 51 203 [Feb 28] 1936. Sabin, A B, Olitsky, P K, and Cox, H R. Protective Action of Certain Chemicals Against Infection of Monkeys with Nasally Instilled Poliomyelitis Virus, *J Exper Med* 63 877 [June] 1936. Schultz, E W, and Gebhardt, L P. Prevention of Intranasally Inoculated Poliomyelitis in Monkeys by Previous Intranasal Irrigation with Chemical Agents, *Proc Soc Exper Biol & Med* 34 133 [March] 1936). In a recent report by Schultz and Gebhardt (Zinc Sulfate Prophylaxis in Poliomyelitis, *THE JOURNAL*, June 26, p 2182) zinc sulfate in 1 per cent solution was found to be the solution of choice. The necessity of careful application by a slender atomizer tip that will insure contact with the olfactory area was described in an accompanying article (Peet, M M, Echols D H, and Richter, H J. The Chemical Prophylaxis for Poliomyelitis, *THE JOURNAL*, June 26, p 2184). The observations in this investigation together with the apparent failure of a similar spray (picric acid and alum) in the Alabama epidemic of last summer make it imperative that the spray should be limited to physicians thoroughly familiar with the technic and in a position to make a controlled evaluation of the method. The occurrence of at least twenty-five cases among those "protected" in Alabama has already confused those who follow the literature on this disease. However, in justice to the method it should be stated that the picric acid and alum applications were not adequately restricted (Armstrong, Charles. Experience with the Picric Acid-Alum Spray in the Prevention of Poliomyelitis in Alabama, 1936, *Am J Pub Health* 27 103 [Feb] 1937).

In the meantime, other evidence has been marshaled that seriously questions the time honored conception that poliomyelitis in man is primarily a nasopharyngeal disease. This new evidence points to the gastro-intestinal tract as the portal of entry of the virus. In the 1936 poliomyelitis epidemic in Chicago, my associates and I were unable to isolate the virus from the nasopharynx of twenty recent convalescents but obtained it five times from the rectal washings of four of the same patients. We (Harmon, P H, Wasbotten, P M, and Levine, Victor. Pathology of Olfactory Bulbs from the 1936 Epidemic of Poliomyelitis in Chicago, *Proc Soc Exper Biol & Med*, to be published) pointed out the collateral evidence of being unable to find alterations in the olfactory bulbs in nine fatal cases from the same epidemic, indicating that the portal of entry was other than the nasopharynx. Toomey has just published a complete summary of other data questioning the nasopharynx as the port of entry for this virus in man (Toomey, J A. Active and Passive Immunity and Portal of Entry in Poliomyelitis, *THE JOURNAL*, August 7, p 402). These data are that 1. There is no obvious contagion in the poliomyelitis of man, as is one of the striking characteristics of those diseases known to be spread through the upper respiratory tract.

2. Monkeys do not contract the disease by the nasopharyngeal route except when heroic methods are used. 3. Sectioning the olfactory tracts in monkeys does not prevent infection when the virus is given by the vascular route. 4. Nasal spraying with zinc sulfate does not prevent the experimental disease when the virus is given either venously or by the intestinal route. 5. Symptoms in man are often exclusively referable to the gastro-intestinal tract. 6. Reflex changes appear in human poliomyelitis similar to those in typhoid, a gastro intestinal disease. 7. The late summer and autumnal prevalence is a characteristic of the gastro-intestinal fevers. 8. The disease can be produced in monkeys by the gastro-intestinal tract. 9. The symptoms so produced experimentally are far milder and more closely resemble the disease in man than the drastic paraplegia that follows the nasal and cerebral introduction of the virus. 10. The toxins of the enteric organisms seem to facilitate the experimental production of the disease. Against this array of evidence, the data favoring the nasopharyngeal portal of entry consist of the experimental evidence that the disease can be so produced in monkeys and the isolation of the virus from that site from human convalescents, from active paralytic and abortive cases and from alleged healthy carriers in man (reviewed by Paul, J R, Trask, J D, and Webster, L T. Isolation of Poliomyelitis Virus from the Nasopharynx, *J Exper Med* 62 245 [Aug] 1935).

A large amount of the force of the latter result is lost when it is recalled that the virus may be found in the nasopharynx after intracerebral and intravenous introduction (Fleener, Simon and Amoss, H L. Persistence of the Virus of Poliomyelitis in the Nasopharynx, *J Exper Med* 31 123 [Feb] 1920. Lennette, E H, and Hudson, N P, Relation of Olfactory Tracts to Intravenous Route of Infection in Experimental Poliomyelitis, *Proc Soc Exper Biol & Med* 32 1444 [June] 1935). Such nasopharyngeal virus might be egressing rather than on its way into the nervous system.

In the light of controversy about the nasopharyngeal portal of entry in man, the cautious physician probably will not advocate nasal sprays for indiscriminate application until reliable evidence is forthcoming to prove the value of this method in the prevention of human poliomyelitis.

FURUNCLES OF THE FACE

To the Editor—With interest I have read the editorial on furuncle of the face (*THE JOURNAL*, July 24, p 278). For a year I have had under my care about 400 mentally ill patients many of whom are liable to dietary indiscretions and as a result prone to the development of furuncles and onychias. Once this condition has developed, the patients are often most uncooperative to nursing care and the infection is liable to respond slowly to treatment. Furthermore, many of these patients are already debilitated from other causes. About eleven months ago the amputation of a finger was necessary in two patients because of osteomyelitis of the phalanges, complicating simple onychias.

For several months these cases have been treated by the application of 5 per cent tincture of iodine and dry dressing, twice a day or in some cases once every hour. Pus under the skin, when present in onychias, is drained and then the tincture of iodine and dry dressing are applied.

This treatment in mentally ill patients is advantageous because little cooperation is required by the patient. The most impressive feature of the treatment has been the manner in which furuncles have subsided without pus formation and without leaving any disfiguration.

J A CUMMINS, M D, Hamilton, Ont

Queries and Minor Notes

THE ANSWERS HERE PUBLISHED HAVE BEEN PREPARED BY COMPETENT AUTHORITIES. THEY DO NOT, HOWEVER, REPRESENT THE OPINIONS OF ANY OFFICIAL BODIES UNLESS SPECIFICALLY STATED IN THE REPLY. ANONYMOUS COMMUNICATIONS AND QUERIES ON POSTAL CARDS WILL NOT BE NOTICED. EVERY LETTER MUST CONTAIN THE WRITER'S NAME AND ADDRESS, BUT THESE WILL BE OMITTED ON REQUEST.

VACCINES FOR POLIOMYELITIS

To the Editor—Please advise me regarding the status of Kolmer's vaccine for the prophylaxis of poliomyelitis. His article in *THE JOURNAL*, Dec 14, 1935, is interesting and assuring, but Leake in *THE JOURNAL*, Dec 28, 1935, reported that twelve persons were given poliomyelitis from the vaccine. This occurrence does not appear so assuring as to its reliability.

L L STARKEY MD, Harlingen Texas

ANSWER—Vaccines prepared from the virus that were designed to "immunize" against human poliomyelitis are at present in ill repute. The present views relating to the vaccines of Kolmer (ricinoleated virus) and Brodie (formaldehyde-virus) are the same as those expressed in the editorial on the status of vaccination against poliomyelitis (*THE JOURNAL*, Aug 29, 1936, p 716).

The problem of specific vaccination in this disease was attacked many years prior to Kolmer's recent use of the ricinoleated vaccine. Flexner and Landsteiner and Levaditi, shortly after the discovery of the virus by Landsteiner in 1909, obtained some evidence of protection with a specific vaccine in only a certain percentage of monkeys so inoculated. Many other investigators have tried almost every conceivable experimental variation in vaccine production in the intervening years but always with the same result: production of virus neutralizing substances in the blood stream of monkeys, but resistance against cerebral and nasal virus tests was obtained in only a few animals. The experimental work of the past decade has produced data which adequately explain such results: neutralizing antibody is produced whenever the virus comes in contact with either a susceptible host (man or monkey) or a nonsusceptible host (other animals). But the presence of neutralizing antibody is not an index of immunity in this disease, as has been abundantly demonstrated both for the experimental disease (Gordon, Schultz and Gebhardt, Rhoads, Sabin and Olitsky and Aycock and Kagan) and in the disease of man (Harmon and others and Brodie and his associates). This fact obtains because of the peculiar pathogenesis of the disease: once the virus has become established in a neuron it appears to be little affected by neutralizing antiserum. E W Schultz (Immunity and Prophylaxis in Poliomyelitis, *THE JOURNAL*, Dec 26, 1936, p 2102) and Schultz and Gebhardt (Zinc Sulfate Prophylaxis in Poliomyelitis, *THE JOURNAL*, June 25, 1937, p 2182) have reviewed these concepts in relation to the newer methods of chemical blockage at the supposed nasopharyngeal port of entry.

Kolmer's use of the ricinoleated vaccine was antedated by the experiments of McKinley and Larson, who demonstrated the infectivity of the vaccine on monkeys. Trials of this vaccine were carried out by Kolmer on nearly 11,000 children during 1935. In these vaccinations, nine cases of paralytic poliomyelitis occurred so closely connected with the vaccination as to suggest that the virus in the vaccine was not sufficiently altered by sodium ricinoleate. The report by Leake (Poliomyelitis Following Vaccination Against the Disease, *THE JOURNAL*, Dec 28, 1935, p 2152) discussed the cases in which both the Kolmer and the Brodie vaccine were administered in the tests mentioned.

The risk attendant on the use of these vaccines in man is too great, especially since their actual preventive value is debatable. The capriciousness of this disease makes it imperative in the future that any proposals for the trial of specific vaccines on man be even more cautiously applied.

PREVALENCE OF SYPHILIS

To the Editor—If available, will you furnish me with statistics of the prevalence of syphilis in (1) general, (2) insane institutions and (3) penitentiaries? I would also appreciate other important facts which would furnish material for the preparation of a paper to be used before organizations of the general public.

MD Pennsylvania

ANSWER—All authorized sources of treatment in socially and geographically representative areas in the United States serving approximately one fourth of the nation's population responded to requests from state and local health authorities to report the number of cases of syphilis under treatment or observation on a given date. These reports indicate that in the

United States there are constantly under observation and treatment at least 683,000 persons with syphilis. This estimate represents the absolute minimum of infected individuals, since it includes only those who are under authorized medical care.

The United States Public Health Service has estimated that there are approximately 160,000 persons with cardiovascular syphilis in the United States. Of these, approximately 40,000 die from cardiovascular syphilis each year. (These estimates are based on the observations from a number of sources indicating that approximately 2 per cent of the population suffer from heart disease, at least 65 per cent of which is syphilitic in origin.)

The U S Bureau of the Census for 1933 gives an average of 18,700 patients with dementia paralytica under treatment in 171 state institutions for mental diseases in the United States.

Among 119,000 persons, which represents the average prison population for federal and state prisons in the United States, sample studies show an average of from 160 to 170 per thousand with a positive serologic blood test for syphilis.

Other important facts which would be of interest are that at last half a million persons acquire syphilis each year in the United States, 100,000 of them before 20 years of age, that there are approximately 25,000 fetal deaths from syphilis each year in the United States, that from the limited data available there is no evidence that there is a downward trend of syphilis in the United States, and that there are at least twice as many known new cases of syphilis each year in the United States as there are of scarlet fever, thirteen times as many as diphtheria, twenty-eight times as many as typhoid, and one and one half times as many as tuberculosis.

DIAGNOSIS OF PNEUMONIA SERUM TREATMENT

To the Editor—A married woman aged 65 had a severe pain at the base of the chest on the right side followed by vomiting and insomnia. The pain tended to spread below the thorax. Two days later a doctor administered mild sedatives and the pain was somewhat lessened. The temperature was about 102.2 F, the pulse 88, the respiration rate 28 and the white blood cell count 10,800. The provisional diagnosis was lobar pneumonia. Sputum could not be obtained, and further action was delayed pending consultation. The consultant rejected the diagnosis of pneumonia suggesting undulant fever and the patient was removed to a city hospital. For the two following days the diagnosis remained doubtful and the next day the relatives were advised that the patient undoubtedly had lobar pneumonia. The eighth day after the onset the patient died. 1. When after the initial attack the presence of pneumonia remains in doubt because of delayed cough, expectoration and dyspnea, what early steps can be taken to verify or disprove the diagnosis? 2. If one has made a diagnosis but sputum is still absent, what is the best way of obtaining a specimen for typing? Or can the type be established in any other way? 3. Failing in efforts to type, should one administer serum of type I or types I and II or any other combination?

MD Maine

ANSWER—The precise diagnosis of pneumonia occasionally requires fine discrimination and laboratory aid. In the case described the provisional diagnosis of lobar pneumonia by the local physician seems justified. The diagnosis of pneumonic consolidation could have been confirmed by roentgen examination. Because approximately 90 per cent of lobar consolidations are due to pneumococcal infection, this diagnosis should have been considered unless undulant fever had been definitely demonstrated. Until the etiologic agent was determined the diagnosis was inadequate.

It is frequently believed that a large amount of sputum is necessary for typing. A fleck may be ample. Many patients with pneumonia have pulmonary secretion which they swallow instead of expectorating. In the absence of satisfactory expectoration it is usually possible to obtain sufficient pulmonary mucus for typing by swabbing the throat, which usually causes cough, after the patient has been turned for a few minutes with the side of the lesion uppermost. When there is much nasal secretion, the larynx may be exposed with a laryngoscope and secretion collected. If there is insufficient mucus for a satisfactory examination the material obtained by swab should be incubated in broth (of pH 7.4 to 7.6, 1 cc) for three hours and then injected into the peritoneum of a white mouse. Pneumococci multiply there and may invade the blood stream of the mouse. The procedures for typing are given in "The Reliability of Sputum Typing and Its Relation to Serum Therapy," by Jesse G M Bullowa in *THE JOURNAL*, Nov 9, 1935, page 1512.

When pneumonia is suspected blood cultures should be made and they should be repeated if the temperature does not fall promptly when they are negative. If the patient with pneumonia vomits mucus may be sought in the vomitus and used for typing.

As a general rule serum should be administered to patients only after the type of the infecting organism has been determined, because specific serums act only on the organisms for which they are made.

Because pneumococci of types I and II are responsible for a greater percentage of pneumonia than any other types (about 30 to 50 per cent), the physician may give serum for these types until their agglutinins are detected in the patient's blood. After the tests for sensitivity, at least 100,000 units of antibody for each type should be given in the shortest possible period. Occasionally the administration of antipneumococcus serum in this way may save life. However, the physician is not absolved from the responsibility of establishing the correct type by further study. He may then administer the appropriate serum if it is necessary and can be secured.

USE OF ARTIFICIAL SUN LAMPS IN ECZEMA

To the Editor—A man aged 28 has had recurrent eczema of the face and arms since early childhood. When the attacks are severe the eczema is of the moist type and when mild a mere dermatitis with intense itching so intense that it interferes with sleep and work. Allergic tests and studies have been of no avail to disclose a causative factor or factors and all treatments prescribed by competent dermatologists have been of but little service. The only relief accorded the patient is by sun baths, which give him complete relief when he can obtain sufficient exposures. As sunlight in this climate is at a great premium in winter this season makes life miserable for him. The logical conclusion seems to be the substitution of artificial sun rays. Kindly suggest the type of rays most likely to be efficacious and the type and power of lamp that would best serve for home treatment. The patient has sufficient mechanical knowledge and judgment to make such treatments safe. If you care to, please recommend some make or makes of lamps that would be suitable.

GEORGE W. ELA, M.D., Pittsburgh

ANSWER—Although some physicians use ultraviolet therapy as an adjunct in the treatment of eczema, there are reports on record to the effect that exposure of eczema to such rays may cause an exacerbation. There are three types of ultraviolet radiation generators available that may be employed for this purpose: the mercury arc in quartz (high vapor pressure), the mercury glow in quartz (low vapor pressure), and the carbon arc lamp. A list of acceptable lamps may be obtained from the Council on Physical Therapy, American Medical Association, 535 North Dearborn Street, Chicago.

SWELLING OF HANDS

To the Editor—For the past three years I have been taking care of a woman aged 55, white, married, who is a housekeeper. She has shown in that time a gradually increasing generalized swelling of the hands to the level of the wrists. Her only complaints with regard to the hands are stiffness of the joints and a certain amount of awkwardness in using them. Occasionally she complains that they are cold and somewhat numb. The hands are a dusky red and are cold and dry; they show a uniform soft tissue swelling which does not pit on pressure. Passively the joints are freely movable without pain but actively she finds it difficult to close her hands completely but feels no tenderness or pain on using them. The radial pulses are equal, regular and normal in quality. The rest of the physical examination reveals the following positive results: The blood pressure ranges from 170/120 to 190/140; the pulse from 90 to 110. The skin has a coppery tinge that has appeared only in the last three years. There is a moderate sized goiter, nodular, which has been present for twenty years and has been slightly larger in the past three years. The heart sounds are of fairly good quality but distant. The urine and blood count have been normal on several examinations. The basal metabolism has been from plus 25 to plus 15 on several examinations. The blood Wassermann reaction has been negative on three examinations. The past history shows one pregnancy normal with one living child. Subsequent pregnancies were deliberately avoided. One operation was performed in 1922 for removal of an ovary and tubes. No serious illness or accident has occurred. All the teeth and the tonsils were removed in 1935. Her complaints besides those referable to the hands are those of a patient with a moderately overactive thyroid gland. In addition she is very introspective and worries constantly about her condition. She refuses operation for the thyroid condition and a course of x-ray therapy by a competent man has had no demonstrable effect. Treatment has been symptomatic. Can you suggest the etiology of the swelling of the hands or any further means of discovering it?

M.D., New York

ANSWER—It is impossible to say what the swelling of the hands is due to. While swelling of the soft tissue is commonly seen in chronic infectious or rheumatoid arthritis affecting the hands, this condition would seem improbable as the patient does not have pain or definite swelling of the joints. However, roentgenologic examination should be made. Search should be made for causes of obstruction of the lymphatic and venous circulation in the upper extremities but it is quite probable that this will not be found. Sclerodema or scleroderma should be quite apparent after the swelling has persisted for three years. Angioneurotic edema and conditions of a similar nature seem excluded by the persistence of the swelling. Renal disease and myxedema seem adequately excluded. Such conditions of swelling of the hands are occasionally seen for which no satisfactory etiology can be determined and for which there is no satisfactory treatment.

DISORDER OF TASTE SENSATION

To the Editor—May I ask what line of inquiry you would suggest in attempting to make a diagnosis in this case? A woman aged 55, single, complains of a disagreeable taste in the mouth constantly present. She cannot enjoy any food or drink because the tongue perceives practically nothing except the bad taste. The tongue feels swollen along the left side which margin looks slightly swollen and has enlarged veins. These veins would probably not have been noticed except for the patient's complaint. At first I thought it was a soreness she felt and when the usual treatment with antiseptics and so on failed to improve it I sent her to her dentist. He also can find no condition to account for the symptoms. Outside of the tongue I have found nothing to blame. There is no pressure on the veins at the base of the tongue. The condition began five or six weeks ago. The past week she stated that the other side began to feel the same way but I cannot see what is doing it. This is a very incomplete question I realize but can you suggest what line of inquiry should be started?

M.D., Illinois

ANSWER—There are multiple factors which might influence the nerves supplying the sense of taste. So little information is given in the inquiry as regards the lines of clinical or laboratory investigation which have already been applied that it is difficult to suggest any specific course. It is well known that pathologic changes in the area of the uncinate gyrus of the brain will affect the sensory nerves of the tongue (Prinz, Hermann, and Greenbaum, S. S. Diseases of the Mouth and Their Treatment, Philadelphia, Lea & Febiger, 1935, p. 510).

Prominences of the sublingual venous supply are common in mouth examination, though usually symptomless unless the condition becomes angiomatous with compression. Certain types of anemias, more especially pernicious anemia, are frequently first discovered by a glossy, sensitive tongue with areas of denuded epithelium, but rarely will the sense of taste be seriously affected.

More common causes of bad taste are imperfect cleansing of pockets or sepsis of the oral cavity. Certain drugs when taken at regular intervals, or even occasional doses, more especially nerve sedatives, basic salts or narcotics, may cause temporary unpleasant sense of taste. Obstruction by calculi of the salivary glands, inflammation, or radiation treatments over the sublingual ducts may cause considerable disruptions of salivary secretion and taste.

Since the patient is 55 years of age she is extremely fortunate if she does not have one or more artificial dentures or restorations. Chemical and metallic tastes that come from basic denture material such as sulfur, or coloring products found in latex-vulcanite dentures are often a source of bad taste as well as the rubber mouth odor. Most of the newer proprietary dental base materials contain such elements as phenolresin, ammonia, camphor or nitrocellulose, which almost without exception will give the wearer an occasional unpleasant taste.

During recent years much research has been done on the possibility and symptoms of electrogalvanism between dissimilar and variously alloyed metallic materials used in dental restorations. Case reports of such cases are now common both in medical and dental literature. A taste of copper, zinc, silver, aluminum, mercury, nickel or phosphorus as well as irritation of the tongue even to the degree of erosion and ulcers, may occur as a result of electrolysis through the saliva between the metallic restorative dental materials.

A more elaborate and explicit aid in the diagnosis of the patient's trouble may be obtained by reviewing the following bibliography:

- Rattner, Herbert. Stomatitis Due to Sensitization to Dental Plates. *THE JOURNAL* June 27, 1936, p. 2230.

IMMUNIZATION TO POLIOMYELITIS AND THERAPEUTIC SERUMS

To the Editor—What is the present status of protective immunization against poliomyelitis? Are the therapeutic serums considered effective after the onset of paralysis?

M.D., Ohio

ANSWER—Serious question having arisen as to the efficacy and safety of protective immunization against poliomyelitis, its use has generally been abandoned. Some workers have believed that serum given in the presence of paralysis offers hope of obstructing the advance of the paralysis when there are signs of activity such as fever and increase in the paralysis within the preceding twelve hours. Usually it is advisable to withhold serum except in cases of definite poliomyelitis in which paralysis does not exist at the time.

GROUND SQUIRRELS AND PLAGUE IN THE
UNITED STATES

To the Editor—How widespread is the infection of ground squirrels with plague infected fleas? I have heard that the infection in ground squirrels is gradually spreading. Have there been any recent cases reported from the interior of the country? What is the danger to any one from handling ground squirrels or their pelts? Would there be any danger to hunters in this respect?

M D Pennsylvania

ANSWER—The existence of rodent plague in ground squirrels has been demonstrated in all the Pacific and Mountain states except Colorado, Arizona and New Mexico. It has not been possible to determine how long the disease has prevailed in the states in which it has been discovered most recently, therefore it cannot be stated with certainty whether or not rodent plague is spreading in the United States. No case of rodent or human infection has been reported in recent years in states east of the Rocky Mountain region. In the opinion of the U S Public Health Service the handling of ground squirrels is dangerous in regions where rodent plague is known to exist.

SKIN INFECTION AMONG WORKERS IN
PLATING DEPARTMENT

To the Editor—I have been taking care of several men who have a breaking out on their hands caused by the work they do. They are all working in the plating department of a factory in which platinum, chromium and nickel are the chief metals used. They come in contact with these metals or the fumes from them. The company is reluctant to let these men go because it takes considerable time to teach new men this kind of work especially since they don't know which one will be susceptible to the disease. Is there any way of testing a new man to see whether he is susceptible to new metals? I have used a considerable number of combinations of ointments and liquids but I seem unable to cure them except temporarily. If you know of anything besides a change of occupation to cure these men please let me know.

M D Iowa

ANSWER—Whenever groups of workers in any given industrial department develop skin diseases in the absence of innovations in trade practices, the physician in charge should become suspicious that the outbreak may be mycotic rather than purely chemical. In the plating industry, many large plants operate year in and year out without a single case of occupational dermatitis. Then without unusual changes in work procedure, numbers of workers may within a few weeks time present disabling skin disorders. On proper examination of skin scrapings, it is often possible to demonstrate various types of fungi, including monilia, which may not be the direct cause of the disturbances but no less contribute to the perpetuation of chemical injury and the exaggeration of chemical injury.

Whenever platers develop skin disease, it is natural to associate causation directly with metals, such as nickel, copper, chromium or cadmium. Despite the actuality of nickel or chromium dermatitis, it is more often true that the dermatitis may be caused in whole or in part by other substances found in the plating department, including acid and alkali baths and cyanide solutions. No simple test or procedure will furnish adequate information as to susceptibility to these multiple and various irritants. As the greater number of substances employed in plating are direct irritants, even in weak solution, little will be gained by patch tests as a measure of sensitization. In the present situation, a number of suggestions of possible helpful nature are now made.

1 Other things being equal, Negroes make good workers in plating departments because of relative nonsusceptibility to skin disease.

2 Dark skinned, swarthy brunet types are relatively less responsive to industrial skin irritants than blonds or red headed workers.

3 If parasitic organisms complicate chemical dermatoses, the condition becomes well nigh intractable if exposure is continued. In the absence of repeated exposures x-ray treatment with or without the use of organic mercury compounds may lead to the disappearance of the mycotic lesions.

4 The wearing of protective garments, especially rubber gloves may serve some useful purpose, provided no fluids are permitted to enter the gloves. In some instances the application of protective emollients, such as are unaffected by plating solution, may be of value. The Milburn Company, Detroit, manufactures a series of protective preparations, some one of which conceivably might be of value.

5 Patch tests carried out with various plating materials in concentrations below ordinary irritating strength may demonstrate a true sensitivity. In this case, affected workers probably should change operations.

6 At the end of the work period the application of fatty materials to the skin of hands and forearms such as hydrous wool fat theobroma oil or a good rosewater ointment may serve a preventive function by replacing the normal fat of the skin removed by the acids and alkalis of plating work.

7 General department sanitation and hygienic practice of workers may play some part in the production of skin disease. As a rule, well cleaned modern plating departments have much less occupational disease experience than disorderly, obsolete departments.

8 A change from hand plating to automatic processes obviously will eliminate much contact between the skin of workers and plating chemicals.

TREATMENT OF CALLUS AND CORNS ON FEET

To the Editor—A woman about 30 years of age has had a heavy corn growth on her feet from an early age. It is around the sides of the toes and the back of the heels and on the bottoms. In 1928 she had them treated by a skin specialist. He used x-rays and radium. From the time of treatment they have had the so called radium blisters that cause such terrible itching and pain. Now they are so bad that all the places especially where the radium was used have sloughed off all the skin and are a mass of flesh and blisters. Can you tell me anything to use to build up the tissues to throw off this condition? A surgeon operated on five places on the feet in the hope of removing all the destroyed tissue but the operation was a failure. Now surgery is out of the question so much of the area of the feet is involved. The patient is working and must be on her feet and as a result is nearly crazy with pain.

H L DUMBLE M D Hood River Ore.

ANSWER—The prognosis in this case cannot be encouraging. Healing of areas in which necrosis has occurred as a result of the use of x-rays and radium with what probably amounts to secondary infection either with pyogenic or with saprophytic organisms is difficult under ideal circumstances. Complete rest for an extended period is definitely indicated. Attempts to treat a condition of this kind while the patient continues to be active on her feet are almost certain to be futile. The feet should be soaked in a solution of dilute potassium permanganate for ten minutes morning and evening. Two teaspoonfuls of a saturated solution of potassium permanganate may be added to one quart of water, which has been previously boiled but allowed to cool. The feet should be kept bandaged loosely and for at least an hour each day should be exposed to the air.

LIGHT AND COLOR FOR OPERATING ROOM

To the Editor—1 Which is the best light for an operating room for a modern hospital? 2 Which is the best color for the walls of an operating room for a modern hospital?

M D Georgia

ANSWER—1 Since daylight is variable and there are many hours when it is not available, it will be assumed that this question refers to artificial lighting. The artificial illumination of operating rooms has been the subject of a great deal of study and experimentation during recent years resulting in the production of various special fixtures that are more or less satisfactory for the purpose. In choosing an operating room special lighting fixture, the following requirements, which are embodied in several units on the market, should be specified.

(a) A constant illuminating intensity at the work place of from 150 to 300 foot candles should be at all times available, with a variable dominant direction to the light.

(b) The lamp should be designed so that more than one filament is available in the event of the burning out of one. Lamps are now available with a ring filament for diffuse illumination and a concentrated spotlight filament for maximum visual efficiency, these may be used separately or simultaneously.

(c) Shadow should be entirely eliminated or minimized.

(d) There should be no glare, and provision should be made to eliminate excess heat.

(e) A lamp should have a constant color value and under certain conditions accuracy of color value attained by the use of approved spectral transmission glass.

(f) The cost of installation, operating and maintenance should be reasonable.

Instead of the separate unit, a system of ceiling lights with prismatic plates or reflectors that focus the light on the work plane is sometimes used, but while satisfactory from the standpoint of illumination, it involves a rather high original cost, requires constant attention and consumes an enormous amount of current.

In all cases general illumination is required in addition to the special lighting which may be of the direct type with a diffusing globe. There should also be a portable spot light preferably of the independent battery type in every operating room for emergency use.

2 The object of using color in an operating room is to decrease glare and to create the best conditions for visual accommodation. Glare not only decreases visibility but causes discomfort and eyestrain disorders and is distracting. To overcome the glare of bright walls that are in the visual field of the surgeon, various colors have been used not only for walls

but for sheets used in the operating field. Wall surfaces and surroundings act either as light reflectors when white or as absorbents when dark, and in the operating room the two extremes must be avoided. The reflecting power of color runs from about 87 per cent for milk white to 10 per cent for black, and so a shade is indicated that will range midway between the two. A dull French or gray-green for the wainscoting extending to a height of about 7 feet, with a lighter gray green above has given great satisfaction but a sky blue wainscot has been used with equal effectiveness. A gray tile floor will add considerably to the eye comfort and visual acuity of the surgeon.

POSSIBLE GONORRHEA AND PROSTATITIS

To the Editor—A man aged 22 single came to me in August 1935 with a history of gonorrhea two years previously supposedly cured in one month. Now four days after coitus he had noted a sticky white urethral discharge. A smear revealed many pus cells but no gonococci. Both glasses of urine were clear but contained shreds. The prostate was neither enlarged nor tender but its secretion was packed with pus. The gonococcus complement fixation was negative. He received irrigations of potassium permanganate 1:8000 and later silver nitrate increasing from 1:8000 to 1:4000. At the same time he was given prostatic massages and sounds were passed. A Kollman dilator was used up to 32 F. After three months a lapse of treatment for one month was instituted. The urine still showed shreds in the first glass and the prostatic secretion still showed numerous pus cells although a notable increase in lecithin bodies was evident. Subsequently the patient has been treated about twice weekly for two or three months with a regular monthly lapse in treatment. Beer liquor and sexual activity cause no exacerbation. Since October 1936 he has received one instillation weekly of 2 cc of 2 per cent silver nitrate into the posterior urethra. The urine is entirely clear but the prostatic secretion still shows many pus cells and clumps. He has received no vaccines and yet once during the past year and a half the complement fixation was positive to become negative subsequently. At no time was the gonococcus found in the urethral or prostatic secretions. What further can be done to clear the prostate? Will it ever clear up? May he marry under the present circumstances? The patient is in excellent physical condition presents no foci of infection (excluding the prostate) and has no symptoms referable to the genito-urinary tract. M.D. New York.

ANSWER.—In this case the question of whether or not gonorrhea ever existed is problematic. The question of whether it is present now must be answered. Cultures of the first urine in the morning and of the prostatic secretion should be made according to the method advised by Luther Thompson (*Am J Clin Path* 5:313 [July] 1935). If these are negative for neisserian organisms there is no reason why he cannot marry.

As regards the persistence of the prostatitis, there are three possible causes. Infection in either the teeth or the tonsils may be the cause. If these possible foci are not involved, a cysto-urethroscopic examination should be done. Thompson and Cook (*THE JOURNAL*, March 9, 1935, p. 805) have shown the importance of a chronic prostatic duct abscess in prolonging an infection in the prostate gland. These duct abscesses should be looked for and, if found, should be treated according to the method of Thompson and Cook.

HYPOTENSION WITH HEADACHES

To the Editor—I have a seemingly peculiar case in that a man aged 60 has been having a severe headache for the past four months. The headache begins in the back of the head and radiates down the nape of the neck. He states that in the morning there is little aching but that it begins late in the forenoon and continues throughout the day and evening. The only physical abnormality is a low blood pressure: systolic 100 diastolic 55. The reflexes are all normal and the eyegrounds are normal showing no muscular defects, weaknesses or contractures. Relief has been given temporarily by the use of tincture of belladonna; the first relief he has had since the headache started but the effect wears out and ever increasing doses are needed. He began at 10 drops three times a day and is now taking 35 drops three times a day. Thyroid extract and chlor of iron, quinine and strychnine do no good. I have observed that while the blood pressure is kept over 115 or 120 the symptoms disappear but as soon as it goes down again they recur. Is there some way I can give more lasting relief to this man?

MAX T. WAINWRIGHT, M.D. Mapleton Iowa

ANSWER.—The association of hypotension with headache such as described is most unusual. In the first place the degree of hypotension is not marked. Secondly, hypotension relative or absolute, is usually most pronounced early in the morning on first arising. Thirdly, tincture of belladonna does not appreciably affect the arterial tension, and yet in this instance it has apparently aided in controlling the pain. One naturally associates such relief from atropine with its effects on the mucous membranes and is curious to know how extensively the question of deep sinus infection (such as of the sphenoid sinus) has been investigated. The pain of sphenoid sinusitis is usually occipital.

If the apparent association of greater comfort and maintenance of the systolic tension over 115 is real, it is highly probable that this elderly patient has considerable cerebral arteriosclerosis. A slight relative hypotension may produce

symptoms due to inadequate cerebral circulation in the presence of arteriosclerosis. Observation of the arterial tension several times a day, when the patient is suffering from headache and when he is free from it, should reveal more precisely the association of the two phenomena. If this relationship is firmly established (the data in the query merely suggest but do not prove a relation between the headaches and hypotension) two therapeutic aids are available. Elderly persons often are greatly benefited by small doses of strychnine ($\frac{1}{100}$ grain [0.0065 Gm.] three times a day before meals), which may be continued for a long time. If this, through a general increase in vigor, does not result in lasting improvement, ephedrine sulfate 0.025 Gm. (three-eighths grain) may be prescribed once daily in the midmorning. Administration of ephedrine should be avoided in the afternoon and evening for it causes active wakefulness or interferes with rest by inducing violent nightmares. The increase in arterial tension that follows the oral administration of such doses of ephedrine sulfate lasts for several hours, but curative relief is not certain.

Before advising either of these two medicinal measures careful exclusion of possible sinus disease and refraction of the patient's eyes should be done. It appears more probable that the headaches are not of purely circulatory origin.

EFFECTS OF THEAMIN (A THEOPHYLLINE PREPARATION) AND AMYTAL

To the Editor—Can any harm arise from giving a 9 year old child one theamin and amytal capsule (Lilly) daily over a period of from three to six months? The capsule is used in conjunction with the usual fluid restriction in the treatment of nocturnal enuresis. M.D. Alabama

ANSWER.—Short of a tendency to habituation, which might assert itself in inability to get along without the dose or a lessening of the therapeutic effect, this combination would not be particularly harmful to a 9 year old child. The rationale for employing a diuretic (theamin) which would increase urinary output and at the same time sedative (amytal) which would tend to make the child sleep through what might otherwise be an effective stimulus from the bladder is difficult to understand. Theamin is a proprietary name for a theophylline preparation and has not been accepted by the Council on Pharmacy and Chemistry.

SYPHILIS AND PREGNANCY

To the Editor—In *Queries and Minor Notes* (*THE JOURNAL*, August 7, p. 451) is a question regarding the treatment of syphilis and pregnancy. The answer to this query includes the following statements:

- 1 The abortion may have been due to her syphilitic infection.
- 2 The treatment indicated. Others feel that there is danger of a serious reaction [to nearsphenamine] late in gestation and prefer the use of heavy metals in the later weeks.
- 3 The positive cord Wassermann is a reliable test.
- 4 The safest course to pursue is to give the new born infant a course of antisyphilitic treatment.

It is conceivable that an overwhelming syphilitic infection might cause an abortion in the second month of pregnancy. This patient however did not have such an infection. Furthermore no instances of fetal syphilis have been reported as occurring before the fourth month of pregnancy at the very earliest. Abortion at this time would certainly not be caused by infection of the fetus.

The recent summary of the Cooperative Clinical Group states that the pregnant woman suffers few untoward reactions to treatment and that both arsenic and bismuth compounds should be given preferably in alternate courses. Most syphilologists are in accord that treatment approaching term should be with nearsphenamine. The most serious treatment reaction hemorrhagic encephalitis usually occurs relatively early in pregnancy and after the first few injections of arsenic. In a recent survey of the literature I found that the most significant factor in the production of this complication was not the use of nearsphenamine but its overuse. McKelvey and Turner's recommendation of 0.3 Gm. is apparently the safest dose.

The positive cord Wassermann reaction is not a reliable diagnostic test since it usually reflects only the condition of the mother's blood at term. The infant may or may not have syphilis when the cord Wassermann reaction is either positive or negative. The positive cord Wassermann reaction indicates syphilis only when a control test on the mother, performed simultaneously is negative. Similarly a positive Wassermann reaction in the first few days of life does not indicate syphilis unless the reagin titer in the quantitative test is definitely higher than that of the mother. If successive tests on the infant show a constantly decreasing titer the child probably does not have syphilis.

If the child does not have syphilis and its chances are only one in ten or one in twenty if the mother has been adequately treated the safest course to pursue is not to give it treatment until a conclusive diagnosis has been made. This avoids the dangers of treatment reactivity on the one hand and stigmatization on the other.

There is one other point which has not been emphasized. This is the treatment of the mother with mercurosal intravenously. Cole and his co-workers have shown that mercurosal is rapidly eliminated from the body largely in the first twenty four hours after injection and is therefore not an adequate and therapeutically active form of mercury. In pregnancy it is particularly important that therapeutically active drugs be used.

FRANK E. CORMIA, M.D. Montreal

Medical Examinations and Licensure

COMING EXAMINATIONS STATE AND TERRITORIAL BOARDS

Examinations of state and territorial boards were published in *THE JOURNAL* September 18 page 978

SPECIAL BOARDS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY *Written examination for Group B applicants will be held in various cities through out the country in April Oral examination for Group A and B applicants will be held at San Francisco in June* Sec Dr C Guy Lane 416 Marlboro St Boston

AMERICAN BOARD OF INTERNAL MEDICINE *Written examination will be held in different centers of the United States and Canada Oct 18* Chairman Dr Walter L Biering 406 Sixth Ave Rm 1210 Des Moines Iowa

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY *Written examinations and review of case histories for Group B candidates will be held in various cities of the United States and Canada Nov 6 and Feb 6 Application must be filed at least sixty days prior to these dates General oral, clinical and pathological examinations for all candidates (Groups A and B) will be conducted in San Francisco June 13-14 Application for admission to Group A examinations must be on file before April 1* Sec Dr Paul Titus 1015 Highland Bldg Pittsburgh (6)

Book Notices

A Manual of Pharmacology By the late Walter E. Dixon, M.A., M.D., B.S. Revised by W. A. M. Smart, M.B., B.Sc., Lecturer in Pharmacology and Toxicology, London Hospital Medical College. Eighth edition. Cloth. Price \$6.50. Pp. 483 with 79 illustrations. Baltimore: William Wood & Company, 1936.

The present volume forms the eighth edition of Dr. Dixon's textbook on pharmacology, the first edition appearing in 1906. Following Dr. Dixon's death the revision of this book has been undertaken by Dr. Smart, a friend of Dr. Dixon. The book has been entirely recast, apparently by Dr. Smart, and it is impossible to tell just how much of the book is due to Dixon and how much to Smart, as the latter says in the preface that he has drawn freely from his lecture notes, which represent a concentration of information gleaned from many sources combined with his own observations. The arrangement of the book is much the same as that of other pharmacologies, no two of which agree, demonstrating the extreme difficulty of finding a logical arrangement for the different drugs which are considered, as it is not possible to get either a chemical or a pharmacologic order. Either arrangement breaks down in many instances.

In looking over the book critically, a number of points impress one. A valuable feature is the emphasis on the chemistry of the drugs. Dr. Smart mentions in his preface that this is largely a feature introduced by himself. Another feature, which would certainly seriously handicap the use of the book by the American medical student or practitioner, is that no United States pharmacopoeial preparations are mentioned, the list of individual preparations being entirely derived from the British pharmacopoeia. On this account alone it would seem that the use of the book would be greatly limited in this country. As one looks through the book one is struck strongly by a number of apparent errors. For example, on page 119 there is a tracing of the action of curare on blood pressure and limb volume. In the note under the tracing it is said that there is a depression of the vasoconstrictor nerves and vasodilatation with fall in blood pressure. The tracing itself, however, shows a definite increase in blood pressure and decrease in limb volume. In the paragraph discussing the excretion of morphine, the views expressed are not in harmony with our present knowledge and would seem to be those which were held twenty-five years ago. Indeed, the description of the action of morphine on the intestine is certainly not in harmony with our present knowledge. It may be questioned whether the statement on page 194 that the mercurials act well in edema of either cardiac or renal origin is really correct. The illustration of the apparatus for employing isolated tissues as given on page 243 would seem to be entirely out of place in a general textbook on pharmacology. Its place would seem to be rather in a laboratory guide. A serious objection might be made to the views expressed on page 245 with regard to the discovery of the new

alkaloid of ergot, where entire credit for the discovery is given to Dudley. Certainly in three other laboratories claims are being made to the discovery of this alkaloid. None of these other groups of workers are even mentioned. The statement that the new alkaloid is the one constituent to which the characteristic effects of ergot are due is also open to question. No one can state positively today the exact relative importance of this new alkaloid in the action of the crude drug. As a matter of fact, in some of the crude drug which is active there is little of the new alkaloid by whatever name the alkaloid may be known. In the discussion of aminopyrine, page 272, no mention is made of its dangerous action on the white blood cells, nor in the discussion of cinchophen is any mention made of its action on the liver. The statement is also made on the same page that in combinations of aminopyrine and the barbiturates the aminopyrine content may cause "a dangerous narcosis." One would question whether the barbiturate constituent may not have had something to do with the narcosis. The suggested rubbing of mercurial ointment into the skin over the affected part in cases of pleurisy, iritis, peritonitis and inflamed joints will probably be a strange suggestion to American clinicians. The discussion of the organic arsenicals, occupying a little more than one page, would seem to be absolutely inadequate, as would also the discussion of the vitamins, which occupies three pages. The posterior lobe of the pituitary is disposed of in less than fifteen lines. It may also be questioned whether the statement that the parathyroid preparations are active when given by mouth is in harmony with the general view. It would hardly seem to be necessary to point out that in cases of poisoning by phosphorus the phosphorescence of the vomited material and of the intestinal contents may be "best seen in the dark." On page 446 it is stated that epinephrine is useful when the heart is stopped, as in drowning or in carbon monoxide poisoning. In such a condition the drug must be injected directly into the muscle of the right auricle. One would be led to question as to how such a technic could be carried out. Finally, as a last example of the inadequacy of some of the text, it may be pointed out that on page 447 the action of liver in macrocytic anemia is disposed of in four lines.

No review would be complete without calling attention to the large number of prescriptions that have been inserted by the revising author. These are in general of a "shotgun" type that were in use some fifty years ago. Indeed, they have been drawn largely from the London Hospital Pharmacopoeia and the B. P. Codex. They remind one strongly of the old books which were formerly popular with medical students in which from 10,000 to 30,000 prescriptions were reproduced, being the favorite combinations of some old-time practitioners of medicine. They are certainly entirely out of harmony with the modern prescribing of drugs. The book, therefore, can hardly be recommended to the American medical student or practitioner.

Medizinische Praxis. Sammlung für ärztliche Fortbildung. Herausgegeben von Prof. Dr. L. R. Grote, Leitender Arzt der Medizinischen Klinik des Rudolf Hess Krankenhauses, Dresden. Prof. Dr. A. Fromme, Direktor der Chirurgischen Abteilung des Stadtkrankenhauses, Dresden. Friedrichstadt und Prof. Dr. K. Warnke, Direktor der Staatlichen Frauenklinik zu Dresden. Band VIII: Das Kropfproblem von Dr. Eugen Bircher, a Spitaldirektor und chir. Chefarzt des Kantospitals Aarau (Schweiz). Paper. Price 12 marks. Pp. 143 with 41 illustrations. Dresden & Leipzig: Theodor Steinkopff, 1937.

The purpose of the monograph of which this is one example is to provide short authentic summaries for busy physicians. The author has been actively identified with the problem of goiter for more than thirty years. All references have been omitted and the names of only a few investigators are mentioned. The text is divided into eight sections, beginning with one on anatomy and chemistry. The others are on physiology, pathology, pathologic physiology including hypothyroidism and hyperthyroidism, endemic cretinism, degeneration and endemic goiter, clinical features and diagnosis of the various types of goiter and their sequelae, clinical features and diagnosis of thyroiditis and malignant tumors, and the prophylaxis and therapy of goiter. The chapter on the pathology of goiter follows the old method of cataloging the anatomic with the clinical picture. Probably the author would complain less of "Babylonian chaos" if the morphologic cycle had been given primary, and the clinical association secondary, consideration.

In the chapter on hypothyroidism and hyperthyroidism, endemic goiter is not considered one of the forms of thyroid insufficiency. Basedow's disease is limited to those cases with genuine exophthalmos. The term "jod-Basedow" is rejected as false, although he perhaps overemphasizes the danger of inducing "thyroidism" by iodine. Endemic goiter is treated under the subhead of endemic cretinic degeneration. Since Paracelsus, endemic cretinism has been considered secondary to endemic goiter. Whether cretinic degeneration is a more complex constitutional disturbance than can be explained on the basis of several generations of thyroid insufficiency may have to await the therapeutic test of goiter prophylaxis. The author believes that the iodine deficiency (either relative or absolute) theory of goiter is unproved and, while admitting a great reduction in the incidence of goiter by the use of iodine, he believes this is not a result of a true prophylaxis but of "prophylactic therapy." He considers true goiter prophylaxis to be of a hygienic nature—better housing, more air and sunlight, balanced diets and pure drinking water. The monograph is an excellent example of how briefly the essential facts of the thyroid and its disease associations can be presented by one who through lifelong study of this problem has combined laboratory research with clinical studies.

Diphtherie und Konstitution Von Dr Frieda Bohning Paper Price, 1 60 marks Pp 24 with 4 illustrations Leipzig Georg Thieme 1937

The study is based on 554 cases of diphtheria occurring in a sanatorium for tuberculous children during the years 1926-1936. The author found that children suffering with frequent colds and children whose parents were susceptible to sore throats and respiratory infections had a higher incidence of diphtheria. The exudative lymphatic constitution predisposes to diphtheria. On admission, 74.8 per cent had large tonsils, 87.8 per cent had enlarged cervical lymph nodes, 59.8 per cent were of the narrow, skinny type of body build, and 39 per cent were children with blond hair and blue eyes. The intensity of the disease showed no definite correlation with constitutional factors. In connection with the question of prevention, it is interesting to note that about 50 per cent of the diphtheria cases occurred during the first thirty-four days after admission, 61.3 per cent within the forty-fifth day and 70.9 per cent within the sixtieth day. Active immunization at the time of admission would have prevented only about one third of the cases, a longer period is needed for the development of immunization, 86.6 per cent of the cases were mild, 3.4 per cent were severe and thirteen patients, or 2.6 per cent, died. The mild course of the disease may have been due to early treatment.

Allgemeine Chirurgie Von Prof Dr D Kulenkampff Leiter der chirurg. Abteilung und Direktor des Heinrich Braun Krankenhauses (staatl. Krankenh.) Zwickau Seventh edition Boards Price 7 50 marks Pp 246 with 15 illustrations Leipzig Johann Ambrosius Barth 1937

This volume, which previously appeared as part 13a of Breitenstein's *Repetitorien*, now comes out as a seventh revised edition and as a separate work. The book is merely a compend and the author in his preface does not claim anything more for it. It is neither a "general surgery," as it is entitled, nor is it comprehensive even as a compendium on the subject. There undoubtedly is a place for such a volume in Germany, otherwise it would not survive to a seventh edition, but such books are not well regarded either by teachers or by students of medicine in this country.

A Laboratory Manual of Physiological Chemistry By D Wright Wilson Benjamin Rush Professor of Physiological Chemistry University of Pennsylvania Third edition Cloth Price \$2 50 Pp 288 Baltimore Williams & Wilkins Company 1937

This book is intended as a teaching manual for medical, dental and veterinary courses. The first sections of the work review qualitative studies on phosphate, calcium, magnesium and chloride, and introduce quantitative work on organic phosphorus, sulfur and nitrogen. Then follow discussions of standard acids and bases, pH , indicators, buffered solutions, colloids, surface tension, and adsorption. Relatively little work is given on the chemistry of carbohydrates, fats and proteins. Phospholipins and cerebroside are not referred to at all, and cholesterol is referred to only in connection with gallstones. The section on the digestive tract is brief and elementary.

Short sections appear on the qualitative examination of milk, bone, muscle, nucleic acid, bile and pathologic urine. The general chapter on blood and hemoglobin includes an advanced treatment of qualitative spectroscopy. The quantitative studies of the blood filtrates and of urine present some of the usual methods with little improvement, precautions or explanatory material. At the conclusion, dietary deficiency experiments are described on rats, pigeons and guinea-pigs for vitamins A, B₁, B, C and D. The book covers a wide range, but one may question whether a more intensive and quantitative treatment of more limited material with emphasis on the chemistry of cell constituents and the composition of blood might not be more helpful to the student.

La tosse. Fisiopatologia clinica terapia Da Antonino Culotta assistente all'Istituto di anatomia patologica della R Università e all'Ospedale Principe Umberto di Palermo. Con prefazione del Prof Armando Businco. Paper Price 30 lire Pp 228 Palermo L. Salpetra Editore 1936

It seems that this is the first Italian monograph on the subject of cough. It is complete, simple and clear and is divided into three parts, as suggested by the title. The first part describes the physiopathology of the cough, its centers and nerve paths, its effects, its significance in medical symptomatology, its varieties and characteristics and its possibilities as a vector of infection. In the second part the author discusses coughing in disturbances of the respiratory system, in extra-respiratory diseases, in old persons and in infants. The third part is devoted to the general treatment of cough, its medical treatment, physical therapy, endotracheal injections and surgical treatment. The simple language used by the author and the clearness of the printed material make the book easy to read and understand, and the numerous marginal notes are helpful in locating points of special interest.

Modern Principles of Ventilation and Heating By T Bedford D Sc, Ph D Investigator to the Medical Research Council's Industrial Health Research Board. Three lectures given at the London School of Hygiene and Tropical Medicine under the Heath Clark Bequest to the National Institute of Industrial Psychology. Cloth Price 4s 6d Pp 85 with 23 illustrations London H K Lewis & Co Ltd 1937

In this little book the author summarizes current views on heating and ventilation in England with respect to temperature, humidity, air movement, air freshness, radiation, drafts and odors. A brief description is given of instruments that register two or more of the thermal factors affecting comfort, and of modern equipment for the control of these factors. Much of the research work described has been carried out by the author and his colleagues in British factories where men performed light work. The comfort standards found there differ considerably from those in the United States, owing to differences in climate, clothing, heating methods and general living conditions. The last two chapters deal largely with effects of high temperatures on output, sickness and accidents in hot trades. A four page appendix gives bibliographic references to recent literature, and there is a complete index in the end. The work as a whole is a compact and condensed exposition of the elements of heating and ventilation, and it should be particularly valuable to beginners and those who have not followed the literature.

Ganzheitsproblematik in der Medizin zugleich eine Einführung in die medizinische Erkenntnislehre Von Prof Dr Theodor Brugsch Boards Price 5 marks Pp 136 Berlin & Vienna Urban & Schwarzenberg 1936

Lotze, who, according to Welch, began as a pathologist and became a great philosopher, once wrote that every natural phenomenon may be investigated not only with reference to the mathematical grounds of its possibility and the causes of its occurrence but also as regards the meaning or idea which it represents in the world of phenomena. Brugsch has in many respects traveled the same path and in this, his most recent treatise, has developed a broad foundation for the contemplation of that aggregate of the sciences which are grouped as medical. Brugsch is concerned with the integration of this aggregate, as he is too in an integrative concept of the object, i.e., the human being about which the aggregate revolves. "Ganzheitsproblematik" has for the moment almost the quality of a slogan in continental and even in British circles. With Botha's support

of the movement termed "Holism," with Aschoff's recent discussion of the same trend, with the entire development of the concept of "constitution" on the one hand and "individuality" on the other as they are related to medical problems, there is evident a striving for some unitarian philosophy to satisfy an obvious void in the field of medical science—a distinct effort for synthesis in the confusing muddle of unlimited knowledge in limited fields. These general problems Brugsch treats in a series of chapters that begin with an examination of Kantian categories, traverse biologic concepts of the normal, vitalism, unity, adaptability, constitution (both in the normal and in the abnormal phase), disease as expressed in inflammation and allergy, heredity, and other related topics. The book is not designed to supply more detailed information for the pathologist or the internist. It is purely an exposition of a personal exploration of the basic problems of the abnormal biology that is called medicine. As such it is interesting because it affords an insight into an orderly contemplation of our science as finally achieved by a mind that has always been known for keen insight. Even Brugsch's style of presentation, at times more abstract than relished by the scientist of today, and at times a bit difficult to follow, by no means impairs the fine values that are presented.

Oxidation of Carbohydrates in Acid Solution. Quantitative Studies from the Biochemical Laboratories of the University of Oklahoma School of Medicine (Aided by a Grant from the Research Appropriation of the University of Oklahoma School of Medicine) By Mark R. Everett, Professor of Biochemistry, and Fay Sheppard, Instructor in Biochemistry. Paper. Pp. 66. Oklahoma City, Oklahoma: University of Oklahoma Medical School, 1936.

In earlier studies the authors called attention to the fact that the monocarboxylic acid lactones obtained by oxidizing aldoses are later oxidized to keturonic acids. In this brochure the quantitative evidence for this interpretation is presented on some fifty carbohydrates and correlated with the structural factors of the pyranoid structure of the respective monosaccharides. It is significant to note that ketoses also yield some keturonic acids and that sugar alcohols and nonreducing glucosides first yield ketoses and then l-keturonic acids. The path and extent of oxidation are in part determined by temperature and concentrations but in the main by three structural factors. The first of these involves substitution of a radical on the OH hydrogen of the reducing carbon in the pyranoid ring. Thus α and β glucosides behave differently, the former are oxidized slowly without hydrolysis, but the β forms are hydrolyzed and oxidized more easily. Substitution of a methyl group on the carbon atom at the other end of the pyranoid ring leads to more easily oxidized carbohydrates. This is well illustrated by the relative ease of oxidation of rhamnose. However, a carboxyl group addition in the same position increases the resistance. The cis-trans isomerism in the furanoid ring also affects the ease of oxidation of the carbohydrates in acid solution to keturonic acids. Complete trans isomerism favors keturonic acid formation by bromine oxidation in acid solution, but cis isomerism hinders it. The oxidation of carbohydrates by nitric acid resembles that by bromine in many respects. These relationships are also borne out by biologic oxidations and color reactions. From the pure organic chemical as well as from the biochemical point of view the value of comparative quantitative studies of the type under consideration cannot be overestimated.

Die Fermente und ihre Wirkungen. Von Prof. Carl Oppenheimer. Dr. phil. et med. Supplement. Lieferung 6 (Bd. II. Spezieller Teil. Hauptteil 13-15). Paper. Price 10 florins. Pp. 783-942 with 12 illustrations. The Hague: W. Junk, 1936.

This supplement to the excellent treatise on enzymes continues the consideration of proteases. It covers in detail the properties, distribution, purification, preparation, activation, inhibition, optimal conditions of action and mode of action of trypsin, rennin, pepsin, papain and cathepsins. At the close of the supplement is included an incomplete treatment of phyto-proteinases. In connection with the discussion of the rate of secretion of pepsin and trypsin, the author also briefly considers the chemistry of secretin, of gastrin and of the gastric anti-anemia factor. In completeness and in organization, this supplement continues to live up to the high standards of the previous supplements and the original treatise.

Laboratory Diagnosis of Psittacosis. Reports on Public Health and Medical Subjects No. 80. Ministry of Health Paper. Price 6d. Pp. 11 with one illustration. London: His Majesty's Stationery Office, 1937.

This official report gives full instructions with precautions for "the examination of pathological material from birds, from experimentally inoculated mice and from human beings suspected of infection with the virus of psittacosis." The methods of demonstrating the virus are described in detail and the microscopic appearances of the virus particles are well illustrated. The report will be of interest and service to all who may be concerned with the laboratory diagnosis of psittacosis.

Synopsis of Pediatrics. By John Zahorsky, A.B., M.D., F.A.C.P., Professor of Pediatrics and Director of the Department of Pediatrics, St. Louis University School of Medicine. Assisted by T. S. Zahorsky, B.S., M.D., Instructor in Pediatrics, St. Louis University School of Medicine. Second edition. Cloth. Price \$4. Pp. 367 with 80 illustrations. St. Louis: C. V. Mosby Company, 1937.

This is an excellent little monograph, well suited to the purposes for which it is intended, and divided into sixty chapters on various pediatric subjects. It should be a practical guide in the teaching of medical students and could also be used as a textbook for nurses. There are many excellent illustrations in addition to nine colored plates. Some recent knowledge is omitted, such as cevitic acid for the treatment of scurvy and the mandelic acid treatment of pyelitis. Also lead poisoning is not listed as a cause of encephalitis.

La migraine ophtalmique. Par G. Renard, professeur agrégé à la Faculté de médecine de Paris, et A. Pascal Mekdjian, assistant d'ophtalmologie à la Polyclinique Ney (Hôpital Bichat). Paper. Price 22 francs. Pp. 146 with 8 illustrations. Paris: Masson & Cie, 1937.

This pamphlet is one of a series on medical and surgical research and its application. In the introduction the authors maintain a broad and open attitude toward the etiology of ophthalmic migraine. The first chapter contains a brief history of the condition. The second chapter reviews the clinical side of the picture, evaluates the symptoms, their duration and evolution, the frequency of attack and the prognosis as to further crises. The third chapter discusses the pathogenesis of ophthalmic migraine. The local and general factors as to cause constitute the subject matter of the fourth chapter. The fifth chapter is headed "migrainous terrain" and discusses the relationship of the digestive function, anaphylaxis and intolerance, the neurovegetative system, the humoral state, the vascular tension and the psychic and the endocrine system. That portion of the chapter dealing with the vascular tension is replete with charts and illustrations indicating a comparison of general and retinal arterial tension in many patients. The sixth chapter discusses the associated morbid conditions such as ordinary severe headaches and epilepsy, and its equivalents. The hereditary factors in migraine are considered in the seventh chapter. In the next chapter a discussion of the treatment includes therapy of the paroxysm, general care of the patient and prevention of further attacks. The final chapter includes the statements that the scotomas of ophthalmic migraine are due to vascular spasms in the region of the visual cortex, that the migrainous pain is probably due to changes in the antidromic fibers at the level of the sympathetics of the trigeminal nerve, that a certain background of a generalized nature exists in these patients, and that treatment depends on the suppression or modification of these factors in the terrain. The bibliography appended is long, but the English and German authorities are incompletely listed.

Clinical Reviews of the Pittsburgh Diagnostic Clinic. Guideposts to Medical Diagnosis and Treatment. Edited by H. M. Margolis, B.S., M.D., F.A.C.P. Cloth. Price \$5.50. Pp. 552 with 6 illustrations. New York: Paul B. Hoeber, Inc., 1937.

Designed to meet the requirements of bedside practice, the Pittsburgh Diagnostic Clinic began in 1931 the publication of a series of brief reviews on selected medical subjects. As in previous volumes a strict adherence to the idea of practicability induced the authors to avoid or eliminate research details, controversial topics and extensive reference to the literature. The style of presentation is simple and easily readable. The space allotted each subject has been determined according to its frequency and importance. The essays discuss such a variety of pathologic conditions as psychoneuroses, abnormalities of growth, hyperthyroidism, diabetes, various types of arthritis,

pernicious anemia, renal diseases and carcinoma of the lung. Eight authors contributed to the volume but there is no lack of uniformity, probably because one man has contributed most. Atrophic arthritis has been treated in a nearly monographic manner. Omission of the evaluation of mucin and histidine preparations in the treatment of peptic ulcer is regrettable. The absence of discussions of recent discoveries, such as insulin shock treatment of schizophrenia or the use of sulfamidate in streptococcal infections, is a demonstration of the rapid progress of medical research with which the books cannot catch up. The material is clearly presented, the synopsis of achievements in the special fields of medicine will be welcomed by those engaged in general practice.

Einführung in die allgemeine Biochemie. Von Prof. Carl Oppenheimer. Paper. Price 7.20 florins. Pp. 227. Leliden. A. W. Sijthoff's Uitgeverij. 1936.

The introductory comments are particularly interesting and worthy of special mention. The author stresses the fact that biochemistry has now become a science that is independent from physics, chemistry and physiology, and that it is no longer to be considered as a simple handmaiden of other biologic disciplines but rather that biochemistry is actually bringing about fundamental and far reaching changes in the sister sciences. The influences are felt particularly in animal and plant physiology and pathology, in microbiology and immunity, in hygiene, in pharmacology and experimental therapeutics, and in technology. He deplores the fact that biochemistry is, nevertheless, not taught as a general science but rather as separate phases in the various biologic sciences, and for this reason he has made a modest attempt to present general biochemistry without the usual limitations to the three forms of life. He deals with those questions which have to do with substances and processes that are characteristic of the living substance, whether animal or plant. The book is not a popular presentation but a scientific and systematic introductory treatment. It treats the subject from the general biochemical point of view with more emphasis on the synthetic and catabolic processes. It is truly descriptive yet fundamentally introductory and sound from the modern point of view. It reflects the author's close contact with the extensive literature he has read as editor of the *Handbuch der Biochemie des Menschen und der Tiere* and as author of *Die Fermente und ihre Wirkungen*.

A Dietary Survey in Terms of the Actual Foodstuffs Consumed. By E. P. Cathcart and A. M. T. Murray. Medical Research Council Special Report Series No. 218. Paper. Price 1s. Pp. 56. London. His Majesty's Stationery Office. 1936.

This is the third in a series of investigations of the food eaten by representative communities in England and Scotland. Former studies of 154 families in St. Andrew's, fifty-six in Cardiff and fifty-seven in Reading are extended to show amounts per man weekly of different types of food, e. g., meats, fish and game, fresh milk, dairy produce (including margarine), bread, cereals and legumes, sugars, vegetables and fruit, for groups on different income levels. The present report also includes some Glasgow families and a group of 109 women students in the College of Domestic Science in Glasgow. From the economic point of view these computations may be very useful, but from the nutritional point of view they still leave much to be learned. All estimates of family needs are based on a single "per man" value, which is related only to energy needs. Such a unit cannot be applied when minerals and vitamins are to be considered, since the requirements for these are not in the same relationship to total calories at all ages. For each nutrient different scales are necessary, based on relative requirement to give for each nutrient a "per man" unit in terms of which family needs can be expressed. A family of five, father, mother and three young children, might have an energy requirement equivalent to 3.4 man units, but it would have a calcium requirement of about 6.7 man units. Therefore total calcium reported as 0.987 Gm. per man daily appears very liberal, but for the family mentioned would mean a total of 3.4 Gm., whereas an adequate allowance would be nearer 4.5 Gm. It would also be helpful in arriving at the other values of these diets to have, in addition to amounts of protein, fat and carbohydrate, which tell so little about the food selection in relation to health and growth, a statement of the percentage of total

calories contributed by each of the classes of foods considered, and the cost of each in terms of the total cost. The authors say wisely that "the main causal factor of inadequate diets in many households is ignorance of how to buy, what to buy and how to use to the best advantage the material bought." The continuation of such studies would reveal more clearly specific dietary defects and result in evidence that could be more effectively used to disseminate knowledge of how to safeguard the family against serious malnutrition. Some further comments on this report will be found in the London letter in *THE JOURNAL*, March 27, page 1129.

Arzneiverordnungen. Ratschläge für Studenten und Ärzte. Herausgegeben von W. Heubner, H. Oetzel und W. Zinn. Im Einvernehmen mit der Deutschen Gesellschaft für Innere Medizin. Cloth. Pp. 216. Leipzig. S. Hirzel. 1937.

The "Arzneiverordnungen" is a cross between New and Non official Remedies and Useful Drugs. As it is written entirely for European German speaking physicians, its usefulness to American physicians is slight. The handy pocket size book is practical and well bound and contains a good therapeutic index, dosage tables for infants, children and adults, and a pediatric diet sheet, besides the rules for dispensing of drugs and the principles of administration. The handbook lists the drugs of the Pharmacopeia and those drugs which proved to be valuable in the clinics and at the bedside.

The Diseases of Infants and Children. By J. P. Crozer Griffith, M.D., Ph.D., Consulting Physician to the Children's Hospital, Philadelphia, and A. Graeme Mitchell, M.D., B.K. Rachford, Professor of Pediatrics, College of Medicine, University of Cincinnati. Second edition. Cloth. Price \$10. Pp. 1,154 with 293 illustrations. Philadelphia & London. W. B. Saunders Company. 1937.

This complete revision of a well known and satisfactory textbook of pediatrics will be useful to teachers, pediatricians, practitioners and students. In the revision, greater emphasis has been laid on preventive measures, anatomy and physiology, growth and development, and the subject of clothing. The artificial feeding of the baby has been put on a simpler basis, and other material in the book has been brought down to date. Charts and photographic illustrations add materially to the value of the book. Numerous journal and book references are given at the end of each chapter. The use of quotations from the periodical literature may occasionally lead to some ambiguity, thus it is stated that "new-born infants from poverty-stricken environments appear to be smaller, in all dimensions and in weight, than those born in more favorable surroundings," which is followed by the statement "In spite of statements to the contrary, there has been proven little, if any correlation between the condition and the diet of the mother during pregnancy, and the weight and condition of the infant." These quotations, coming from different sources, seem to be exactly opposite in meaning. The authenticity of the material included in the book, and the clinical descriptions, are beyond criticism.

Physiological Chemistry. By J. F. McClendon, Ph.D., Professor of Physiological Chemistry, Medical School, University of Minnesota, Minneapolis, and the late C. J. V. Pettibone. Sixth edition. Cloth. Price, \$3.50. Pp. 454 with 34 illustrations. St. Louis. C. V. Mosby Company. 1936.

This rather elementary textbook of physiologic chemistry is intended to cover the descriptive as well as the laboratory side. The chemistry of cell constituents is presented in an elementary manner, the style is rather disconnected in many places, and the order of presentation is not the most logical. The laboratory instructions for the most part cover crude qualitative tests without much in the way of critical evaluations of either qualitative or quantitative methods. This textbook does not meet the requirements of the better class medical schools.

Travaux pratiques de bactériologie. Par Henri Bonnet, chef des travaux de bactériologie et Armand Nérot, assistant de bactériologie à la Faculté de médecine de Paris. Préface du Professeur Robert Debré. Paper. Price 38 francs. Pp. 178 with 82 illustrations. Paris. Masson & Cie. 1936.

The text of this book, written for third year medical students, is condensed, clear and precise. Each chapter begins with a brief discussion of the type of specimens to be examined. Consideration is given to the principal pathogens for man, the

methods of isolating and identifying them, and their morphologic, cultural, biochemical and serologic characteristics. One chapter is included on the complement fixation reaction and one on the flocculation reaction. The text is beautifully illustrated with numerous drawings and photomicrographs, as well as with six colored plates.

Bureau of Legal Medicine and Legislation

MEDICOLEGAL ABSTRACTS

Malpractice Abandonment of Patient—The plaintiff was treated at the Budge Memorial Hospital by one of the physician-defendants, for an infected finger. After four days of treatment, during which the condition of the finger improved, the patient over the protest of the attending physician left the hospital after paying the amount that was due at that time. The attending physician advised him to continue at home the treatment he had been given at the hospital and advised the plaintiff to return at once for further treatment if the finger became worse. The finger did become worse and the patient returned for further treatment. An examination disclosed the necessity for immediate surgical intervention and the plaintiff was prepared for an operation. The physician, however, refused to proceed with the operation until, as testified by the plaintiff, an old bill of some years' standing was settled. The physician, on the other hand, testified that he merely asked that some arrangement be made to take care of the expense of the proposed operation as a condition precedent to the operation. Apparently not being willing, or able—the record does not show which—to meet the condition prescribed by the physician, the plaintiff found it necessary to apply to another physician for treatment, necessitating a walk of several blocks in the rain and occasioning a delay of several hours in treatment. Subsequently an amputation of the infected finger became necessary. Thereafter, the plaintiff sued the physician who first treated him, joining the physician's partner as a defendant, contending (1) that they were negligent in treating the plaintiff and in discharging him from the hospital before his condition warranted it, and (2) that while he was a patient of the defendants and in immediate need of medical and surgical care they refused to treat him and abandoned his case. The trial court directed a verdict in favor of the physicians, and the plaintiff appealed to the Supreme Court of Utah.

There was no evidence, said the Supreme Court, that the defendants were negligent in the treatment that was actually rendered or that the plaintiff was improperly discharged from the hospital. The trial court, therefore, properly directed a verdict for the defendants on the first cause of action. With respect to the second cause of action, namely, the alleged abandonment of the plaintiff by the defendants, the Supreme Court pointed out that a physician, on undertaking an operation, is under a duty, in the absence of an agreement limiting the service, to continue his attention after the operation so long as the case requires attention. The obligation of continuing attention can be terminated only by the cessation of the necessity that gave rise to the relationship, or by the discharge of the physician by the patient, or by the withdrawal from the case by the physician after giving the patient reasonable notice so as to enable the patient to secure other medical attention. A physician has the right to withdraw from a case, but if the case is such as to require further medical or surgical attention he must, before withdrawing from the case, give the patient sufficient notice so that the patient may procure other medical attention if he desires. In *Mucci v Houghton*, 89 Iowa 608, 57 N W 305, the court said:

If a physician or surgeon be sent for to attend a patient the effect of his responding to the call in the absence of a special agreement will be an engagement to attend the case as long as it needs attention unless he gives notice of his intention to discontinue his services or is dismissed by the patient and he is bound to exercise reasonable and ordinary care and skill in determining when he should discontinue his treatment and services.

In *Ballou v Prescott* 64 Me 305, the court said:

If he [the physician] is called to attend in the usual manner and undertakes to do so by word or act nothing being said or done to modify this undertaking it is quite clear as a legal proposition that not only reasonable care and skill should be exercised but also continued attention so long as the condition of the patient might require it, in the exercise of an honest and properly educated judgment, and certainly any culpable negligence in this respect would render him liable in an action—*Barbour v Martin* 62 Me 536 *Shearman & Redfield on Negligence*, Sec 441.

In *Lawson v Conaway* 37 W Va 159, 16 S E 564, 18 L R A 627, 38 Am St Rep 17, the court said:

When a physician is employed to attend upon a sick person his employment continues while the sickness lasts unless put to an end by the assent of the parties, or revoked by the express dismissal of the physician. In the absence of special agreement his engagement is to attend the case as long as it requires attention, unless he gives notice of his intention to discontinue his visits or is dismissed as aforesaid, and he is bound to exercise reasonable and ordinary care and skill in determining when his attendance should cease.

In the opinion of the Supreme Court of Utah in the present case, the relationship of physician and patient theretofore existing was not terminated when the patient left the hospital, as contended by the defendants. As the court viewed the evidence, it showed that the physician-defendants in refusing to proceed with the operation unlawfully abandoned the case. The trial court, therefore, erred in directing a verdict for the defendants on the abandonment cause of action. The case was remanded to the trial court for a new trial.

Two justices, however, agreed with the physicians' contention that the evidence disclosed that the relationship of physician and patient was terminated when the plaintiff himself abandoned the hospital. The physician-defendants, in the opinion of these two justices, had a right to refuse to incur the obligation and responsibility incident to one or more operations and the treatment and attention which would be necessary and that, even though a relationship of physician and patient existed at the time of the proposed second operation, the physicians had a right with proper notice to discontinue the relationship. While the plaintiff's condition was acute and needed immediate attention, the evidence showed that he received that attention at the hands of the other physician to whom he turned. The record disclosed no evidence that the plaintiff sustained any injury by reason of the physicians' refusal to render the treatment. The trial court, in the opinion of the two dissenting justices, did not err in directing a verdict for the physicians on both causes of action—*Ricks v Budge et al (Utah)*, 64 P (2d) 208.

Workmen's Compensation Acts Tuberculosis of Spine Allegedly Activated by Trauma—The worker, an attendant in a gasoline station, had tuberculosis of the spine in a dormant state for several years. On Jan 4, 1934, in the course of his employment, he slipped on some oil and fell, striking his back against a door sill. Immediately thereafter he suffered pain in his back and was in distress. He continued to work for about five or six weeks but had an increasing stiffness of the spine. During the early part of February he began "taking treatments for his back," the nature of which the record does not disclose. On February 28 he called a physician, who discovered a swelling in the right lumbar region, which subsequently was found to be an abscess, admittedly caused by the tuberculous spine. In May, roentgenograms showed an "acute destructive" Pott's disease involving several dorsal vertebrae. He became increasingly worse and died in March 1935. An autopsy showed that tuberculosis was present in many parts of the body, including a large tuberculoma of the brain. The widow instituted proceedings under the Minnesota workmen's compensation act, which the employer defended by contending that the fall did not activate a dormant disease but was the result of the tuberculoma of the brain, which had affected the motor tracts. The employer argued that its contention was substantiated by the fact that on the second day after the fall the worker's use of his right hand was impaired. From an award of compensation to the worker, the employer appealed to the Supreme Court of Minnesota.

The sole question presented to the court was whether there was sufficient evidence to support the commission's conclusion that the fall and not the pre-existing tuberculosis of the spine had caused the abscess on the worker's back. The court held that the evidence was sufficient to support the commission's conclusion that the fall and not the pre-existing tuberculosis of the spine had caused the abscess on the worker's back. The court affirmed the award of compensation to the worker.

condition and contributed to his death. The worker had performed his usual duties around filling stations for five or six years, had attended the furnace at home, shoveled snow from sidewalks, played ball, and was generally active up to the time of his fall. He appeared to be in good health. A medical witness, called by the widow, testified that from the history of the case it was his opinion that the tuberculous condition of the spine was present at the time of the fall but in a quiescent or arrested state. Another witness stated that tuberculosis of the spine is never cured, only arrested, and that the arrest depends on what material forms around the diseased area. Activity of ordinary work or an injury, this witness testified, may be enough to break down this material. Pott's disease, a witness testified, could not be active to any great extent and the patient remain ignorant of its activity. This witness could not say that the blow *certainly* activated the tuberculosis but did testify that it *probably* did, in view of the "relatively latent period between the time of his blow and the period the activity became manifest." With respect to the employer's claim that the tuberculoma of the brain was present at the time of the fall and probably caused it, one of the widow's medical witnesses stated that when tuberculosis actively invades the brain it is "pretty rapid fire, it is usually twenty-one to thirty days after he gets the tuberculosis disease that he dies." There was evidence, however, offered on behalf of the employer by another medical witness that the tuberculoma of the brain had existed previous to the fall.

We have, therefore, said the Supreme Court, a man admittedly tuberculous for several years. Quite conclusively proved was the fact that up to the time of the fall he was employed and satisfactorily filled a position requiring sustained activity. He was also active outside his work. According to the opinion of the expert witnesses, it would have been "unusual" for a person with a tuberculous brain to carry on the duties required of the workman. Two competent medical men stated it as their opinion that the disease was quiescent at the time of the fall. That the deceased suffered a fall on January 4 was undisputed. Within a period when the activity of the disease might manifest itself the abscess on the back appeared. The possibility that the disease was lighted up by work rather than the fall seemed to the court to be negated by the activity of the deceased up to the time of the fall. In the opinion of the Supreme Court there was sufficient evidence before the commission to justify its finding that the worker's death was due to the fall. The award in favor of the claimant was therefore affirmed.—*Reynolds v Cities Service Oil Co (Minn)*, 270 N W 912

Malpractice Osteomyelitis Following Extraction of Tooth—The defendant, a dentist, extracted the plaintiff's lower right second molar. Four days later the patient began to experience pain and again consulted the dentist. Finding inflammation around the lower right third molar the dentist, after a roentgenogram had been made of it, recommended its removal. After the extraction, the patient continued to have a "grinding pain" and consulted a physician, who discovered that the soft tissues near the tonsils were infected. A peritonsillar abscess was lanced and later a diagnosis of osteomyelitis was made. Attributing the osteomyelitis to the extraction of the third molar, the plaintiff sued the dentist. The jury returned a verdict for the patient, and the defendant brought exceptions to the Supreme Court of New Hampshire.

The dentist testified that, while the third molar was not decayed there was an abscess between it and the site from which the second molar had been extracted. He extracted the third molar, he stated, to obtain better drainage of the abscess. The gums were inflamed and spongy, and the alveolar process was absorbed, leaving the tooth very loose, just holding by flesh. When a tooth is loose in this manner, he testified, the space between the tooth and the gum forms a pocket for infection and under such circumstances it is good dental practice to remove the tooth. The only expert called by the patient was the physician who treated him. This physician disclaimed any qualification as "an expert on dentistry" and did not know the degree of skill and knowledge possessed by the average dentist practicing in the community in which the defendant

practiced. The witness testified, however, that there is a principle in surgery never to remove a sound organ when it is surrounded by infected tissues, that the removal of a sound tooth from an infected area permits a chance for seepage and allows more space for the infection to get into the blood and to become localized in the bone, and that, in his opinion, the removal of the third molar resulted in the osteomyelitis. Four dentists testified on behalf of the defendant and each testified that proper practice required the removal of the tooth. None of these dentists stated that it was not good dental practice to extract the tooth under the conditions described by the patient.

A person, said the Supreme Court of New Hampshire, who holds himself out as practicing a particular profession is required only to possess the knowledge and to exercise the care and skill of the ordinary practitioner of that profession in the same or similar localities. The burden was on the plaintiff to prove the liability of the defendant, but the court could find nowhere in the record any evidence that the defendant did not possess the learning and exercise the skill and care of the average dentist in the community in which he practiced or that he had departed from the standard imposed on him by law. A dentist does not insure his patients against infection following the extraction of teeth. Since the patient failed to produce any evidence with respect to the negligence of the defendant, the dentist's motion for a directed verdict should have been granted.

The Supreme Court accordingly entered a judgment for the dentist.—*April v Perout (N H)*, 188 A 457

Druggists Liability for Sale of Proprietary Medicines—A druggist who sells a proprietary medicine in an original unbroken package, which was asked for by the customer, assumes no liability for any imperfection in the medicine unless he knows of the imperfection, said the court of appeals of Georgia, division No 1. He is under no duty to open and analyze a proprietary medicine in an original package.—*Howard v Jacobs Pharmacy Co (Ga)*, 189 S E 373

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers in continental United States and Canada for a period of three days. Periodicals are available from 1927 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them. Titles marked with an asterisk (*) are abstracted below.

Subarachnoid Injection of Alcohol—In their clinic thirty-three patients, all of whom were believed to have incurable malignant tumors, have received subarachnoid injections of alcohol. Peyton and his co-workers studied at necropsy the spinal cords of four patients who lived from three to six months after injection. A series of experimental injections in five dogs also was made but the results were not satisfactory. It was difficult or impossible to obtain even approximately the same conditions as obtain in man and impossible to determine whether or not a satisfactory injection was accomplished, that is, one which would relieve pain if it were present. Microscopic study of the four spinal cords indicates that relief of pain, when it does occur, is due to destruction in the posterior rootlets but that there is also an extensive degeneration of the posterior columns of the cord. A satisfactory result was obtained in at least 33 per cent but in not more than 51 per cent of the thirty-three patients. Serious complications occurred in two patients, one of whom, however, had a preexisting paralysis due to a progressive lesion of the cord. This partial paralysis was precipitated into a complete paralysis by the injection. A sufficient proportion of patients are benefited to justify the small risk of a serious injury to the spinal cord, provided the procedure is limited to the treatment of intractable pain associated with malignant disease of hopeless prognosis.

Tumor of the Femur—Smith presents a report of a Ewing's tumor of the femur operated on in 1909, and without recurrence twenty-eight years later. So far as is known, it is the only case of its kind in which so long a period of survival has been recorded. The case is registered with the Bone Sarcoma Registry of the American College of Surgeons and the original pathologic sections of the tumor have been reviewed by numerous pathologists, consultants of the Bone Sarcoma Registry, who have agreed as to its diagnosis.

Coexistence of Lymphocytic Leukemia and Advanced Tuberculosis—The coexistence of typical lymphocytic leukemia and of clinically active far advanced pulmonary tuberculosis in the case that Ryan and Medlar observed shows that active pulmonary tuberculosis and lymphocytic leukemia can be associated (contrary to the dictum of Parker and his collaborators). It is impossible to state whether the diseases occurred simultaneously or whether one followed the other. No etiologic relationship of the processes can therefore be determined. It is well known that in uncomplicated tuberculous cases a high percentage of lymphocytes is a favorable sign, yet in this case such an interpretation of the leukocytic picture would be erroneous. The blood contained from fifty to more than a hundred times as many lymphocytes as normal and still there was an active progressive pulmonary tuberculosis. In such a condition one may regard the lymphocytes as being abnormal in function and hence unable to participate in the tuberculous process. The majority of the tuberculous lesions did not differ essentially from those in persons without leukemia. In some areas lymphocytic infiltration was so excessive that it appeared as if these cells were multiplying within the tuberculous foci. It is not possible to determine whether any abnormality of functional activity existed in the lymphocytes, but at least they showed a tendency to migrate to the locations where normal lymphocytes are commonly found. Unless the lymphocytes in lymphocytic leukemia are nonfunctional the case suggests that a lymphocytosis by itself is not of prime importance in tuberculosis. The authors believe that the chemical damage produced in the tissues by the presence and growth of the bacteria is responsible for the leukocytic invasion. The nature of chemical damage produced determines the type or types of leukocytic infiltration found. Unless a physicochemical condition exists within a tuberculous lesion which attracts lymphocytes, they will not migrate into it regardless of how many may be available in the circulating blood.

Transthoracic Treatment of Tuberculous Cavities—In their method Jacobs and Beloff attempt to attack the cavity directly through the chest wall, injecting colloidal copper morrhuate into it. The precise mode of action of the copper morrhuate appears to depend in its greatest degree on the stenosis of the bronchus draining the cavity. There is a chemical pneumonitis set up in the pericavernous parenchyma which may play some part in the healing process, as may also the constitutional effect of the copper, a heavy metal, when absorbed into the blood stream. Transthoracic injection is not the procedure of choice in the eradication of any previously untreated cavity. It is admittedly a method to be used when other treatments have failed. The cavity must be easily accessible. The cases best suitable are solitary large cavities. Chronic cavities, surrounded by relatively clear parenchyma, are more ideally suitable for injection than recent cavities, especially when, in the latter case, the adjacent parenchyma is the site of bronchopneumonic tuberculosis. A thin capsule of the cavity is more easily dealt with than a heavy thick one. A cavity with a fibrous wall would appear a safer type of lesion for injection than one with a necrotic caseous wall. With the patient lying horizontally on the fluoroscope table, the roentgenologist notes on the skin the position at which the puncture should be made and the direction to be taken by the needle. The skin is anesthetized with 1 per cent solution of procaine hydrochloride. A spinal needle is used for the puncture. This is attached to a 10 cc syringe carrying procaine, and the needle is pushed through the skin, thoracic wall musculature and pleura, the procaine being injected as the needle is advanced. When it is judged that the needle has traversed the pleura, traction instead of pressure is made on the piston of the syringe, so that, if the needle enters the gas-filled cavity, it will be recognizable by withdrawal of gas into the syringe. When it appears certain that the needle has entered the cavity, the procedure by trial and error, checked by the fluoroscope, is carried out until the needle point is unquestionably lodged within the cavity. The first dose of colloidal copper morrhuate is 2 cc, injected through the needle into the cavity. Subsequent injections are from 10 to 20 cc, the increase depending on whether the preceding dose was well tolerated. Injections are made at weekly intervals, and the series of injections used was a total of six. Following the injection of the drug, the patient is immediately placed in the head-elevated position on the movable fluoroscope table and kept there for ten minutes and then sent back to bed. In approximately twenty injections that were made through the thoracic wall, the authors have had only one notable reaction, during a febrile period the cough and expectoration were increased, but symptoms subsided coincidently with the fall in temperature (four days).

Acacia in Pulmonary Hemorrhage—Berghausen reports two cases of severe recurring pulmonary hemorrhage in which the intravenous injection of 30 Gm of acacia in 500 cc of physiologic solution of sodium chloride was followed by a cessation of the hemorrhage. In one case there was no recurrence for thirty-four months, when the patient failed rapidly after a severe hemorrhage.

Digitalis in Body Fluids—During the treatment of patients with congestive heart failure, Schnitker and Levine have occasionally observed that from twenty-four to forty-eight hours after diuresis has been produced by salyrgan or mercurin or with theophylline the patient has become ill with nausea, vomiting, giddiness, headache and considerable weakness. In fact two patients, not alarmingly ill before such supplemental diuresis, came to rapid unexpected death in this sickness a day or two after salyrgan had been given. With the elimination of from 2,000 to 6,000 cc of fluid from the cavities of the body and interstitial spaces through the blood stream and out through the kidneys, it seemed to them that a plausible explanation for such symptoms would be "redigitalization." In other words, if substances which act like digitalis could be found in edematous fluid from the pleurae, peritoneum and leg, the transportation of that fluid through the body to the kidneys during active diuresis in a patient who is digitalized would expose the cardiovascular and nervous systems to the contained digitalis and would cause further action of the drug. The symptoms experienced by these patients would then be those of intoxication from digitalis. Twenty-nine specimens of fluid from twenty-four patients were examined. Eighteen fluids were from known digitalized patients. Thirteen of these gave positive evidence of digitalis by the biologic method. The results were questionable in four cases and negative in one case. Two specimens from patients with questionable digitalization gave doubtful results. Nine specimens of fluids from patients with tuberculosis, neoplasm or cirrhosis of the liver, none of whom had been given digitalis, were used as controls. None of these showed any effects of digitalis. The amount of digitalis recovered from the thirteen fluids seemed to be significant and sufficient to cause clinical symptoms in patients under the conditions discussed. The qualitative Keller-Kiliani test for deso-cyclobohydrylate gave positive reactions for five of eleven specimens of fluid showing the effect of digitalis by the biologic method. It is believed that active substances of digitalis are present in the fluids of the body of digitalized patients and that they can be recovered.

Effect of Parenterally Administered Peptone—The possibility of supplying the nitrogen requirements of the body parenterally led Milles and Seed to investigate the effect of protein split products given by this route. They used bactopeptone, which, according to the analysis submitted by the manufacturers, is constant in composition. Concentrations of 1, 5, 10, 20 and 30 per cent were used, and the solutions were carefully made up in sterile water and passed through a Berkefeld filter. A 1 per cent solution of bactopeptone is hypotonic, causing hemolysis of the red blood cells; this concentration was made up in a buffered saline solution. Since solutions of peptone give a strongly positive reaction to the biuret test, the urine was collected and examined by this method. Solutions of various concentrations of this peptone up to 500 cc failed to cause perceptible damage when injected into dogs either in single doses or daily up to three weeks. Diuresis of varying

degree resulted, depending on the concentration of the solution and on the rate of injection. A pronounced drop in spinal fluid pressure and a slight drop in blood pressure were noted. Chemical examination of the blood showed little change resulting from the injection. No antigenic effects were demonstrated. When 300 cc of a 15 per cent solution of bacto-peptone was injected intravenously into a man, it failed to cause a reaction. However, a chill and fever resulted when a 20, 25 or 30 per cent solution was used.

Subarachnoid Hemorrhage—Strauss and Tarachow contend that spontaneous subarachnoid hemorrhage is a syndrome which may occur in a variety of pathologic states and that the prognosis varies with that of the underlying or associated pathologic process. They investigated 105 cases in an attempt to find the incidence of systemic or local disease, cardiorenal vascular disease, acute or chronic infections and blood dyscrasias and also features that might lead one to suspect congenital cerebral aneurysm. 1 Spontaneous subarachnoid hemorrhage bears the prognosis of the underlying disease. 2 Spontaneous subarachnoid hemorrhage may be symptomatic of cardiorenal vascular disease, tumor of the brain, subacute bacterial endocarditis, purpura, polycythemia, Hodgkin's disease or myeloid leukemia. It may be associated with cerebrospinal syphilis, tuberculosis, diabetes, epilepsy or acute glomerulonephritis, or there may be no clinically discoverable disease. 3 In the only four cases in which the hemorrhage was associated with clinically definite cerebrospinal syphilis, death occurred. 4 The prognosis tends to be worse with the presence of generalized vascular disease and better in the absence of clinically discoverable disease. 5 In the absence of discoverable disease the prognosis becomes worse, the older the patient. 6 In the absence of generalized disease a history of proved or presumptive previous attacks tends to make the prognosis better. This history is usually found in young persons and suggests congenital aneurysm or aneurysm with cerebral arteriosclerosis in young persons. 7 The average duration between the observed attack and the next expected attack is two years and six months. 8 Presumptive recurrences occur, even though not proved by examination of the spinal fluid.

Psychoses and Pernicious Anemia—From 1931 to 1935 inclusive 255 patients were admitted to Bellevue Hospital and discharged with the diagnosis of pernicious anemia. Of this group, forty subjects were treated in the medical service of the psychiatric division. In analyzing the mental symptoms presented in the forty cases Herman and his associates found, in addition to the independent mental states, four well defined clinical types: an acute confusional state in fourteen, a paranoid condition in seven, an affective reaction in six and an organic deterioration type in five. Some mental diseases occurring in association with pernicious anemia may have no etiologic relationship. The conditions shown by eight of their patients

fall in this group, the diagnoses were as follows: acute alcoholism, transitory psychosis with an episode of excitement and hallucinosis, schizophrenia, paranoid psychosis in a psychopath, cerebral vascular thrombosis, catatonia of unknown type and senile psychosis (two cases). These psychoses, either by history or by the course in the hospital, proved in the opinion of the authors to be unrelated to the anemia.

Tuberculous Reinfection—Reichle and Gallavan encountered seven cases in a total of 800 routine necropsies which yielded suggestive evidence of the existence of reactivated primary tuberculous infection. The frequency of the phenomenon cannot be determined by morphologic study, since the fugitive nature of reactivation, the fact that it must proceed to dissemination or subside in healing, tends to obliterate, in either case, the evidence necessary for its demonstration at necropsy. Since, despite these inherent difficulties, it is possible to demonstrate seven cases in 800 routine necropsies, endogenous reinfection should be accepted as a significant mode of extension of pulmonary tuberculosis.

Menorrhagia—Schulze, with the hope of establishing definitely the limitations of radium therapy and the most desirable dosage to effect certain results, observed 204 women over a period of at least two years and up to twenty years who were so treated for menorrhagia. Only cases in which there were no determinable gross pathologic lesions are included in the study. In the majority of cases the menorrhagia was controlled, but normal periods were rarely restored, in only 35 per cent of the women less than 35 and in 7 per cent more than 35 years of age. In the adolescent group of six, only one was restored to normal by radium. Only 13 per cent of the young women and none more than 35 years of age became pregnant after irradiation. Satisfactory dosage is difficult to establish since although, in general, the results are fairly uniform, the individual variation in response to a given dose is so great that the result is entirely unpredictable. Amenorrhea has resulted from 400 millicurie hours, normal periods have been restored by

1,525 millicurie hours, and profuse hemorrhage has continued after repeated treatment with 1,024 and 1,594 millicuries, respectively. Women more than 35 years of age will generally become amenorrheic or have very scanty or infrequent periods even with small doses. In younger women the prospect of a return to normal is somewhat better but should never be promised. In the adolescent group, results with radium have been poor, and it should be used not at all or only as a last resort. A careful explanation of the possible consequences of the treatment is due the patient and may save much dissatisfaction.

Cevitamic Acid in Treatment of Whooping Cough—

Ormerod and Unkauf used cevitamic acid in the treatment of nine cases of whooping cough. In each case, diagnosis was made from a history of contact with known cases together with personal observation of the typical cough, vomiting and nocturnal paroxysms. Treatment consisted of the daily administration of from 125 to 500 mg of cevitamic acid for from three to eleven days. The cough was usually moderated in from three to seven days and disappeared in from five to fifteen days. The danger of overdosage seems negligible. Animals have received 2,000 times their estimated requirements without any deleterious effects. Any excess is excreted by the kidneys.

Suicide—Franks made a study of 352 consecutive cases of attempted suicide admitted to the Toronto Psychiatric Hospital from Nov. 1, 1928, to Oct. 31, 1935. The subjects received physical and mental examinations and the actual suicidal attempts were studied in relation to basic and immediate causal factors. It is suggested that suicide may be prevented by (1) raising the standard of educational achievement of the populace, (2) good mental, physical and public health measures, (3) teaching certain groups among the public and professions an appreciation of suicidal danger signals, (4) abolishing the stigma attached to the act, (5) minimizing publicity, (6) protecting heights by simple, practical means, (7) encouraging medical books to allow more space for information on suicide, (8) elaborating the teaching with regard to suicide in medical, social and legal schools, (9) training youth to take responsibility, (10) encouraging any factors that will build up the solidarity of the group in which the individual finds himself, (11) an investigation to ascertain why there is a greater tendency for foreign-born persons to suicide than native-born, (12) establishing a fixed regular routine day for the unsettled person which will bring satisfaction and contentment to him and (13) establishing clinics to which such distressed persons may come

for help and guidance. Apart from the patients with mental disease, the majority were pleased that their attempt had been a failure and after a short course of psychotherapy developed a good attitude toward the future.

Spanish Moss—In an endeavor to find out whether Spanish moss (*Dendropogon usneoides*) played any part in the causation of hay fever, asthma or contact dermatitis, Metzger secured a number of blooms, separated the pollen, identified the pollen microscopically and made a small amount of pollen extract. He then exposed a series of fourteen slides on the limb of a tree completely surrounded by the moss during its flowering period. Ten yards from the tree a similar series was exposed, as was also another series in the window ledge of his home, 50 yards from the nearest bit of moss. The total number of granules of the pollen found on the fourteen slides exposed in this location was seven. Selecting a group of thirty patients with asthma or hay fever or both, whose history showed that their trouble was worst at the time Spanish moss bloomed (May), he tested them with the extract obtained from the pollen. One patient showed a definite positive reaction to the scratch test, and one showed a single positive reaction to the intradermal test. Both of these patients showed positive reactions to practically every pollen extract to which they were submitted. Therefore it was concluded that these two patients were not specifically sensitive to the pollen of Spanish moss alone and that Spanish moss is not a causative factor in hay fever, asthma or contact dermatitis, either from the pollen or from the dried material of the plant.

Toxicity and Pathology of Selenium—With a view to obtaining more information regarding the possible effects of the more or less continuous ingestion of small amounts of selenium on the health of the population exposed to it, Smith and his associates conducted a detailed investigation of the various aspects of the toxicology of selenium. Their report deals with the acute toxicity and with the effects of continuous administration of small subtoxic doses of selenium as sodium selenite or sodium selenate in several species of laboratory animals. The acute toxicity of selenium in the rat on intravenous injection is the same whether given as selenite or selenate, 3 mg per kilogram of body weight of either being fatal in about 50 per cent of the animals. The oral minimal lethal dose of these compounds in the rabbit is the same. On intravenous injection in rabbits sodium selenite is relatively more toxic, its minimal lethal dose being 15 mg per kilogram of weight reckoned as selenium, as against from 2 to 25 mg of sodium selenate. The continuous administration of small doses of selenium as sodium selenite or selenate is cumulative in its effects. There is no evidence of acquired tolerance to selenium. The chronic toxicity of selenium varies in different species and in different individuals of the same species. The rat is the most resistant and the cat the most susceptible of the species examined. The gross and microscopic pathologic changes are also quite variable in chronic selenium poisoning. The incidence of cellular pathologic changes in the order of diminishing frequency are as follows: gastric, hepatic, hematologic, reticulo endothelial, renal, cardiac and serous effusions. The symptomatology of milder forms of chronic selenium poisoning is most likely to point to gastric or hepatic dysfunction and possibly to disturbances of the hematopoietic organs.

Skeletal Deformities in Children—Bisgard classes thoracogenic scolioses into two types, pleurogenic and thoracoplastogenic. Both are preventable and curable if corrected in their incipience. Pleurogenic deformities can be prevented by (1) the prevention of the formation of pleural scar through early cure of the empyema or pleuritis and (2) the constant attention to maintenance of straight alignment or preferably of overcorrection of the spine. This can be accomplished by means of (1) postural wedging, (2) corrective casts of plaster of paris to the body and (3) resection of ribs on the side of the concavity. To facilitate correction and the use of corrective measures, it is helpful to anesthetize the area of the wound by crushing the intercostal nerves which innervate that area. Extensive and rigid deformities of the spine and costal framework are incurable. To prevent and correct thoracoplastogenic scoliosis, postural wedging should be instituted within a few days after operation and maintained for at least six weeks, or until the reparative processes have fixed the thoracic wall. The procedure is carried out with the patient lying on the operated side but with the wedge placed exactly opposite or slightly caudal to the apex of the curve. With cooperation from the patient, compression by postural wedge may be started immediately, or a day or two after operation, and within a few days may be maintained almost continuously.

Treatment of Asthma—Boch states that the greatest value derived from the use of ephedrine sulfate and sodium or potassium iodide in the treatment of bronchial asthma and asthmatic bronchitis is obtained only if administered at a time when the bronchial tree is about to enter into a spastic state. The patients themselves feel a constriction in the chest or a beginning slight wheeze, a warning of the oncoming paroxysm. Some patients give a clear history of periodicity of attacks. It takes about one hour for these drugs to exert their influence in the body, if taken orally. As a rule no patient escapes taking these drugs at bedtime. Very few patients need them in the morning. The dosage should vary with the intensity of the symptoms. Ephedrine sulfate has been given in doses of from three-eighths grain (0.024 Gm.) to more than 1 grain (0.065 Gm.) by mouth from once to five times in twenty-four hours. Potassium or sodium iodide is usually administered in the form of a saturated solution, of which from 5 to 40 minims (0.3 to 2.6 cc.) at a dose are given, in half a glass of water, from once to four times daily, as needed. Ephedrine may render the patient slightly nervous, tremble in the first few days or two weeks, it may also produce some insomnia. These undesirable effects as a rule disappear promptly. The iodides may cause a watery nasal discharge at times and acne-like lesions of the skin. If the dose is reduced or omitted for a day or two, these symptoms promptly disappear. On resumption, the tendency for these symptoms to recur is lessened. Twenty-two patients suffering from bronchial asthma or asthmatic bronchitis have been under treatment, some as long as one year, those with the shortest record have been under treatment for five weeks. Seventeen patients (eight suffering from bronchial asthma, eight from bronchitis with asthmatic symptoms and one from bronchiectasis with asthmatic symptoms) have obtained positive relief from symptoms. The duration of the illness of these patients varied from three to eighteen years. Withdrawal of the drugs caused prompt return of the symptoms within forty-eight hours. The drugs were discontinued in the other five patients because of the mild symptoms in two, and in three because their value could not be determined.

Perforation of Gastro-Intestinal Tract—The observation that fasting animals withstand experimental perforation better than animals which recently have taken food prompted Bergh and his co-workers to undertake a study of some of the factors influencing the development of peritonitis following perforation. Perforations were established at various levels of the gastro-intestinal tract of 145 laboratory animals under pentobarbital sodium anesthesia, and with aseptic precautions, after periods of fasting and also following the ingestion of food. Most intestinal perforations consisted of an unsutured incision 1 cm. in length in the axis of the intestine along the antimesenteric border. All animals were observed for signs of peritonitis and those which died were subjected to necropsy. Many of the surviving animals were killed or operated on to observe the healing process. Bacteriologic studies were made in cases in which peritonitis developed. There appeared to be no relationship between the location of the perforation in the wall of the stomach and the development of peritonitis. Perforation of the stomach containing food was performed in thirty animals. There were twenty-six deaths from peritonitis, a mortality of 86.7 per cent. Bacteriologic studies of the peritoneal exudate revealed the presence of a variety of organisms. Perforation of the stomach of fasting dogs immediately before and after the administration of liquids was carried out in seventeen animals, with three deaths from peritonitis, a mortality of 17.6 per cent. Perforation of the empty stomach through an area previously injected with a sclerosing solution was carried out in ten dogs. Four of these animals died from peritonitis, a 40 per cent mortality. Necropsies revealed that the perforations had failed to heal in the fatal cases. Perforation of the duodenum was established in sixteen dogs, with a mortality of 81.2 per cent from peritonitis. Perforation of the jejunum at distances varying from 15 to 90 cm. from the duodenojejunal angle was carried out in nine dogs. The mortality rate from peritonitis was 44.4 per cent. There was no definite relationship between the level of perforation and the mortality rate. Perforation of the lower ileum was performed in nine dogs and all died from peritonitis within seventy-two hours. Necropsy revealed that the perforation had remained open in every case. Of seven dogs in which the cecum was perforated, two died. An identical mortality was found in a similar series of perforations of the descending colon. In eight animals the

rectum was perforated by means of a scalpel introduced through the anus. Perforation into the peritoneal cavity was verified in each instance by abdominal exploration. Only one animal died. The others showed a small linear scar without the formation of adhesions. The mortality following rupture of the gastrointestinal tract as observed by the clinician is governed by the same factors that determine the mortality in experimental perforation. These may be listed as follows: (1) the number and virulence of the escaping organisms (size of the perforation, length of time the perforation remains open, number of organisms at the level of the perforation, amount and fluidity of material in the viscous at the time of perforation and forces tending to carrying contents of the viscous out into the peritoneal cavity) and (2) the general and local resistance of the host.

Effect of Surgical Drainage on Functionless Kidneys
—In 260 cases in which surgical drainage was performed on the kidney for conditions other than lithiasis, Schulhof performed forty operations on apparently functionless kidneys. Of this group, ten cases were selected because relatively complete studies were carried out. In nine cases there was pus in the urine. Positive cultures were obtained in six cases, *Escherichia coli* being the predominating organism. *Pseudomonas*, *Proteus ammoniae*, *Aerobacter aerogenes* and micrococci were other offenders. In four cases in which *Escherichia coli* had been demonstrated before operation, cultures of it could not be obtained from the postoperative specimens. The value for blood urea was normal in eight cases before operation, abnormal in two. In eight cases the left kidney was involved, in two the right kidney. Nephrostomy was performed on eight patients and cutaneous ureterostomy was resorted to in two. In five cases in which both dye tests and intravenous urography were employed to ascertain differential renal function, there was close agreement between the two concerning the state of renal efficiency. In most cases the time that elapsed between the operation and the postoperative tests of renal function was about twenty days. Definite improvement was noted in renal function in each of the ten patients as a result of surgical drainage. In four the drained kidney functioned as well as the opposite kidney, in five function returned to approximately 50 per cent of that of the other side and in one function returned to the extent that good visualization was delayed to the sixty minute intravenous urogram.

Angina Pectoris and Insulin—Jordan states that only with meticulous care can one so regulate the dosage as to control the diabetes and at the same time avoid insulin reactions. Elderly diabetic patients are subject to cardiac attacks and one must be careful to avoid injury to the heart and not precipitate such an attack by an overdosage of insulin. During a period of only nineteen months the author encountered four diabetic patients with cardiac attacks (angina pectoris and coronary thrombosis) and a fifth patient in this period developed congestive failure apparently due to an overdose of insulin.

*Regional Enteritis Report of Five Cases A S Jackson Madison—p 632

Regional Enteritis—Jackson divides the course of regional enteritis into four phases. 1 Symptoms at first are suggestive of acute intra-abdominal inflammation and especially appendicitis. 2 The symptoms of the second phase of the disease may simulate those of ulcerative colitis, with attacks of diarrhea and crampy abdominal pain. These cases may go unrecognized for months or years, all the while large amounts of bismuth and bland foods being consumed. In some cases there may be loss of blood with resultant anemia, as well as malaise, fever and loss of weight. 3 The ulcerative phase is followed by a stenotic process. As a result of the extreme thickening of the intestinal wall, the lumen of the intestine gradually becomes constricted, leading to signs and symptoms of partial intestinal obstruction. 4 In the last stage of regional enteritis, multiple fistulas develop that may open either internally or externally through the abdominal wall. Merely excising this fistulous tract does not effect a cure, since it is necessary to resect the involved portion of the intestine. Successful results in the alleviation of regional enteritis depend on early recognition and the institution of proper treatment. Considerable evidence has accumulated to show that, if the condition is recognized in the first stage, merely sidetracking the loop of diseased intestine may effect a cure. If the disease has reached an advanced stage, such as the stenosing phase, only resection will suffice and this procedure may have to be repeated. However, even in the later phases of regional enteritis it may be advisable to perform conservative surgery by one or more stages. The sidetracking procedure has not always proved satisfactory even in the early stage of the disease, and the process has in some instances progressed, requiring further and more radical measures. In the majority of cases reported, appendectomy has been previously performed with failure to relieve symptoms. This emphasizes the importance of a careful diagnosis and imposes on the surgeon the necessity of a thorough abdominal exploration in every case of abdominal disorder in which surgical intervention is employed.

- Clinical Study of Respiratory Movements in Hemiplegia L C Kolb and F Kleynjens—p 259

Pressure of Cerebrospinal Fluid and Subtentorial Tumors—Bedford produced artificial intracranial subtentorial tumors in twenty-one dogs with absorbent cotton impregnated with petrolatum wax and observed their influence on the pressure and the circulation of the cerebrospinal fluid and on the venous pressure in the torcular. The tumors, with one exception, were extradural in situation. The animals were usually allowed to survive for six days. During the survival period they maintained good health and were symptomless. When examined at the end of this period, the pressure of the cerebrospinal fluid in the cisterna magna was found to be raised. The venous pressure in the torcular and the arterial pressure in the femoral artery were within normal limits. Hydrocephalus was encountered in four of the animals. The dilatation was moderate in degree, and involved the lateral and third ventricles, although the aqueduct and the fourth ventricle presented definite evidence of slight dilatation. India ink introduced into the cisterna magna spread over the entire cerebral hemispheres in all animals investigated in this way. The experiments indicate that there may have been an increased production of cerebrospinal fluid by the choroid plexuses which was brought about by a mechanism still undetermined. The absorption apparatus may have been unable to deal with the excess of fluid, or the cerebrospinal fluid channels distal to the cisterna magna may have been relatively too small to permit it to circulate freely. Displacement of the brain stem may have led to an obstruction of the circulation of the cerebrospinal fluid at some point between the cisterna magna and the base of the brain. The obstruction was probably incomplete or intermittent in character.

Effects of Roentgen Treatment of Gliomas on Surrounding Tissue—From their observation on the effects of x-rays on normal nervous tissue and on the various members of the gliomas, O'Connell and Brunschwig conclude that 1. Roentgen irradiation is capable of giving rise to degenerative changes in the tissues of the central nervous system. These changes involve not only the nerve cells but also the neuroglia and blood vessels. 2. The alterations in vascular structure do not appear to be responsible for the production of the parenchymal changes. Both are the result of irradiation. 3. Roentgen therapy, preceded by accurate pathologic diagnosis and a decompression, is of value in the treatment of the gliomas. Medulloblastoma and to a less extent glioblastoma multiforme react most favorably to this treatment. 4. Since certain of the more benign gliomas possibly undergo malignant dedifferentiation, surgical treatment of these should be followed by roentgen irradiation in an effort to prevent or retard this change. 5. The margin between the optimal dose for the destruction of the neoplasm and a dose that is less than the minimal one for permanent damage to the normal tissues is a very narrow one. Thus the maximal normal tissue tolerance dose would represent a point beyond which irradiation is futile and harmful. From the cases cited by the authors, it appears that large doses of the magnitude of 15,000 roentgens, even though administered during a series of treatments extending over several months, are excessive and eventually induce irreparable damage in the brain without destroying or permanently controlling the growth of the glioma. In planning courses of therapy, the tumor dose of 4,000 to 4,500 roentgens is desirable if at all possible.

Epidemic Myalgia in Children—Pickles discusses the epidemiology and progress of myalgia and stresses the importance of diagnosis, which, from the nature of the disease, allows one to give an unqualified good prognosis. In children the diagnosis has to be differentiated from acute pneumonitis and from acute abdominal conditions, of which acute appendicitis and intussusception would be the most likely. The almost invariable absence of vomiting is the most important point in arriving at a diagnosis. The rarity and lack of prominence of cough and the association of a much increased respiratory rate with abdominal pain are also of importance. Treatment does not seem to have any effect, but hot applications are appreciated, and when the diagnosis is safely made, an appropriate dose of nupenthen can be given. The only possible danger in the disease is that it might, quite excusably, come under the care of the surgeon.

Action of Choline Esters in Myasthenia Gravis—According to Fraser and his associates, in two patients with myasthenia gravis the subcutaneous injection of acetylcholine, acetyl β -methyl choline and carbaminoyl choline produced recovery of muscle power which was delayed and prolonged compared with the effects of dimethyl carbamic ester of hydroxy phenyl-trimethyl ammonium methyl sulfite, the physostigmine derivative. Choline had no remedial effect. The intra-arterial injection of the physostigmine derivative caused recovery in the muscles of the injected limb before the muscles of the body in general. The intra-arterial injection of carbaminoyl choline produced a slight local remedial effect followed by a delayed and prolonged effect similar to that following subcutaneous injection. The intra-arterial injection of acetylcholine and acetyl β -methyl choline produced only delayed and prolonged effects similar to those following subcutaneous injection. The significance of these results is discussed and it is suggested

that the choline esters are utilized in the elaboration of a precursor from which acetylcholine is set free at the neuromuscular junction, and that a defect in the production of acetylcholine is present in myasthenia gravis

Typical Indian Diets—Aykroyd and Krishnan found that the addition of liquid skimmed milk, reconstituted from powder, to the diet of children in residential hostels in South India produced an acceleration of growth and a marked improvement in general condition. The diets consumed by the experimental groups were typical South Indian diets. The addition of an amount of soya bean supplying rather more protein did not bring about the same effect. Parallel experiments were carried out on rats. The growth of rats on a typical South Indian diet was enhanced by the addition of small quantities of milk, whole or skimmed, and eggs. Soya bean was found to be a relatively poor supplement. The addition of green leafy vegetables, dhal arhar, black gram, red-palm oil, gingelly oil and ground nuts did not markedly increase the nutritive value of the basal diet, as assessed by the rate of increase in body weight. The most serious defect in South Indian diets is their deficiency of one or more of the food factors contained in skimmed milk. It is at present impossible to say which of these factors is the most important. It is, of course, advisable that when skimmed milk is added to the diet of children attention should simultaneously be given to vitamin A intake. Unquestionably, it is preferable that Indian children should consume whole milk locally produced. At present, however, in many parts of the country, it is a case of imported milk or no milk at all. It remains questionable whether, in many areas, demand for milk can create an adequate local supply. It will be some time before cheap standard milk products, locally produced, become available in quantity in India.

*Enteric Carrier Survey in an Institution W P O Callaghan—p 261
Report on Three Urinary Tests in Cancer Cases E Harvey—p 267

Enteric Carrier Survey in an Institution—During the investigation that O Callaghan discusses, 1,134 mixed specimens of urine and feces were examined culturally from 1,134 separate individuals. The investigation was conducted with the minimal material possible and by no means represents the number of examinations deemed necessary for a thorough survey of the number of people under observation. At least three and possibly more successive specimens would more truly represent the carrier distribution in the population of the institution under discussion. In this limited investigation, seven women carriers were found, three of these harbored *Bacillus typhosus* and four of them *Bacillus paratyphosus* B. Of the carriers

found, only one had suffered from enteric fever while in the institution, and this was a case of typhoid. In the remaining six carriers there is one patient about whom it can be stated that she never suffered from clinical enteric infection either within or without the institution so far as it is possible to determine from her past history. About the other five carriers there is no history forthcoming beyond the statement that they did not have clinical enteric infection during their time of residence in the institution. The cultural detection of enteric carriers, although a difficult and laborious one, is at the same time a practicable preventive measure in the control of enteric fever. While a preliminary Widal test may have a directive value in some instances in the location of enteric carriers for subsequent cultural confirmation, the Widal test when negative does not exclude the carrier condition. In the epidemiologic investigation of enteric fever too much weight should not be given to the previous personal history, in attempts to delimit the "carrier suspects." It is now known that both transitory and even chronic carriers exist, in whom it has not been possible to establish that they ever had declared infection. Experience with Wilson and Blair's medium gained in the investigation, and from a not inconsiderable experience with it in routine laboratory practice, shows that it is at least as good as any selective medium so far used in such work, judging from the reports available.

*Measurement of Cardiac Output in Man A M Cooke and J G Priestley—p 104

Measurement of Cardiac Output in Man—Cooke and Priestley made their observations on four subjects, one of whom was not very suitable as he was known to have some pulmonary fibrosis and a low vital capacity. The subject, fasting since the night before, unless otherwise stated, sat in a deck chair in a semireclining position. He remained at rest for at least twenty minutes before beginning an experiment. The output of the heart per minute must be a definite quantity, though variable and subject to physiologic control. Any method of measuring the output of the heart by observation of the amount of a foreign gas absorbed by the blood passing through the lungs in a given time must give results which are less than the true figures. This source of error does exist, and the indications are that it is not negligible. There is also another source of error which must be considered. The validity of the acetylene method depends on the completeness with which mixing of the inspired gas mixture with the residual air in the lungs is brought about. The venous carbon dioxide method is also subject to error, owing to the return of blood abnormally highly charged with carbon dioxide before the second sample of alveolar air can be taken. This must raise the venous carbon dioxide content and increase the auriculoventricular difference found, thus causing the calculated value of the heart output to be below the true resting figure, but this effect is less than in the foreign gas method, owing to the shorter time taken by the experimental procedure. On the whole it seems likely to the authors that the results which they obtained on all their subjects agree with expectation, viz, that the venous carbon dioxide results indicate a slightly greater output than the acetylene results and that the difference decreases as the experimental time of the acetylene method is

brought down nearer to that of the venous carbon dioxide method. Even with the combined method, one subject gave a much higher output as calculated from the venous carbon dioxide than as calculated from the acetylene procedure. It is suggested that this discrepancy may be explained by individual variations in the carbon dioxide content of the mixed venous blood caused by deep breathing and possibly by the effect of carbon dioxide on the circulation.

Sulfanilamide in Treatment of Urinary Tract Infections—Kenny and his associates present the clinical and bacteriologic results of treatment with sulfanilamide of forty-six cases of *Bacillus coli* infection of the urinary tract causing symptoms in pregnancy, the puerperium, and before and after gynecologic operations. A description of a few cases of pyelitis and cystitis treated by the same method is also given. The preparation was administered orally in 0.5 or 0.6 Gm doses three times a day for from five to seven days. No other treatment was employed, nor was there any restriction of diet or fluids. Of the sixteen patients with pyelitis of pregnancy the drug appeared to bring about a rapid remission of symptoms and sterilization of urine. Five of the patients had albuminuria or other signs of preeclamptic toxemia before treatment was instituted for pyelitis, but in none was the condition aggravated in any way. Six patients have had during pregnancy, at varying intervals after treatment, a recurrence of bacteriuria. Seventeen patients with *Bacillus coli* infections of the urinary tract and pyrexia of the puerperium (with or without pathogenic organisms in the genital tract) responded as rapidly and completely as in pregnancy. In every case the symptoms abated in two or three days, and the urine became sterile and free from pus in an average of three days. So far, three months later, there has been only one patient with clinical and bacteriologic relapse, and she was relieved rapidly by the same means. The nine patients with preoperative and postoperative urinary infections were rendered free from infection and dysuria in about three days. In the medical department four patients with urinary infections have been treated. One was a patient with disseminated sclerosis and defective bladder control. *Bacillus coli* disappeared after three days of treatment, *Bacillus proteus* was more resistant, and it took seven days to clear the urine completely. Relapse occurred, but the original type of infecting organism has not reappeared, and it is hoped that small daily doses of sulfanilamide will diminish the infection and relieve symptoms. Two other patients had chronic pyelitis of some months' duration, which had resisted other methods of treatment, including mandelic acid, but yielded rapidly and permanently to sulfanilamide. The fourth patient had acute cystitis of ten days, unrelieved by large doses of alkalis and sedatives. Twelve hours after treatment was begun with sulfanilamide, frequency and dysuria ceased, forty-eight hours later the urine was free from the pus cells and *Bacillus coli* with which it had been heavily loaded. Relapse has not been reported in any of these last cases. Toxic manifestations, such as sulfhemoglobinemia, methemoglobinemia and headache, appeared in a few cases but were not taken as an indication to discontinue treatment. The bactericidal power of the urine is roughly proportional to the sulfanilamide content. Strains of *Bacillus coli* are not all equally susceptible to this bactericidal action, some being almost completely resistant.

Induced Epileptic Fits as Treatment of Schizophrenia

—According to Fimefs, epileptiform fits induced by metrazol, either alone or in combination with insulin coma, have been used at the Three Counties Hospital for several months with fairly good results. Although no imposing figures of recoveries

can yet be produced and the treatment is very active and somewhat radical, no ill effects have been observed in carefully selected healthy young patients. The method appears especially beneficial in early psychoses, the stuporose and the catatonic.

Pathology of Prelaryngeal Gland—Collet points out that the prelaryngeal gland was first described by Engel in 1859. This gland or accumulation of lymph nodes exists in about 50 per cent of normal subjects. After describing the localization of the prelaryngeal gland on the cricothyroid membrane and its connection with other glands, the author takes up its pathology, particularly its involvement in tuberculosis and in cancer, reviewing the literature and cases of his own observation. He emphasizes that the involvement of the cricothyroid gland in tuberculosis is not exceptional. What is more rare is that a voluminous adenopathy appears in this region. This adenopathy, which forms an indurated mass, exactly in the middle, has a tendency to suppuration and fistulization. It develops in several weeks. In the beginning it may appear as an acute abscess, but generally it is painless and without functional disturbances. It concurs most often with tuberculous lesions of the larynx, but these laryngeal lesions may be absent, the tuberculosis may be only a pulmonary one. It is not necessary to try to establish a topographic relation between the involved laryngeal region and the cricothyroid gland as close as the normal anatomy might suggest: the lesions are quite diverse, most often quite advanced, in one case the lesion was strictly subglottic. In cancer of the larynx, the cricothyroid gland may become involved, but only rarely is there a voluminous adenopathy with a tendency to suppuration and necrosis. The author observed only one case of laryngeal cancer in which a suppurating prelaryngeal adenopathy developed comparable to that in tuberculosis.

- Enologic Identity and Neoplastic Nature of Acute and Chronic Forms of Myeloid Leukemia in Mice. E. Storti—p. 97
- *Possible Cardiovascular Accidents in Medication with Acetylcholine. C. Sarrouy and R. Raynaud—p. 111
- *Accidents in Arteriography with Contrast Medium. R. Garraud—p. 114

Cardiovascular Accidents in Medication with Acetylcholine—Sarrouy and Raynaud point out that the pharmacodynamic action of medicaments occasionally brings surprises. When the exhaustion of the supply of acetylcholine obliged them to use ampules that were approximately four or five years old, the substance had a hypertensive effect. They illustrate this effect with the blood pressure graphs of two dogs. To

explain this unforeseen behavior of acetylcholine they review the pharmacodynamics concerning the cardiovascular effect elicited by the intravenous injection of acetylcholine in animals, pointing out that the drug produces two different types of cardiovascular effects, one characterized by hypotension and cardiomoderation and another which, although it remains latent in the normal subjects, is indicated by slight fluctuations. They report four cases. A man, aged 72, had tolerated the first three injections of acetylcholine quite well, but a fourth injection provoked a sudden attack of fainting with slowing down of the respiration, an enormous decrease in the arterial pressure, facial pallor, profuse sweating and dizziness. These symptoms disappeared again in about fifteen minutes, but the man felt a thoracic constriction for about half an hour. Two more of the reported histories were similar to this one, but in the fourth patient, a woman with hypertension, an injection of acetylcholine caused symptoms indicative of the possible hypertensive effect of the drug. The woman had a sudden pectoral pain, a sensation as if a bar was pressed on her chest, with precordial constriction and dorsoscapular irradiation of the pain. The arterial tension was not measured during this crisis. The authors do not wish to discredit medication with acetylcholine but think that accidents, which may eventually be caused by it, should nevertheless be known.

Accidents in Arteriography with Contrast Medium.—Garraud says that it is difficult to estimate the frequency of accidents in arteriography, because the majority of authors fail to give exact figures. He cites one author who, in 129 arteriographies with iodine compounds as the contrast medium, observed six cases of aggravation of gangrene. Another author, who used thorium dioxide sol as the contrast medium in 300 cases of arteriography, observed only one accident of a dyscrasic nature, which was rapidly curable. After citing several other reports, the author concludes that the accidents are comparatively rare. The accidents are more frequent in men than in women and are most frequent in children and in aged persons. Of eleven cases, two concerned children and nine persons beyond the age of 55. The author says that the complications of arteriography are most frequent in obliterating arteritis of the senile type. The concentration of the opaque solution plays an important part. To avoid accidents it is necessary to find a solution as nearly isotonic to blood as possible and one which with minimal concentration produces maximal contrast. Moreover, the technic of injection of the contrast medium is important. Injections should not be repeated, at least not at intervals of several minutes, and it is necessary to avoid great pressure. The symptoms of the accidents may be differentiated into benign and grave. The author regards as benign the pure hematomas and the so called contrastomas. Under the heading of grave accidents he discusses the shock reaction, which in most cases takes a favorable course in that it quickly subsides again. However, the injection of the contrast medium may also cause an aggravation of the gangrene, which will necessitate amputation. Dyscrasic disorders, although rare, do occur. Dos Santos observed a case in which a veritable flocculation of the blood took place. Even death has been known to follow the injection of contrast medium for the purpose of arteriography.

*Statistics on Etiology of Tuberculous Meningitis. P. Nobecourt and S. B. Briskas—p. 1131
Cancer of Esophagus. J. Guiseux—p. 1135

Statistics on Etiology of Tuberculous Meningitis.—The statistics presented by Nobecourt and Briskas cover the fifteen years from 1921 to 1935 inclusive and concern children up to the age of 15. Among 13,331 hospitalized cases, 344 cases of tuberculous meningitis were discovered. It does not occur in infants who have not completed their third month of life and it is rare between 3 and 12 months (1.2 per hundred cases of the general morbidity) and becomes slightly more frequent between 12 and 18 months (2 per hundred cases), but after that it increases, reaching 5.2 per cent of the general morbidity in children of 3, 4, 5 and 6 years of age. It is most frequent during the fifth year of life, in that it attains a frequency of 6.2 per cent of the general morbidity. The incidence decreases

again from the sixth year on, amounting to 3.5 per cent of the general morbidity in children from 7 to 10 years of age, 2.2 per cent in those from 11 to 15 years of age. It is about the same in boys and girls, but during the second year it is twice as frequent in girls as in boys. As to seasonal fluctuations, the maximum is reached in March and the minimum in October. It is more frequent during summer (April to September) than during the winter months (October to March). The incidence of tuberculous meningitis has slightly decreased in recent years. This diminution seems to be connected with that of tuberculosis in general. With respect to other tuberculous disorders, the occurrence of tuberculous meningitis is relatively small among children less than 18 months old (approximately 25 per cent). It increases to 5.3 per cent during the fifth year of life and after that it subsides again to 1.8 per cent. The source of the infection remains unknown in the majority of cases of tuberculous meningitis.

Sciatica in Bothrioccephalus Disease. E. Frauchiger—p. 717
Vitamin A Treatment of Hyperthyreoses. R. Tislowitz—p. 717

Serous Meningitis and Disease of Young Swineherds.—Fatzer says that in recent years reports from many countries have mentioned a serous meningitis of unknown etiology and of benign course. The disease occurs almost exclusively in young persons. Following a prodromal stage that is characterized by general indisposition and may last several days, fever and severe headache develop and meningitic symptoms occur. Rigidity of the neck, Kernig's sign, constipation, slight albuminuria, changes in the pupils and hypersensitivity. The cerebrospinal fluid is usually entirely clear, in rare cases it is slightly opalescent. However, the cell count is frequently extremely high. The reactions of Pandy and Nonne are usually positive and the mastic and colloidal gold reactions show a meningitic curve. A similar symptomatology is found in meningitis or meningismus in various diseases, but these differ from the described cryptogenic form in that their etiology is known. In this connection the author mentions meningitis in the course of typhoid, of pneumonia of malaria and so on. In analyzing the cryptogenic cases of serous meningitis that came up for observation at the university clinic in Basel she gives especial attention to two, which were of the type designated as "maladie des jeunes porchers" (disease of young swineherds). A knowledge of the symptomatology of this disorder is important in that it may readily be confused with influenza or forms of typhoid. It is assumed that the disease of young swineherds (it develops after contact with diseased pigs) is a systemic disease in which the meningitic symptoms more or less predominate. It is probable that there are also abortive forms. Lumbar puncture is the best therapy, and some French authors recommend venesection. The etiology is still unknown. Bacterial, serologic and animal experiments produced negative results. However, French authors have recently isolated a filtrable virus from the blood of a patient with disease of young swineherds. The mode of transmission is still unknown.

Corynebacterium Diphtheriae in Feces.—Ciantini made cultural examinations of the feces of forty-one patients suffering from pharyngeal diphtheria of different intensity. The diphtheria bacillus is frequently cultured from the feces of patients suffering from grave and hypertoxic forms of the disease. It is cultured in scant quantities only during the acute period of the disease when the production of pharyngeal exudates

is persistent. When the acute period subsides, the feces do not contain any more diphtheria bacilli. Pergola's liquid culture medium gives better results than the other known culture mediums for diphtheria bacilli in identifying the latter from the feces. According to the author the elimination of diphtheria bacilli through the feces is due to deglutition of fragments of pseudomembranes which are resistant to the dissolving action of the gastric juices and preserve the bacilli. Disappearance of the bacilli from the feces, when the acute period of the disease is over, is not caused by bacteriophage.

Flies in Transmission of Undulant Fever—Negro made bacteriologic studies of flies experimentally infected with undulant fever. He found that flies act as agents by mechanical external transmission of *Brucella melitensis* and that they are reservoirs of the virus, which they ingest and maintain living in their bodies for more than a week. According to the author, the outbreaks of undulant fever which develop in rural areas in which there are many flies, and none of the animals in the stables are infected, are due to the flies. It seems obvious that infected flies transmit the infection which they carry from remote stables directly to the food of man. The author points out the epidemiologic role of domestic flies in undulant fever. It shows the advisability of making obligatory the provision of screens for the doors and windows of stables in which there are infected animals as a controlling measure of the disease.

*Tuberculous Splenomegaly with Liver Cirrhosis and Tuberculous Banti's Disease. C. Fittipaldi—p. 275

Resection of Small Intestine. Experiments in Relation to Functions of Liver. P. Barco—p. 292

Tuberculous Splenomegaly, Liver Cirrhosis and Banti's Disease—According to Fittipaldi there is a form of tuberculosis with an early selective development in the spleen and liver and the clinical picture of Banti's disease. The author reports a case in a child, aged 9. At necropsy, miliary tuberculosis, recently diffused to the lung, liver, spleen, peritoneum, kidneys and bone marrow, and tuberculous leptomenigitis were found. Besides miliary tuberculosis there were intense tuberculous splenomegaly of long duration and atrophic cirrhosis of the liver, also of long duration, with ascites. The anatomic picture of the liver process was the typical one of atrophic cirrhosis. The author discusses the relation between tuberculosis and atrophic cirrhosis of the liver. He believes that tuberculosis may cause chronic hepatitis of a fibrous noncirrhotic type as well as that with the typical anatomic picture of atrophic cirrhosis. The latter, according to the author, is caused by chronic intoxication of the liver with tuberculous toxins from the spleen that enter the organ through the portal blood.

Blood in Colitis from Intestinal Parasitism. Hemometry. Puncture of Sternum and Blood Medullary Equilibrium in Amebiasis. F. Ciancio—p. 398

Lipids in Blood in Liver Diseases—Campana determined the amount of lipids in the blood of twenty-one patients suffering from liver diseases. The patients were classified into two different groups: those suffering from jaundice in recently occurred occlusion or in acute hepatitis and those suffering from

liver cirrhosis without jaundice. According to the author, the lipids in the blood, especially phosphatides and free cholesterol, are greatly increased in all cases of jaundice from stasis or acute hepatitis. The increase of free cholesterol in the blood is proportional to that of bilirubin in the blood. It is probably due to biliary retention. The increase of phosphatides in the blood seems to be caused by diminished or abolished function of the liver in fixing the phosphatides. The total and combined cholesterol in the blood and the other fractions of blood lipids are diminished in nonicteric liver cirrhosis. The lowering is proportional to the intensity of liver disease. The ratio of blood cholesterol esters and free cholesterol in the blood is diminished in jaundice from stasis and in nonicteric liver cirrhosis. The diminution of the ratio is proportional to the intensity of liver dysfunction for the process of esterification. The behavior of the ratio cholesterol esters and free cholesterol points to the presence of liver insufficiency. However, up to now its diagnostic and prognostic values are not precise.

Physiology of Cardiac Valves and Dynamics of Heart Beat. E. Schultz—p. 1194

Cardiac Changes in Women with Uterine Myoma—Dietel points out that, although the possibility that myoma might cause cardiac changes has been denied, the problem has not been solved. To clarify this problem the author studied blood pressure, electrocardiograms and basal metabolism in eighty women with myoma and compared the results with the observations on eighty women without myoma. He was unable to detect the so-called myoma blood pressure, that is an increase in blood pressure. However, the electrocardiograms of the women with myoma showed an increased incidence of deviations from the normal. These changes, however, were not uniform but of various types, such as sinus tachycardias, fibrillation arrhythmias and particularly a predominance of the left side. In this connection the author points out that hearts which have been impaired by thyrotoxic conditions likewise show various changes in the electrocardiogram and that the changes observed in the myoma patients were similar to those encountered in thyrotoxicosis. From these changes and from the increase in the basal metabolic rate, which was observed in many of the women with myoma, the author concludes that the thyroid action may be abnormal in women with uterine myoma.

Vitamin Therapy of Nervous Diseases—Heiman reports thirty cases in the treatment of which he resorted to a preparation of vitamin B₁. The clinical histories of fifteen of these cases are reported in detail. He thinks that the injection of the B₁ preparation is indicated in all disturbances of the peripheral nervous apparatus. On the basis of theoretical reasoning, he differentiates two groups of nervous diseases. The first group includes those disorders in which a deficiency of vitamin B₁ is presumably involved. The author includes in this group, among others, polyneuritis caused by alcohol, lead, thallium, arsenic, diabetes, beriberi, pellagra, carcinoma, pregnancy, edema due to starvation, and inanition. Although it may not be possible to demonstrate an absolute or relative vitamin deficiency in all these conditions, there are nevertheless indications of a relationship. The second group of disorders includes those peripheral nervous disturbances in which pain predominates or plays a part. It has been found by experience that these dis-

orders respond to vitamin B₁ favorably. Since vitamin B₁ shows a greater affinity for the centripetal than for the centrifugal nerves its application is especially suited in disorders that involve chiefly the sensory nerves. Central nervous disturbances, such as myelitides, funicular myelitis, multiple sclerosis and hereditodegenerative diseases, do not respond to treatment with vitamin B₁, according to the author's experience. He suggests that, in the initial stage of multiple sclerosis, the preparation of vitamin B₁ be tried.

*Technic of Swallowing in Painful Dysphagia J Flesch—p 1260

Roentgenography by Lateral Pelvic Exposure in Obstetrics—Reichenmiller makes the lateral pelvic exposure while the woman is reclining in the horizontal position. If the pelvis is symmetrical this exposure insures the parallelism between the natural plane of the conjugata vera and its plane in the picture, which is an indispensable requirement for the obstetric measurement of the pelvis. Another advantage of this method of exposure is the slight dose of rays required for it (from 9 to 12 roentgens). In the course of nine years the author has used this method in approximately 350 cases. He considers it a valuable and reliable aid in obstetric examination. He found the method so reliable that in many cases the prognosis of the delivery can be made on the basis of this roentgenography alone. Moreover, the low dosage reduces the possibility of ray injury to a minimum. Nevertheless, the indications for the use of this method should be carefully evaluated. It is advisable, especially when external obstetric examination indicates a disproportion between the fetus and the osseous birth canal, that is, in case of narrow pelvis. In the interest of asepsis it should be done before vaginal examination is resorted to. The latter should be done only if the lateral pelvic roentgenogram proves inadequate.

Technic of Swallowing in Painful Dysphagia—Flesch describes a method which makes it possible to swallow liquid food quickly and painlessly in such conditions as tonsillitis, peritonsillar abscess, after tonsillectomy, after lancing of abscesses in the region of the tongue or the larynx, during pharyngitis and so on. After describing the mechanism of swallowing under normal conditions and after showing the difference between the swallowing of solid and liquid foods, the author states that, if the patient with painful dysphagia takes into his mouth an amount of fluid that will puff out his cheeks, while he is in the sitting position, and then assumes the horizontal position and, after the quantity of fluid has passively filled the space up to the anterior palatine arch, swallows it on command all at once, the following takes place. The quantity of fluid fills the spherical space between soft palate tonsils and pharyngeal wall. The pharyngeal constrictors act on a soft fluid cushion that gives no resistance, and, when the pharynx is opened, the fluid food streams without resistance, with only slight pressure, almost automatically into the esophagus. The author has used this method successfully for almost ten years.

Esmarch's Method for Expelling Blood in Resection of Uterus—Holzbach points out that the literature contains many reports about the difficulty of arresting hemorrhage in cesarean operations. He describes a simple method which

permits operation on the uterus in almost complete bloodlessness. The essential part of his method is the application of an elastic ligature. A rubber tube is placed around the cervix uteri, is drawn tight and fastened with a clamp. This method of ligation makes possible the practically bloodless performance of all types of uterine sections. The author has used this method for almost fifteen years for the "small cesarean sections", that is, for the abdominal evacuation of the pregnant uterus during the first few months of gestation. The method is helpful also in Doerfler's uterine section. In the nonpregnant uterus the blood perfusion is slightly different from that of the pregnant uterus, but even here the described method of ligation can be used.

*Question of Prophylaxis of Typhus A. V. Knack—p 1155

Lambliogenic Addisonism—According to Dreyfus, addisonism is a milder form of Addison's disease. He says, that too little attention is given to lambliasis, although the search for the cysts in the stools is comparatively simple. The same technic can be used as in searching for the ova in case of helminthiasis, with the difference that greater magnification is necessary. Moreover in view of the wide use of duodenal catheterization, even the detection of living lamblia should not be difficult, provided the juice is examined immediately after withdrawal. Following these remarks the author gives a detailed clinical history of a patient who gradually developed the symptoms of addisonism. At first the diagnosis was indefinite, for pernicious anemia and hemochromatosis were likewise thought of. But as soon as the diagnosis had been definitely established, the etiology was searched for. There were no signs of inflammatory degeneration tuberculosis, syphilis or tumor of the adrenals. When the examination of the duodenal juice disclosed enormous numbers of living lamblia and the cysts of *Lamblia intestinalis* were discovered in the stool, the author recalled cases with a similar symptomatology and lambliasis was regarded as the etiologic factor of the addisonism. The patient whose history is reported died as the result of cardiac insufficiency and pulmonary edema with ascites and anasarca. A necropsy was refused. But the author suggests that the millions of lamblia parasites, probably by the elimination of a toxin, impaired the hematopoietic apparatus as well as the adrenals, so that the symptomatology of addisonism developed.

Prophylaxis of Typhus—Knack directs attention to the value of Weigl's vaccination in the prophylaxis of typhus. On the basis of experiences with this method in China, he recommends this vaccination particularly for missionaries, physicians, nurses, laboratory workers, explorers and others who have to live in regions in which typhus is likely to appear. Moreover, he thinks that Weigl's prophylactic vaccination may also eventually be of use in military medicine.

Prophylaxis and Treatment of Tetanus—Kostunovich and Chernaya demonstrated in experiments on guinea-pigs the importance of treatment of the wound in the prophylaxis as well as in the active treatment of tetanus. The tetanus bacillus is an anaerobe particularly sensitive to oxygen. Wounds contaminated with the bacillus heal readily, since they do not cause suppuration and have but little proteolytic effect. Timely

injection of antitetanic serum is a real prophylactic measure, but, the authors emphasize, it is capable of neutralizing only that toxin which is not bound to the nervous tissue. Furthermore, it is rapidly eliminated. For this reason a second prophylactic injection, from seven to eight days after the first, is recommended. The authors quote Hauke, who had collected reports of 2,000 cases in which tetanus had developed after a single prophylactic injection of antitetanic serum. The serum has no bactericidal effect against the bacilli themselves. For this reason the authors consider early treatment of the wound the most important prophylactic measure against tetanus. Their animal experiments clearly demonstrate that prophylactic injection of serum alone is not effective in preventing tetanus. They therefore recommend that every wound suspected of harboring foreign material be widely opened under general anesthesia, that foreign bodies and dead tissue be removed and that the wound be left wide open. In wounds so treated, tetanus almost never develops. This fact explains Bohler's skeptical attitude toward the prophylactic serum treatment of tetanus. In the active treatment the authors prefer an almost continuous tribrom-ethanol narcosis and injection of antitetanic serum in doses of from 5,000 to 10,000 units every two or three days. The treatment of the wound is as important here as in the prophylactic treatment.

Treatment of Pain and Insomnia C. T. Van Valkenburg—p. 3675

Mold (Cephalosporium) as Epiphyte on Renal Calculus—Oomen reports the history and the postmortem examination of a man, aged 44, whose urine contained large quantities of mycelium. The mycelium masses originated in the closed right half of a horseshoe kidney, where they grew on an oxalate stone in the renal pelvis. The postmortem examination showed only minimal changes in the pelvic wall, whereas various signs of chronic inflammation were present in the parenchyma, but there were no mold fungi. The mold could be isolated only from the calculus and its immediate surroundings, none being found in the parenchyma. The left half of the kidney likewise contained a pelvic stone, and a moderate pyonephrotic destruction was present with signs of chronic inflammation in the parenchyma. The only infectious organism that could be found was *Bacillus coli*. The patient had had symptoms of renal calculus for a number of years but stated that recently his attacks of colic had become more frequent and that they often vanished when much soft material was evacuated with the urine. The change in the subjective complaints was preceded by mycotic processes of beard, hands and nails. The process on the nails still existed at the time of admission to the hospital. Material from the nails yielded several fungi and yeasts, but none of them seemed to be the cause of the ungual mycosis. Neither the fungus that was found in the kidney nor other pathogenic hyphomycetes could be cultivated from the ungual material. The only species of fungus that could be isolated from the urine, especially from the urine of the right kidney, has been described in the literature as *Acremonium potronii* Vuillemin. However, systematic examination of the fungus revealed that it was a *Cephalosporium*, not an *Acremonium*. In the future it should therefore be referred to as *Cephalosporium potronii* (Vuillemin) Oomen. Species of *Cephalosporium* have often been indicated as originators of cutaneous and tonsillar disorders but their presence has never been detected in the internal organs.

Sedimentation Speed as Diagnostic Aid in Malignant Tumors—Koster shows that the sedimentation speed has a tendency to decrease in stored citrate blood. This "retardation reaction" as such is of no importance, since stored blood always undergoes changes. However, careful observation of the retardation reaction reveals certain characteristics. The author

made studies on 100 healthy persons, 460 patients with nonmalignant disorders, 112 patients with malignant tumors (carcinomas, sarcomas, seminomas, lymphosarcomas, chorionepitheliomas) and fourteen patients with malignant granulomas. He found that in normal persons and in patients with nonmalignant disease the sedimentation rate of the blood decreases during storage of twenty-four hours. In malignant tumors and in lymphogranuloma the retardation reaction shows considerable deviations. In nonmalignant disorders deviations from the retardation reaction may occur under the influence of medicaments or of considerable heating of the blood and in blood from dying persons. The author thinks that the variations in the behavior of stored blood can be explained by ionic changes. If the test is carried out with the observance of the necessary precautions and is done repeatedly, the late retardation in the sedimentation speed can be used in the differentiation between malignant tumors and lymphogranulomas on the one hand and benign disorders on the other.

Solid Subperitoneal Tumors M. S. Cohen—p. 3834

Stenosing Proctitis—Stolte reports the clinical history of a man, aged 38, who for several years had been in the Dutch East Indies. Home in Europe for a furlough, he asked medical advice on account of rectal disturbances. The correct diagnosis encountered considerable difficulties. Examination of the rectal mucosa for various tropical organisms produced negative results. Moreover, there were no signs of syphilis or chancroid, and gonorrhea was extremely doubtful. Finally a Frei test was made and produced a positive reaction. The patient now admitted that during the previous year he had been treated for tropical buboes in the right groin. About one year after the first appearance of the proctitic symptoms, an increasing rectal stenosis developed. The fact that the symptoms exacerbated in the course of the Frei test is regarded as a further proof of an etiologic connection with venereal lymphogranuloma. Local irrigations and treatment with an antimony preparation were ineffective, for the stenosis progressed further. The improvement that was finally obtained was ascribed to the fever which first followed a blood transfusion and which later was induced by the injection of a bacterial protein.

*Serum Proteins in Leukopenia Contribution to Illumination of Question of Seat of Formation of Serum Proteins J. Bing and P. Plum—p. 738

Serum Proteins in Leukopenia—In their study of the serum proteins in thirteen cases of leukopenia due to various causes, Bing and Plum found no relation between the blood content of protein and of granulocytes. They state that these cases, together with their earlier cases and the literature, show that in different disturbances with hyperglobulinemia there is an increased number of plasma cells and cells belonging to the reticulo endothelial system inside and outside the bone marrow, which indicates that the globulin formation takes place in these cells. Three peculiar cases of chronic leukopenia are described. In the first, in a woman, aged 32, having scattered infections with considerable leukopenia, leukopenia and hyperglobulinemia persist after the end of the infections, at times accompanied by fever, swelling of the lymph glands and rheumatic pain. The cause is not known. The second patient, a woman aged 64, became dull and tired after antisyphilitic treatment. The objective symptoms were leukopenia, increased sedimentation reaction and hyperglobulinemia, five months later, splenomegaly and anemia developed. Improvement resulted after treatment with liver and two injections of arsphenamine, but the leukopenia and hyperglobulinemia continue. The last case is that of a man aged 65, with lymphatic leukemia and unusually pronounced hyperglobulinemia (up to 886 per cent of globulin).
